The process of reduction and rectification as described applies also to toluidine, and modifications of the process are also in use for the production of xylidine and alphanaphthylamine, and of the reduction portion for the manufacture of metaphenylene- and metatolylene-diamine from the respective dinitro- compounds.

Catalytic Reduction of Nitrobenzene.—This is effected by passing a mixture of nitrobenzene vapour and hydrogen (or other reducing gases) over a catalyst heated to a suitable temperature (usually 200°–300°). The catalysts which have been proposed are copper (Eng. Pats. 13149, 15334, 1914; 5692, 6409, 1915; U.S. Pat. 1207802; D. R. PP. 139457, 282568; Fr. Pat. 312615), nickel (Eng. Pats. 16936, 22523, 1913; D. R. P. 282492; Fr. Pats. 458033, and 1st addition), iron oxides (Fr. Pat. 462006), iron (D. R. P. 281100), and silver or gold (D. R. P. 263396).

Many patents have been taken out for the electrolytic reduction of nitrobenzene, but it is doubtful whether this process is used on the large scale.

The reduction of nitrobenzene may also be carried out by boiling it with sodium disulphide solution (D. R. P. 144809), and an 80 p.c. yield of aniline is said to be obtained by heating chlorobenzene with ammonia and a little copper sulphate (Eng. Pat. 3966, 1908; D. R. P. 204951; Fr. Pat. 397485).

Valuation of Commercial Aniline Oil.

Aniline oil, as it occurs in commerce, may contain as impurities water, traces of insoluble hydrocarbons and of orthotoluidine, sometimes traces of hydrogen sulphide, and, if carelessly made, of nitrobenzene, benzene, and ammonia. Besides these, which should be carefully tested for, there is possibly a certain amount of aminothiophen, which has no deleterious action for most, if not all, of the purposes for which aniline is used, and which, moreover, for the present at least, cannot readily be got rid of.

The method of testing usually adopted is to determine the boiling-point of the sample. For this purpose 100 c.c. are introduced into a small boiling flask with side tube, and distilled through a short condenser into a graduated 100 c.c. cylinder. Readings of the thermometer are taken as each 10 c.c. of the cylinder fills, and the last when 95 c.c. are filled. An alternative method is to take readings of the cylinder at each fifth of a degree rise of the thermometer. It is also usual to note the temperature when the first drop has fallen from the condenser. The thermometer readings should be corrected for barometer and immersion of mercurial column in the vapour of the liquid, and of course for the errors peculiar to the thermometer in use.

A few fragments of platinum wire, fire-brick, or wrought iron, should be placed on the bottom of the flask, and great care used to adjust the size of the flame and rate of boiling. The flask also should be held by the neck in a good clip over the naked flame, gauze being apt to cause currents of heated gas to flow up round the neck of the flask and superheat the vapour.

The specific gravity of the sample may also be taken (pure aniline has a specific gravity of 1·0265–1·0267 at 15°), although this indication is not of great moment if the boiling-points are good.

The following is an example of the determination of the boiling-point (Walter, Chem. Zeit. 1910, 34, 702):—

Temperature.	P.c. over.	Temperature.	P.c. over.
182·4°	3	183·2°	20
182·6°	4	183·4°	97
182·8°	5·5	183·6°	98
183·0°	11	183·8°	99

If, in carrying out the boiling test, the temperature rises considerably at the end, the presence of toluidine may be suspected. This can be detected when a considerable quantity of commercial pure aniline is made into acetanilide. On recrystallising this and working up the mother liquors, a small quantity of impure acetyl compound of low melting-point will always be found in the most soluble portion, or first mother liquors.

Pure aniline melts at −6·2°, and boils at 80°–81°/20 mm. and 184·4°/760 mm.

Aniline may be tested for insoluble oils by dissolving 10 c.c. in 40 c.c. of hydrochloric acid and 50 c.c. of water. The solution should be quite clear.

Nitrobenzene shows itself with the insoluble hydrocarbons. A very delicate test for it is to shake the sample of aniline violently for a few minutes, and then to notice the colour of the froth. The merest trace of nitrobenzene colours it a very distinct yellow.

The presence of water may be detected by distilling the sample (100 c.c.) as for a boiling-point determination, and collecting the first 10 c.c. in a narrow graduated cylinder of 15 c.c. capacity, shaking with 1 c.c. of saturated sodium chloride solution, and reading off the volume of the latter. The method will not show the presence of less than 0·3 p.c. of water, consequently, 0·3 c.c. must always be added to the amount of salt solution observed. It is not usual for aniline, sold as pure, to contain more than 0·5 p.c. of water.

Toluidine liquid should boil at 197°–198°, show a sp.gr. of about 1·000, and contain 30–40 p.c. para-, the rest ortho- toluidine.

Orthotoluidine. The sp.gr. of commercial orthotoluidine should be about 1·0037; b.p. about 197°–198°; should not solidify on cooling to −4°. The pure substance boils at 199·7°, and does not solidify at −20°. Its density at 15°, compared with water at 15°, is 1·0031.

Paratoluidine. When pure, this melts at 45° and boils at 200·4°/760 mm. and 86°–87°/10 mm. Its density is 1·046. Lunge (Chem. Ind. 1885, 8, 74) has published a table showing the specific gravities of mixtures of *o*- and *p*-toluidine.

For the estimation of small amounts of *p*-toluidine in *o*-toluidine, Schoen's method is perhaps the best. A standard oil is prepared, containing 8 p.c. of *p*-toluidine and 92 p.c. of *o*-toluidine, 1 c.c. of which is dissolved with 2 c.c. of pure hydrochloric acid in 50 c.c. of water, and oxidised cold by adding 1 c.c. of a saturated solution of potassium dichromate. After standing for two hours, the product is filtered, the precipitate being washed with water, and the filtrate and washings made up to 100 c.c. The toluidine to be tested is treated in the same manner, and compared colorimetrically with the above solution. J. C. C.

ANILINE BLACK *v.* Dyeing.

ANILINE BLUE *v.* Triphenylmethane colouring matters.

ANILINE BROWN *v.* Azo- colouring matters.

ANILINE SALT. The commercial name of aniline hydrochloride $C_6H_5{\cdot}NH_2,HCl$.

It is prepared in large quantities, for the use of calico-printers, who employ it in the production of aniline black. The process consists in mixing the calculated quantities of pure aniline and hydrochloric acid in lead-lined or nickel-lined tanks, and allowing the salt to crystallise, freeing it from mother liquors in a centrifugal machine, and drying at a low temperature. The hydrochloric acid used should be of good quality, free from iron and even from traces of copper, or the salt will rapidly blacken.

The mother liquors may be neutralised with lime or soda, and the aniline recovered, or they may be boiled down and used in making magenta by the nitrobenzene process, &c.

'Aniline salt' occurs in commerce in large white, nacreous and much-contorted plates.

The great desiderata for the calico-printer are that the salt should be made from pure aniline and should be dry and normal, containing 93 parts of aniline to 36·5 parts of hydrochloric acid; it should be free from sand and grit, which injure the printing machines.

J. C. C.

ANILINE YELLOW *v.* Azo- colouring matters.

ANIMAL OILS and **FATS** *v.* Oils and fats.

ANIME and **ANIMI** *v.* Oleo-resins.

ANISEED. (*Anis*, Fr., Ger.) The fruit of the *Pimpinella Anisum* (Linn.), cultivated in Malta, Spain, and Germany. Used for the preparation of anise oil and cordials. Alcohol extracts 36·24 p.c. of this spice (Biechele, Pharm. J. [3] 10, 878).

ANISE CAMPHOR *v.* Camphors.

ANISE OIL. The essential oil of aniseed, obtained by distilling it with water. According to Landolph (Compt. rend. 81, 97; 82, 226), it contains 90 p.c. of *anethole*, boiling at 22·6°. Anethole, according to Perkin (Chem. Soc. Trans. 32, 668), is p-allylanisole $C_6H_4(OMe)CH:CH{\cdot}CH_3$; he obtained it by heating p-methoxyphenylcrotonic acid.

Anise oil is sometimes adulterated with fennel oil; this can be detected by heating the oil, when the fennel odour becomes perceptible.

Star anise oil has a similar colour and taste, but it does not solidify at 2° (*v.* Oils, Essential).

ANISIDINE. $NH_2{\cdot}C_6H_4{\cdot}OMe$. *Orthanisidine.* Obtained by the reduction of orthonitranisole with tin and hydrochloric acid or iron and hydrochloric acid (Meister, Lucius, and Brüning, D. R. P. 7217 of Dec. 3, 1878), is a colourless oil, which freezes at 2·5°, boils at 226·5° at 734 mm. pressure (Mülhaüser, Annalen, 207, 239); at 225° at 760 mm. (Perkin, Chem. Soc. Trans. 69, 1210), and has a sp.gr. 1·108 at 26°. Can also be prepared by heating a mixture of *o*-aminophenol, potassium methyl sulphate, and potassium hydroxide solution under pressure. When diazotised and treated with β-naphtholdisulphonic acid (R-acid), it yields *anisole-red* (*v.* Azo- colouring matters). A mixture of orthanisidine (2 mols.) and paraphenylenediamine (1 mol.) is converted, on oxidation with potassium dichromate, into a reddish colouring matter formerly employed under the name *safranisole* (Kalle & Co., D. R. P. 24229 of Oct. 27, 1882; expired March, 1885). Anisidine is used for making chrome fast yellow G-G. azoeosin G and azocochineal.

Paranisidine, obtained from paranitranisole by reduction with tin and hydrochloric acid, crystallises in prisms which melt at 55·5°–56·5° (Lossen, Annalen, 175, 324) and boil at 245°-246° (Salkowski, Ber. 7, 1009); 243° at 760 mm. (Perkin, Chem. Soc. Trans. 69, 1210); *p*-anisidine, *o*-sulphonic acid, prepared by boiling the hydrogen sulphate of *p*-anisidine, when diazotised and coupled with *β*-naphthol, yields an azo-compound forming red lakes with baryta, alumina, &c. (Aktiengesellschaft fur Anilin-Fabrikation, D. R. P. 14665).

Chloranisidine, when diazotised and coupled with *β*-naphthol, yields a red compound insoluble in water (Julius, Ludwigshafen and Jahrmaht, U.S. Pat. 695812); *p*- and *m*-nitroanisidine, when diazotised and coupled with *β*-naphthol, yield red and pink dyestuffs (Imray, Eng. Pat. 25756; J. Soc. Chem. Ind. 1898, 1039; and Freyss, J. Soc. Chem. Ind. 1901, 356); *o*-iodo-*p*-anisidine, when diazotised and treated with naphthol sulphonic acid, yields a red dye, similar to that obtained from *p*-anisidine (Reverdin, Ber. 29, 997).

Anisidine condenses with orthoformic ester, and the resulting compound is used as an anæsthetic (Goldchsmidt, Eng. Pat. 9792; J. Soc. Chem. Ind. 1899, 606).

ANISOCHILUS CARNOSUS (Wall.). An Indian plant belonging to the Labiatæ and containing a volatile oil. Used in quinsy.

ANISOLE. *Anisoil; Methylphenyl ether*

$C_6H_5{\cdot}O{\cdot}CH_3$.

Preparation.—Anisole can be obtained by distilling anisic acid or *o*-methoxybenzoic acid with baryta, or by heating potassium phenate with methyl iodide at 120° (Cahours, Ann. Chim. Phys. [3] 2, 274; 10, 353; 27, 439). It is prepared by passing a current of methyl chloride over dry sodium phenate heated at 190°-200° (Vincent, Bull. Soc. chim. 40, 106), and by heating phenol with methyl alcohol and potassium bisulphate at 150°-160° (Act. Ges. für Anil.-Fabrik.; D. R. P. 23775). It has been synthesised by fusing sodium benzene sulphonate with sodium methoxide (Moureu, J. Pharm. Chim. 8, v. 211).

Properties.—It is a colourless ethereal liquid, which boils at 155°-155·5° at 762·3 mm. (Schiff, Annalen, 220, 105) at 153·9° (corr.) (Perkin, Chem. Soc. Trans. 69, 1240); melts at −37·8° (Von Schneider, Zeit. Phys. Chem. 19, 997) and has a specific gravity 0 991 at 15° (*v.* OILS, ESSENTIAL).

ANISOMELES MALABARICA (R. Br.). A much-esteemed Indian plant belonging to the Labiatæ; an infusion of the leaves is used in intermittent fevers, and the essential oil is applied externally in rheumatism.

ANISOTHEOBROMINE. Trade name for an addition product of theobromine sodium and sodium anisate.

ANKERITE. A member of the group of rhombohedral carbonates containing calcium, magnesium, and iron, with sometimes a little manganese. The formula is like that of dolomite with the magnesium partly replaced by iron; in normal ankerite it is $CaCO_3{\cdot}Mg_{\frac{1}{2}}Fe_{\frac{1}{2}}CO_3$. The angle between adjacent faces of the rhombohedral cleavage is 73° 48′. D 2·95–3·1; H 3½–4. The mineral forms white, greyish, or brownish cleavage rhombs, cleavage masses, or granular masses. It occurs in some abundance with chalybite ($FeCO_3$) in the iron mines of Eisenerz in Styria, Londonderry in Nova Scotia, and in northern New York. The white, thin platy seams often seen in coal consist usually of ankerite. L. J. S.

ANKOOL, AKOLA, DHERA, BARK. The root bark of *Alangium Lamarckii* (Thw.), one of the Cornaceæ, used in leprosy and skin-diseases (Dymock, Pharm. J. [3] 9, 1017).

ANNATTO. This is derived from the fruit of the *Bixa orellana* (Linn.), a shrub found native in Central America, and cultivated in Brazil, Guiana, Mexico, the Antilles, and India.

To prepare the dyestuff, the seeds and pulp are removed from the mature fruit, macerated with water, and the mixture is left to ferment. The product is strained through a sieve, and the colouring matter which settles out is collected, partially evaporated by heat, then placed in boxes, and finally dried in the sun.

Annatto comes into the market in the form of cakes, and among the different varieties Cayenne annatto is the most esteemed, and is considered to be the richest in colouring matter. It should contain from 10 to 12 p.c. of the pure dye, and not more than 5 p.c. of ash, whereas the amount of colouring matter in the Bengal product is frequently lower than 6 p.c.

In 1848 Dumontal devised a new method for the preparation of annatto, in which fermentation is avoided, and the pulp is simply washed out from the capsules and off the seeds. This product known as *bixin* is said to be five to six times more valuable than ordinary annatto (Crookes, Dyeing and Calico-Printing).

The colouring matters of this dyestuff were first investigated by Chevreul (Leçons de Chimie appliquée à la Teinture), who isolated two substances, one yellow, which was called *orrellin*, soluble in water, and a second, *bixin*, which is red and very sparingly soluble.

Bixin, the useful colouring matter, was subsequently examined by numerous chemists, who were only successful in preparing it as an amorphous powder, and its isolation in a crystalline condition was first achieved by Etti (Ber. 7, 446; 11, 864).

Etti digested 1·5 kilos of purified annatto with a solution of 150 grams of calcined soda ash in 2·5 kilos of 80 p.c. alcohol on the water-bath at 80°. The mixture was filtered and the residue pressed between warm plates, and again extracted with 1·5 kilos of warm 60 p.c. alcohol.

The alcoholic filtrate was diluted with half its volume of water, concentrated, sodium carbonate solution added, and the crystalline precipitate of sodium bixin was collected after several days, and pressed. The product purified by solution in 60 p.c. alcohol at 70°–80° and reprecipitation with sodium carbonate was finally made into a cream with alcohol, and this, when neutralised with hydrochloric acid, yielded crystalline bixin.

A simpler method has been more recently devised by Zwick (Ber. 30, 1972). Well-dried annatto is extracted for twenty-four hours with boiling chloroform, the extract evaporated, and the residue thoroughly exhausted with ligroin. The product is crystallised from chloroform, and after washing with ligroin is repeatedly recrystallised from the former solvent.

Bixin $C_{28}H_{34}O_5$ (Etti, *l.c.*; Marchlewski and Matejko, Chem. Zentr. 1906 [ii.] 1265) consists of brown-red or deep-red rhombic crystals, which, when slowly heated, melt at 191·5°, and when rapidly heated at 198°. It is sparingly soluble in the usual solvents, and of these it is most readily dissolved by chloroform or alcohol. Concentrated sulphuric acid dissolves bixin with a cornflower-blue colouration, and this reaction is given by minute traces of the substance (*cf.* Crocin and Nycanthin).

Monosodium bixin $C_{28}H_{33}O_5Na+2H_2O$ is best prepared by dissolving 10 grams of bixin in a solution of 1·2 grams of sodium carbonate in 300 c.c. of 12 p.c. alcohol at 70° (Etti, Zwick). It is deposited on cooling in dark-red iridescent crystals, and can be obtained in the anhydrous condition by recrystallisation from 70 p.c. alcohol (Marchlewski and Matejko).

Disodium bixin $C_{28}H_{32}O_5Na_2+2H_2O$ is obtained when 20 grams of bixin is dissolved in a solution of 10 grams sodium carbonate in 600 c.c. of boiling 12 p.c. alcohol. It consists of a dark-red amorphous powder (Etti). *Monopotassium bixin* $C_{28}H_{33}O_5K+H2_2O$ and *dipotassium bixin* $C_{28}H_{32}O_5K_2+2H_2O$ have also been prepared.

Bixin contains one methoxyl group. Distilled with zinc-dust, bixin yields, according to Etti, *metaxylene*, *metaethylxylene*, and a hydrocarbon $C_{14}H_{14}$, b.p. 270°–280°.

According to Zwick, bixin is readily reduced by sodium amalgam, and a compound $C_{23}H_{40}O_7$ is thus produced. Marchlewski and Matejko, on the other hand, studied the action of zinc-dust and acetic acid, and obtained in this manner an orange-coloured crystalline substance which possessed a strong metallic lustre. When slowly heated it melts at 200·5°, but if the operation is carried out rapidly, at 208°–210°. This compound is evidently of an unstable nature, for whereas when freshly prepared it gives C=75·4, H=7·7 p.c., on standing for some days in the air it becomes colourless and then gives C=58·6, H=5·8 p.c. At 100° this change occurs more rapidly.

More recently there has been much controversy as to the correct formula for bixin.

Van Hasselt (Chem. Weekblad, 1909, 6, 480) contends that pure bixin, which melts at 189°, is $C_{29}H_{34}O_5$ rather than $C_{28}H_{34}O_5$, as proposed by Etti (*l.c.*). If heated at 190° in a current of hydrogen, 1 gram mol. of bixin yields 1 gram mol. of *m*-xylene, and no other volatile product, though it is not to be considered that a *m*-xylene nucleus exists as such in the bixin molecule. No palmitic acid could be obtained from bixin as Zwick suggests. Whereas both Etti and Zwick described mono- and dipotassium salts of bixin, the latter is not in reality a compound of bixin, but of a new substance termed *norbixin* $OK·C_{28}H_{30}O_3·OK$, produced by a substitution of a methyl of the methoxy group present in the former by potassium (Rec. trav. chim. 1911, 30, 1). Norbixin $C_{28}H_{32}O_5$ consists of a light red-coloured crystalline powder which decomposes at about 240°, and is distinguished from bixin by its insolubility in chloroform.

Potassium bixinate with methyl sulphate gives *bixin methyl ether* $B(OMe)_2$, or $C_{30}H_{36}O_5$, plates, m.p. 156° (1909), and the same compound is obtained when a solution of bixin in methyl alcohol is treated with potassium hydroxide and methyl sulphate (1911). On treatment with potassium hydroxide, bixin methyl ether is converted into norbixin. *Bixin ethyl ether* $C_{31}H_{38}O_5$, violet crystals, melts at 138°, and by methylation forms *norbixin methyl ethyl ether* OMe·B·OEt, m.p. 149°.

Potassium norbixin, obtained from bixin and alcoholic potash, gives with ethyl sulphate *norbixin diethyl ether* $C_{28}H_{30}O_3(OEt)_2$, m.p. 121°, together with *norbixin ethyl ether*

$$C_{28}H_{30}O_3(OEt)(OH),$$

m.p. 176°.

The relationship between norbixin, bixin, and bixin methyl ether is shown as follows :—

OH·R·OH OH·R·OMe OMe·R·OMe

According to Hasselt, *iso-bixin methyl ether*, m.p. 149°, is produced when norbixin ethyl ether is methylated, and it is thus evident that the two hydroxyls of norbixin are not symmetrically situated. *Iso-bixin* OH·R·OMe, melts at 178°, and may be obtained by the partial hydrolysis of bixin methyl ether, and this, by ethylation with ethyl sulphate, gives norbixin diethyl ether, m.p. 121°, the methyl being thus replaced by an ethyl group. Iso-bixin is distinguished from bixin by the greater stability of its methyl group in presence of potassium hydroxide solution.

The product of the reduction of bixin obtained by Marchlewski and Matejko, and referred to above, is considered by van Hasselt to consist of *dihydrobixin* $C_{29}H_{36}O_5$. He has also described *dihydrobixin methyl ether* $C_{30}H_{38}O_5$, m.p. 174°; *dihydro-iso-bixin* $C_{29}H_{36}O_5$, m.p. 190°; and *dihydro-norbixin* $C_{28}H_{34}O_5$, which decomposes at 235°.

By the action of bromine, bixin yields *bixin decabromide* $C_{29}H_{34}O_5Br_{10}$, whereas bixin methyl ether yields the analogous compound

$$C_{30}H_{36}O_5Br_{10},$$

and both these substances are colourless amorphous powders. Attempts to benzoylate or acetylate bixin were unsuccessful.

On the other hand, Heiduschka and Riffart (Arch. Pharm. 1911, 240, 43) consider that the old formula $C_{28}H_{34}O_5$ for bixin is preferable to that of $C_{29}H_{34}O_5$, advocated by van Hasselt. Bixin, by the action of bromine in the presence of chloroform, gives the compound $C_{28}H_{34}O_5Br_{10}$, 4HBr, melting at 143°, and this by heating at 100° is converted into the decabromide $C_{28}H_{34}O_5Br_{10}$, which can be obtained crystalline from alcohol, but is unstable. By the action of chlorine on bixin and norbixin respectively, the amorphous compounds $C_{28}H_{34}O_5Cl_{10}$, 4HCl and $C_{27}H_{32}O_5Cl_{10}$, 4HCl can be prepared.

Van Hasselt (Rec. trav. chim. 1914, 33, 192), however, maintains that his formula for bixin $C_{29}H_{34}O_5$ is correct, and states that the discrepancy shown by the results of his own work and that of Heiduschka and Riffart arises from the fact that bixin is readily susceptible to oxidation with the formation of amorphous products. The bixin of these latter authors was not completely pure, and it is quite correct that specimens which are purified by their method give figures in harmony with the older formula $C_{28}H_{34}O_5$. Again, the analytical numbers given by Marchlewski and Matejko for hydrobixin are explainable if bixin is given the formula $C_{29}H_{34}O_5$.

A new formula $C_{25}H_{27}O_3 \cdot OMe$ for bixin was now suggested by Herzig, Faltis, and Mizzan (Monatsh. 1914, 35, 997), who state that it is difficult to correctly analyse bixin unless special precautions are adopted. *Dihydrobixin*, the product of the action of zinc-dust and acetic acid on bixin, melts at 178°–179°, whereas the methyl ether obtained by means of diazomethane and bixin, or methyl sulphate and potassium bixin, melts at 158°.

Though, as Hasselt states, bixin at 190°–200° yields *m*-xylene, the reaction is hardly of a quantitative nature, in that the crude oil, though containing this hydrocarbon, possesses no constant boiling-point. Rinkes (Chem. Weekblad) suggests that the formula of bixin is $C_{27}H_{32}O_4$, though Herzig and Faltis (Ber. 1917, 50, 927) in reply, reiterate that the expression $C_{26}H_{30}O_4$ is to be regarded as correct, and that the real difficulty lies in the combustion of this colouring matter. Heiduschka and Panzer (Ber. 1917, 50, 546) point out, however, as the result of further investigation, that the main difficulty is in the purification of the substance. The most satisfactory products are those obtained by means of acetone and ethyl acetate, which, when analysed, give figures agreeing with the formula $C_{25}H_{30}O_4$.

When ozonised, methyl bixin forms an *ozonide*, and this by distillation, and partly by the action of calcium carbonate, gives among other products, *methyl-β-acetyl acrylate*, and a crystalline compound $C_8H_{10}O_3$, m.p. 85°, which yields an oxime, m.p. 106°, and may be the methyl ester of a ketonic acid. Methylbixin thus appears to contain the linkage

$$\ddot{C}\cdot Me\cdot CH : CH\cdot \ddot{C}\cdot OMe$$

(Rinkes and Hasslet, Chem. Weekblad, 1916, 13, 244, and 14, 888).

Sodium hyposulphite reduces bixin to *α-hydrobixin*, red needles, melting about 200°, norbixin to *α-hydronorbixin*, violet crystals, and methylbixin to *α-hydromethylbixin*, violet needles, m.p. 190°–192°.

On the other hand, with titanium sesquioxide, bixin gives *β-hydrobixin*, norbixin *β-hydronorbixin*, and methylbixin *β-hydromethylbixin*, the latter of which melts at 170°. By the action of zinc-dust both *α*- and *β*-hydrobixins are converted into the same *γ-hydrobixin*, yellow crystals, m.p. 207° (van Hasselt, *ibid.* 1916, 13, 429).

In a further communication Heiduschka and Panzer (Ber. 1917, 50, 1525) again maintain the probability of the formula $C_{26}H_{30}O_4$ for bixin.

Dyeing Properties.—Annatto is still employed to a fair extent for colouring oils and butter, but is almost extinct as a dyestuff in this country. As the orange-red colour which it yields is extremely fugitive to light, it has at no time been very extensively used. On the other hand, it resists the action of soap and dilute acids very well.

In order to dye cotton, the annatto is first dissolved in a boiling solution of carbonate of soda, and the goods are then entered and left in the bath for a quarter of an hour. They are subsequently pressed out, and washed in slightly acidulated water or alum solution.

For silk, the bath is made up with equal parts of annatto and sodium carbonate; soap is also usually added, and the dyeing is continued at 50° for about an hour, according to the shade required. The colour produced can be rendered somewhat more yellow by passing the fabric through a weak solution of tartaric acid.

Wool is dyed at 80°–100° without any addition to the bath. A. G. P.

ANNEALING. (*Le recuit*, Fr.; *das Anlassen*, Ger.) A process which is applied principally to glass and metals for the purpose of rendering them softer or less brittle. The process itself always consists in the application of heat for a period of time, which may vary from a few minutes to many hours, and which may be followed by very slow cooling; the object of the process is to permit the material to attain approximate equilibrium in regard to its internal structure. This state of normal internal equilibrium may be disturbed either by the effects of rapid cooling or by the application of mechanical deformation. The former is most frequently met with in glass, and in large metal castings, while the latter is found in 'wrought' metal of all kinds.

In the case of substances which are poor conductors of heat, such as glass, and also in masses of metal which are so large that thermal conductivity cannot produce reasonable uniformity of temperature, relatively rapid cooling sets up severe stresses, owing to the fact that the outer or most rapidly cooled layers solidify or become hard and rigid first; subsequently the internal portions of the mass endeavour to contract in cooling, but find themselves constrained by their attachment to a relatively rigid external envelope; the tendency to thermal contraction is therefore overcome by severe tensional stresses. A body in this condition, while it may present the phenomenal strength of a 'Rupert's drop,' is liable to sudden fracture, particularly if the surface is cut or broken. The annealing of glass has been studied with great care (Twyman, Journ. Soc. Glass Technology, vol. i. 1, pp. 61–74), and it has been shown that glass behaves as a true fluid whose change of viscosity with temperature follows an exponential law, so that the viscosity is halved for each rise of temperature of 8° C. If, then, a piece of glass has been so cooled as to be heavily stressed internally, these stresses will be released if the temperature is raised to such a point that the viscosity becomes low enough for appreciable flow to take place in a few seconds. The temperature required for this purpose may be defined as 'the annealing temperature,' and although it is not a definite critical temperature, the rapidity with which the viscosity or 'stiffness' of the glass changes with temperature makes it possible to approximate to a definite 'annealing temperature' for each kind of glass. Experimentally this may be done by heating an internally-strained specimen of the glass in an electric tube-furance while keeping it under observation by means of a beam of plane-polarised light passing through the glass while in the furnace-tube. When thus examined under 'crossed Nicols' the presence of internal stress makes itself apparent by a more or less well-defined cross, or at least by light and dark shading. This appearance remains practically unchanged (unless the heating is very slow), until the annealing temperature is reached, when the markings suddenly disappear. Such glass can then be fully annealed by heating to this temperature, followed by cooling in such a manner that no fresh internal stresses are set up. This usually implies very slow cooling until the glass is stiff enough to be free from further risk in this respect. It should be noted, however, that slow cooling in itself is of no special advantage; all that is required is the maintenance of the greatest possible uniformity of temperature throughout the mass so that all parts of it shall cool as nearly as may be simultaneously. In bodies like glass, which are poor conductors of heat, this can only be attained by extremely slow cooling, except where very thin pieces are concerned. In the case of metals, which are good conductors of heat, extremely slow cooling is not necessary in order to avoid the development of severe internal stresses, and as very slow cooling is undesirable in most metals because of the tendency to produce coarse and weak microstructures, it is never employed intentionally. Annealing is, in fact, generally applied to metals for other purposes.

Metals in the cast or other 'normal' condition consist of aggregates of minute crystals of approximately equal dimensions in all directions; when metal is mechanically deformed, as by hammering, rolling, or other working process carried on in the cold, these minute crystals are elongated in the same general sense as the mass of which they form part, and this deformation of the crystals is accompanied by the well-known hardening of the metal under cold work. This is due in part to the internal rearrangement which each crystal undergoes, and in part to the partial and local destruction of the crystalline arrangement itself, accompanied by the formation of a hard amorphous 'phase' (Ewing and Rosenhain, Phil. Trans. 1899, ser. A. cxcii. 353–375; Beilby, Phil. Mag. 1894). When the metal is subsequently annealed, *i.e.* heated to a suitable temperature, the metal 'recrystallises,' the crystals rearrange themselves, and the original condition is approximately restored. In some metals the molecular mobility is such that recrystallisation takes place slowly even at the ordinary temperature (lead: Ewing and Rosenhain, Phil. Trans. 1900, cxcv. 279–301; brass: Cohen, Rev. general des Sciences, April 30, 1910); but in the greater number of cases a high temperature is required. In the great majority of pure metals, and in some alloys, the rate of subsequent cooling is immaterial so far as the softening effect is concerned; but in certain metals and in a large number of alloys either allotropic or other changes take place during gradual cooling, and these transformations are more or less inhibited by rapid cooling; in such metals the rate of cooling through the 'critical temperatures' at which these changes occur is of material importance. The most striking example is found in carbon steels containing upwards of ½ p.c. of carbon, which are moderately soft if cooled slowly down to a temperature of 650°, but become exceedingly hard if suddenly cooled from a temperature above 700°. In the case of hardened tool steel, the process of annealing consists in raising the steel to such a temperature (above 700°) that the changes which were suppressed when the steel was hardened by quenching are allowed to take place during the heating and cooling process.

In modern 'high speed tool steels' the presence of a considerable percentage of tungsten (16–20 p.c.) or of molybdenum, has the effect of raising the annealing or softening temperature very considerably. Prolonged exposure to a temperature near 900° C. is required to bring about full softening, and tools made of these steels retain their cutting edge at a dull red heat (near 700° C.), while a carbon steel becomes useless at a much lower temperature (near 400° C.). It is this property which makes it possible to use 'high speed' tools for working at rates which generate far more heat than carbon steel tools could withstand.

A special form of annealing known as 'normalising' is now frequently applied to mild steel with highly beneficial results. The process consists in heating the steel to a temperature just above the highest critical point (from 830° C. to 900° C., according to the carbon content), keeping it there just long enough to ensure that the whole mass has attained the desired temperature, and then allowing the steel to cool rapidly, usually by taking it out of the furnace and cooling it in the air. This treatment results in the refining of the structure of the steel (*see* METALLOGRAPHY) with a very considerable concomitant improvement in the physical properties, more especially as shown by the notched-bar impact test.

In many metals the annealing process is liable to be complicated by the effects of chemical actions between the metal and its solid or gaseous surroundings, as well as by the effects of the growth of the constituent crystals of the metal; at high temperatures these crystals tend to increase in size, and the resulting coarsening of the grain of the metal leads to a deterioration in mechanical properties. Annealing at an unduly high temperature or for too long a time thus becomes 'over-heating,' and is injurious to almost all metals and alloys, notably to steel and brass. W. R.

ANODYNINE. Identical with antipyrine (*q.v.*).

ANOGON. Trade name for the mercury salt of 2·6-diiodophenol-4-sulphonic acid.

ANONA MURICATA (Linn.). A decoction of the root is used as an antidote for fish-poisoning, and the bark serves as an astringent. The leaves are useful in softening abscesses, and from the seeds a wine can be prepared which is said to be beneficial in cases of diarrhœa (Chem. Zeit. 10, 433; J. Soc. Chem. Ind. 5, 332).

ANORTHITE *v.* FELSPAR.

ANOZOL. Trade name for a preparation of iodoform deodorised by 10–20 p.c. of thymol.

ANTACEDIN. *Calcium saccharate.*

ANTALGINE. Trade name for salicylaldehyde-α-methylphenyl hydrazone. Used for neuralgia and rheumatism.

ANTHEMOL *v.* CAMPHORS.

ANTHIONE. Trade name for a solution of potassium persulphate. Employed as a photographic reagent.

ANTHOCYANINS. Many brilliant natural effects are due to the colouring matters of this group. They have been the subject of investigation for many years past, but it is only since the work of Willstatter and Everest (Annalen, 1913, 401, 189) that chemical knowledge concerning them has been placed upon a satisfactory basis.

Marquart (Die Farben der Blüten, Bonn, 1835) first introduced the term *anthocyan*, using it for the blue pigments present in flowers; gradually, however, the term became extended to include all red, purple, and blue flower, berry, or leaf sap-pigments, whilst the terms *anthocyanin* and *anthocyanidin* were introduced by Willstatter and Everest to designate the glucoside and non-glucoside anthocyan pigments respectively.

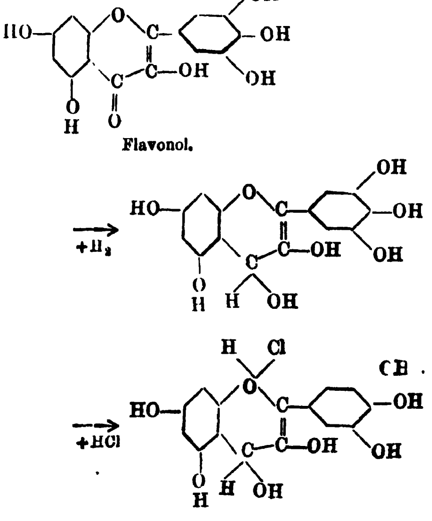
In 1837, Berzelius (Annalen, 21, 262) attempted to isolate and purify various pigments of this class, and his method, which involved the use of lead salts, was adopted by many later investigators, but rarely with any success. Morot (Annales des Science nat. [3] 13, 160 [1849-1850]) attempted to obtain a pure pigment from the cornflower, whilst Fremy and Cloëz (J. Pharm. Chim. [3] 25, 249) worked on various flowers, including the cornflower, violet, iris, dahlia, rose, and peony, and concluded that all anthocyan colours were produced by a single pigment which they called *Cyanin*. (This name was given to the cornflower pigment in 1913 by Willstatter and Everest.) In connection with the supposed identity of all anthocyan pigments the work of Overton (Pring. Jahrber. f. wiss. Bot. 1899, 33, 222), of Weigert (Jahresber. d. k. k. önol. und pomol. Lehranstalt in Klosterneuburg, 1894-1895), and the earlier work of Berzelius (*l.c.*), Fremy and Cloëz (*l.c.*), Filhol (Compt. rend. 39, 194; J. pr. Chem. 1854, 63, 78), Wigand (Bot. Ztg. 1862, 123), Hausen (Die Farbstoffe der Blüten und Früchten, Würzburg, 1884, 8), and Wiesner (Bot. Ztg. 1862, 392), should be referred to.

Filhol (*l.c.* 1854) and Morren (1859) carried out a number of qualitative investigations bearing upon the formation of pigments in flowers.

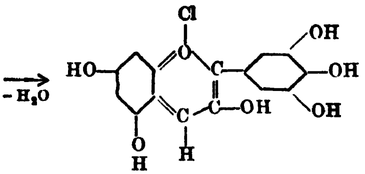
Work of a more definitely quantitative character was attempted by Glénard (Compt. rend. 47, 268; Jahrber. 1858, 476), using red wine, and Senier (Jahrber. 1878, 970), using *rosa gallica*, and this was followed by that of Heise (*cf.* Chem. Centrblt. 1889, ii. 953; and 1894, ii. 846) and Glan (Dissertation, Erlangen, 1892), in which the pigments of red wine, the bilberry, and flowers of the deep-red hollyhock were examined, and as the result of this the question of the glucosidal nature of these pigments was raised, a question first settled by the work of Willstatter and Everest in 1913.

The first description of an anthocyan pigment in crystalline condition was published by Griffiths (Ber. 36, 3959; Chem. News, 1903, 88, 249), the pigment being that of the scarlet pelargonium. Somewhat later, Molisch (Bot. Ztg. 1905, 145) obtained the same, and several other pigments of the series, in crystalline condition on microscope-slides, and his work led Grafe (Sitzber. k. Akad. d. Wiss. Wien, 1906, 975; 1909, 1033; and 1911, 765) to attempt to obtain similar results on a large scale, but although he succeeded in procuring crystalline compounds in a number of cases, his chemical results have been largely disproved by the later work of Willstatter and his collaborators.

A considerable amount of investigation has been carried out upon the relationship existing between the anthocyan pigments and the yellow sap colouring matters—flavones and flavonols. Hope (Trans. Roy. Soc. Ed. 1836) developed ideas concerning this matter; Morot (*l.c.*), as also Filhol (*l.c.*), touched upon it, whereas Fremy and Cloëz (*l.c.*) criticised the drawing of conclusions as to such relationships whilst so little was known concerning the pigments involved. Martens (*l.c.*) suggested that the yellow and red sap-pigments have their origin in a faintly yellow-coloured substance produced in the sap of all plants and which passes by oxidation—particularly in light—into the yellow sap pigments, and that these, by further oxidation and light, pass in their turn into anthocyans. As the result of much botanical work, theories have been put forward by Wheldale, by Keeble, Armstrong, and Jones, and by others, which resemble that of Martens in that oxidation of the yellow sap pigments—flavones or flavonols—is considered to be one of the essential steps in the formation of anthocyan pigments. These ideas, which were becoming very generally accepted, have been disproved by Everest (Proc. Roy. Soc. 1914, B. 87, 444; and 1914, B. 88, 326), who succeeded in discovering the real relationship that exists between these two groups of pigments, and the manner in which the yellow sap pigments could be converted into anthocyanins. He showed that anthocyanidins are produced by reduction of flavonols, followed by spontaneous oxonium-salt formation and dehydration, a series of changes that may be expressed thus:—



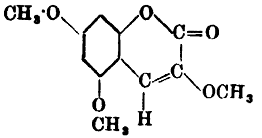
Flavonol.



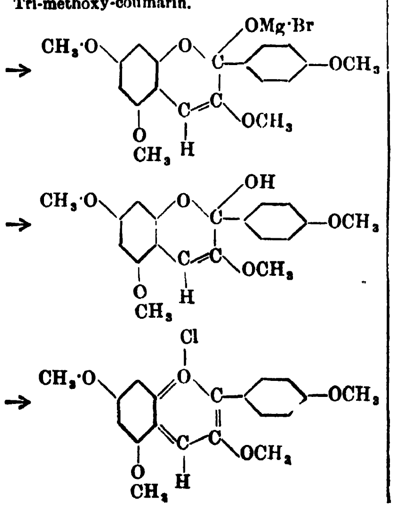
Anthocyan.

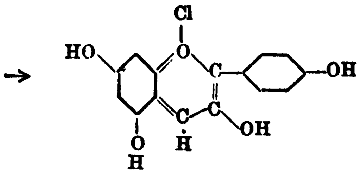
In like manner he obtained anthocyanins when glucosides of the flavonols were used. The evidence thus obtained by synthesis, and the structure proposed by Everest were in complete agreement with the results of analytical work, carried out independently and concurrently, by Willstätter and his collaborators in the extension of their work on the anthocyan pigments, and they, after repeating the work of Everest, confirmed it (Sitzber. d. K. Akad. Wiss. Berlin, 1914, 769), and in this way obtained synthetic cyanidin chloride and proved it to be identical with Willstatter and Everest's cyanidin chloride, obtained from the cornflower. In connection with the production of anthocyans from flavone derivatives, the following papers should also be noted, viz. Stein, J. pr. Chem. 1862 and 1863; Hlasiwetz und Pflaundler, Sitzber. Wiener Akad. Wiss. mat.-natw. Klasse. 1904; Watson, Chem. Soc. Trans. 1914, 105, 389; Combes, Compt. rend. 1913, 157, 1002, and 1454.

A further interesting synthesis of an anthocyanidin (pelargonidin) has since been carried out by Willstatter and Zechmeister (Sitzber. d. k. Preuss. Akad. d. Wiss. Berlin, 1914, 886), who made use of a totally different series of reactions which may be represented thus :—



Tri-methoxy-coumarin.

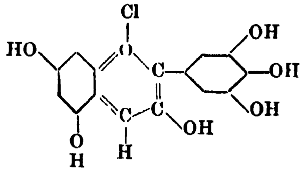




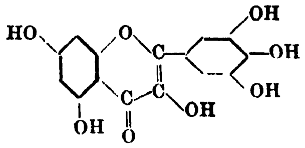
Pelargonidin chloride.

In this way the structure of all the anthocyan pigments thus far investigated has been established. It is interesting to note that all are derivatives related to flavonols, and in this connection Everest (*l.c.*) has pointed out that as flavones are also met with in plants, and that they yield red pigments on reduction, there is every reason to expect that anthocyans related to them may be brought to light as the result of further research.

It would seem that these pigments are formed in Nature from flavonol derivatives first produced in the plants. Direct chemical evidence of this has been obtained by Everest (Roy. Soc. Proc. 1918, B. 90, 251). He has isolated the anthocyan pigment *violanin*, a glucoside of delphinidin,

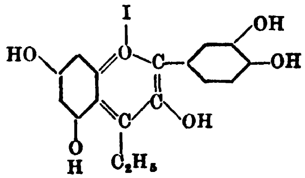


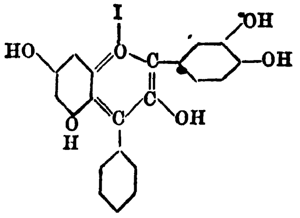
from the purple-black viola (Sutton's) 'Black Knight,' and has shown that, unless gossypetin is present, which appears unlikely, this pigment is accompanied in those flowers by a glucoside of myricetin :

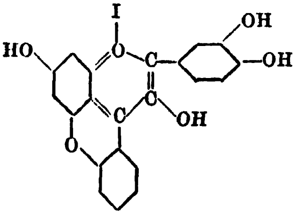


myricetin being the flavonol which would yield delphinidin by reduction.

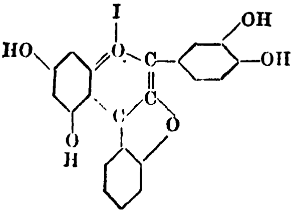
Some interesting substitution derivatives of the anthocyan series have been prepared by Watson (Chem. Soc. Trans. 1914, 397; 1915, 1477), as the result of treating flavone and flavonol derivatives with various Grignard reagents. The following are typical examples of such compounds :—







or



In 1913, in connection with their investigation of the cornflower pigment, Willstätter and Everest (*l.c.*) showed that all anthocyan pigments occurred in plants as glucosides (named by them *Anthocyanins*), and this generalisation has been supported and confirmed by all more recent work. In some few instances, however, *e.g.* in the black grape, a small percentage of sugar-free pigment (named *anthocyanidin*) has been found to accompany the glucoside.

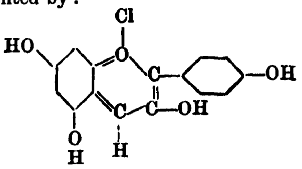
These authors introduced an important reaction whereby it is possible to determine whether a given anthocyan pigment is a glucoside or not. When a solution of the pigment in dilute aqueous acid (preferably *ca.* 0·5 p.c. HCl) is shaken with amyl alcohol (free from pyridine), the pigment, if a di-glucoside remains almost quantitatively in the aqueous layer, but if it is a mono-glucoside (rhamno-glucosides behave in this test very similarly to mono-glucosides), then an appreciable percentage of the pigment (*ca.* 10 p.c.) passes to the amyl alcohol, but this can be removed by shaking the alcohol layer repeatedly with fresh acid. If the pigment is a non-glucoside it passes quantitatively into the amyl alcohol, and shaking with fresh aqueous acid does not withdraw it.

The Anthocyanidins.

All the anthocyanins hitherto investigated are derivatives of three anthocyanidins, viz. *Pelargonidin*, *Cyanidin*, and *Delphinidin*, or of methyl ethers of these compounds.

Pelargonidin, which was first isolated in the form of its diglucoside, *pelargonin*, from the *Pelargonium zonale* (Meteor), may be obtained by the hydrolysis of that or any other of its glucosides isolated by Willstätter and his collaborators; such compounds occur in the following flowers, either alone or mixed with other anthocyan pigments, viz. purple-red summer aster, *Callistephus chinensis* (Nees), syn *Aster chinensis* (Linn.); the scarlet Salvia, *Salvia coccinea* (Linn.), and *S. splendens* (Sello.); the rose-coloured cornflower; scarlet-red gladiolas; and *Zinnia elegans* (Jacq.). The colouring matter is most readily isolated as the crystalline chloride.

Pelargonidin chloride $C_{15}H_{11}O_5Cl$, or 3 : 5 : 7-trihydroxy - 2 - *p* - hydroxyphenyl - 1 : 4 - benzo-pyranol anhydrochloride, has the structure represented by:



and crystallises with one molecule of water, this being removed only by drying in high vacuum at 105° C.

By the action of hydrochloric acid a related product is formed, the constitution of which is not settled. Pelargonidin chloride has been observed to yield three different crystalline forms: (i.) red tablets; (ii.) red-brown four-sided prisms; and (iii.) yellow-brown swallow-tail twin crystals (*cf.* Willstätter and Bolton, Annalen, 1915, 408, 42; and 1916, 412, 133); it is difficultly soluble in cold dilute acids, more soluble in warm; in alcohol it is very easily soluble. An acid solution of the chloride gives a blue colouration on addition of sodium carbonate solution, but ferric chloride does not produce any colour reaction. Unlike any other known pigment of this series, it shows two absorption bands, one in the yellow-blue portion of the spectrum, the other in the violet, the latter being the one not observed in other cases. The compound does not melt below 350° C.

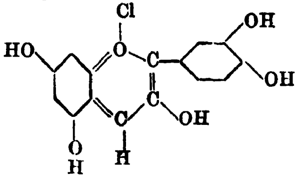
When decomposed by heating with concentrated caustic potash, or by fusion with potash, the decomposition products are mainly phloroglucinol and *p*-oxy-benzoic acid, but a small quantity of protocatechuic acid is also formed.

Pelargonidin **ψ-base** $C_{15}H_{12}O_6$, colourless prisms, not melting below 350° C., is formed when the chloride is heated with water (preferably by addition of a trace of sodium bicarbonate), the product extracted with ether, and crystallised from water. It is very easily soluble in alcohol, ether, and hot water; acidification of an aqueous solution with HCl causes the deposition of the chloride.

Pelargonidin chloride dyes wool (tin mordant) purple-red, and tannined cotton bluish-red; it does not dye unmordanted wool.

Cyanidin, first isolated by Willstätter and Everest (*l.c.*) from the blue cornflower pigment (cyanin), may be obtained by hydrolysis of this or any other of its naturally occurring glucosides, or from its methyl ether, peonidin, by demethylation. Glucoside-pigments derived from cyanidin have been isolated from, or detected in, the flowers of blue, and deep purple, cornflowers, *rosa gallica*, peony, chrysanthemum, dahlia (deep red), aster, poppy, *Zinnia elegans*, gladiolas (hybrid), *gaillardia bicolor*, *helenium autumnale*, *tulipa gesneriana*, *tropæolum majus*, and in the fruits, or berries, of the sweet cherry, sloe, cranberry, red currant, raspberry, and mountain ash. In some cases they are accompanied by derivatives of other anthocyanidins (*see* various papers by Willstätter and his collaborators).

Cyanidin chloride $C_{15}H_{11}O_6Cl$, 3 : 5 : 7-trihydroxy-2-*m* : *p* : dihydroxyphenyl-1 : 4-benzopyranol-anhydrochloride :



crystallises readily from 20 p.c. HCl, when its pure glucosides are hydrolysed by boiling with this reagent for three minutes, the crystals, long red-brown needles with metallic lustre, contain $1H_2O$, which is very difficult to remove, complete drying being only obtained at 105° C. in high vacuum. The anhydrous salt does not melt below 300° C.; if dried at 50° C. it melts at once if dipped into a bath at 220° C., but does not melt if put in at 200° C., and the temperature then gradually raised. It is very soluble in methyl, or ethyl alcohol; fairly soluble in dilute sulphuric acid; difficultly soluble in HCl. Neutral alcoholic or aqueous solutions lose their colour on standing owing to *pseudo*-base formation, acids reproduce colour, slowly if cold, rapidly if warm. The absorption spectrum shows one broad band with ill-defined edges.

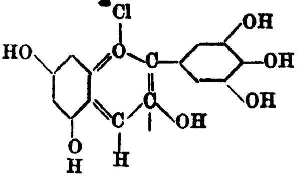
Cyanidin colour base, separates in crystalline condition when a hot concentrated solution of the chloride in alcohol is mixed with twice its volume of water (*cf.* Willstatter and Nolan, Annalen, 1915, 408, 13). It is fairly soluble in alcohol or pyridine.

Cyanidin pseudo base $C_{15}H_{12}O_7$, crystallises with one mol. H_2O when a dilute solution of the chloride in alcohol is mixed with twice its volume of water, warmed gently, then, after it has become colourless, evaporated *in vacuo*, extracted with ether, and the product crystallised from water. Readily soluble in water, alcohol, acetone, or glacial acetic acid, it is insoluble in benzol; with soda it gives a yellow colouration, with HCl cyanidin chloride is formed and crystallises out. When decomposed by means of fused alkali protocatechuic acid and phloroglucinol are produced.

Cyanidin chlorides dyes wool (tin mordant) blue-violet, cotton (tannined) violet, and unmordanted wool fine rose (Willstätter and Mallison).

Delphinidin, first obtained by Willstatter and Mieg (Annalen, 1915, 408, 61) from the pigment of purple wild delphinium (delphinin), may also be obtained by hydrolysis of violanin, the only other glucoside of delphinidin itself that has as yet been isolated, or by demethylation of its mono- or di-methyl ethers, several of which occur, as glucosides, in a variety of flowers and fruits.

Delphinidin chloride $C_{15}H_{11}O_7Cl$, 3 : 5 : 7-trihydroxy-2-*m* : *m* : *p* : trihydroxyphenyl-1 : 4-benzopyranol-anhydrochloride :



prepared by boiling the above-named glucosides with 20 p.c. HCl for two minutes, rarely separates pure from the hydrolysis as it is affected by concentrated hot HCl. Four distinct crystalline hydrates have been described by Willstätter and Weil (Annalen, 1916, 412, 178), viz. with $1H_2O$, $1\frac{1}{2}H_2O$, $2H_2O$, and $4H_2O$. W. and W.'s 'first hydrate' ($2H_2O$) separates from cold, aqueous alcoholic hydrochloric acid solutions (prepared by addition of 7–20 p.c. HCl to an alcoholic solution of the colour) when the alcohol is allowed to evaporate slowly; it forms aggregates of prismatic tablets; their 'second hydrate' ($1H_2O$) separates from cold, 3–5 p.c. hydrochloric acid as thin, sharply-cut, deep-violet, rhombic tablets; their 'third hydrate' ($4H_2O$) is deposited from 5 p.c. hydrochloric acid in the form of fine red-brown prisms and needles; their 'fourth hydrate' ($1\frac{1}{2}H_2O$) separates from hydrochloric acid containing more than 20 p.c. HCl, and is readily prepared by adding concentrated HCl to a solution of the colour in water, or dilute HCl, when an amorphous precipitate is first produced, but this slowly crystallises. All the above hydrates lose their water of crystallisation in a vacuum desiccator at room temperature. Of these hydrates the third and fourth appear most readily obtainable.

The chloride is easily soluble in methyl, or ethyl alcohol, and in water—the aqueous solution soon deposits violet flakes of the colour base—it is difficultly soluble in dilute sulphuric acid; ether extracts a portion of the colour from an aqueous solution, but shaking the ether extract with aqueous acid completely removes the colour. Addition of soda to an acid solution yields a fine blue colour; ferric chloride added to an alcoholic solution gives a pure blue, to an aqueous solution a violet colouration. When the chloride was treated with caustic potash (75 p.c.) at 250° C., Willstätter and Mieg obtained phloroglucinol, pyrogallol, and a small amount of gallic acid. The absorption spectrum consists of one band (yellow-green), which is fairly well defined.

Delphinidin sulphate, long prisms, from hot dilute sulphuric acid. *Iodide*, brown prisms, or leaflets, obtained by boiling the chloride with concentrated hydriodic acid and phenol. *Picrate*, fine red-brown needles and prisms, difficultly soluble in water. *Colour base*, amorphous violet precipitation deposited from neutral aqueous solutions of the chloride on standing. *Pseudo base* $C_{15}H_{12}O_8$, obtained by warming a dilute solution of the chloride with a trace of primary sodium phosphate, extracting with ether and recrystallising the product from water or ether; colourless prisms, no melting-point;

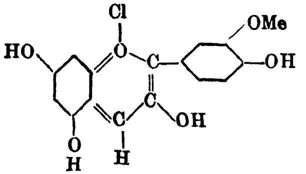
easily soluble in alcohol, acetone, ethyl acetate, or glacial acetic acid, less soluble in ether, insoluble in benzol; aqueous soda dissolves it with a yellow colour, aqueous hydrochloric acid converts it into the chloride.

Delphinidin chloride dyes mordanted wool (tin) blue, with violet tinge, tannined cotton blue-violet, and unmordanted wool violet.

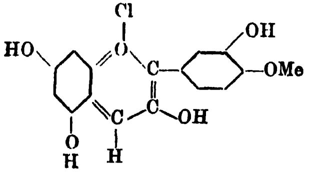
METHYL ETHER OF CYANIDIN.

Peonidin, obtained by Willstätter and Nolan (Annalen, 1915, 408, 156) from the pigment of the deep violet-red peony, has been proved by them to be a mono-methyl ether of cyanidin.

Peonidin chloride $C_{16}H_{13}O_6Cl$ forms a crystalline hydrate with $1H_2O$, long red-brown needles, fairly soluble in cold water, very soluble in hot: very soluble in alcohol; very difficultly soluble in cold, easily soluble in hot 1 p.c. HCl, recrystallising well from this medium. With boiling hydriodic acid it yields cyanidin iodide; an acid solution yields a blue colour on addition of soda; ferric chloride gives no characteristic colour reaction From the ferric chloride test, together with the alkaline decomposition, which yielded evidence of a methyl ether of the phenolic acid, but no methyl ether of phloroglucinol, and further, as the result of Zeisel estimations, Willstatter and Nolan suggest the formulæ:



or



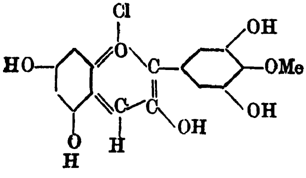
as probable for peonidin chloride.

Peonidin sulphate, brown-red needles, from 7 p.c. aqueous sulphuric acid.

METHYL ETHERS OF DELPHINIDIN.

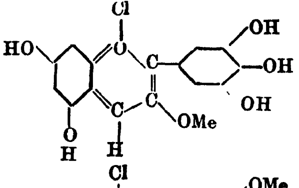
(a) *Mono-methyl Ethers.*

Ampelopsidin, isolated as the *chloride*, $C_{16}H_{13}O_7Cl$, by Willstatter and Zollinger (Annalen, 1916, 412, 216) from the pigment of the ampelopsis (*see* below), crystallises in prisms containing water of crystallisation, the amount of which has not yet been definitely settled, and probably has the structure:

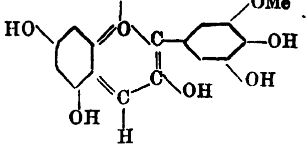


Its investigation is not yet complete.

Myrtillidin has been obtained from the pigments *myrtillin* or *althein* (*see* below) by Willstätter and Zollinger (Annalen, 1915, 408, 83; and 1916, 412, 205) in the form of the crystalline *chloride* $C_{16}H_{13}O_7Cl$, clusters of deep brown prisms, or red-brown prismatic tablets, containing $1\frac{1}{2}H_2O$. Upon evidence obtained from alkaline decomposition, and consideration of the ferric chloride reaction, W. and Z. consider that the chloride has one of the following structures, viz.:



or

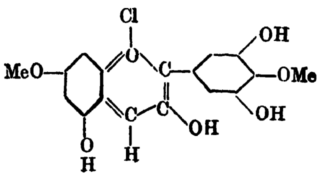


Petunidin, prepared by Willstätter and Burdick (Annalen, 1916, 412, 217) from the pigment of the cultivated petunia (*see* below), forms a crystalline *chloride* $C_{16}H_{13}O_7Cl$, yellow-brown prisms, or rhombic leaflets, containing $2H_2O$; it is closely related to, but somewhat different from, myrtillidin, and W. and B. consider that petunidin is represented by one, and myrtillidin by the other of the two structural formulæ set out above under myrtillidin, but at present a decision between them is not possible.

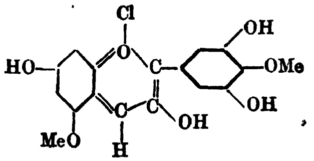
Anthocyanidin from Vitis Riparia Pigment. This product is probably one of the other possible mono-methyl ethers of delphinidin, but the work on it as yet is very incomplete.

(b) *Di-methyl Ethers.*

Malvidin. This compound has been isolated from the pigment of the wild mallow (*see* below) by Willstätter and Mieg (Annalen, 1915, 408, 122), who obtained it in the form of its crystalline *chloride* $C_{17}H_{15}O_7Cl$, deep-brown needles or prisms, often in rosettes, containing $2H_2O$, of which the last $1H_2O$ can only be removed at 105° C., in high vacuum. It does not melt below 300° C. Easily soluble in methyl or ethyl alcohol, but the solution in methyl alcohol soon deposits a crystalline precipitate; fairly soluble in amyl alcohol, it is difficultly soluble in dilute sulphuric acid. It gives no ferric chloride reaction, from which, and the fact that they obtained evidence from alkaline decomposition, that one MeO group was in each of the benzene nuclei, W. and M. have put forward the structural formulæ:



or

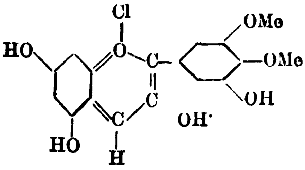


for this compound.

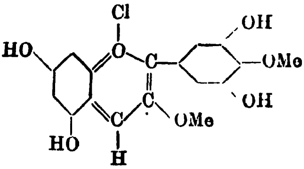
Picrate, red-brown needles, difficultly soluble in water.

Oenidin has been prepared by Willstatter and Zollinger (Annalen, 1915, 408, 83; and 1916, 412, 195) from the pigment of the black grape, or red wine. It appears to exist in black grapes, with the glucoside oenin.

Oenidin chloride $C_{17}H_{15}O_7Cl$ crystallises in deep brown prisms or needles, with bronze reflex, containing $1\frac{1}{2}H_2O$, of which the last half molecule is not removed until heated to 135° C. in high vacuum. It is readily soluble in water, in methyl or ethyl alcohol, in dilute HCl or dilute sulphuric acid; an acid solution becomes violet on addition of soda, but blue with caustic soda. From the products of alkaline decomposition (which showed that no MeO group was present in the portion of the molecule which yielded phloroglucinol, but at least one was in the other phenyl group), and the absence of a ferric chloride reaction, Willstatter and Zollinger have proposed the following formulæ for this compound, viz.:



or



Picrate, fine deep red prisms, very difficultly soluble in water.

All the above-mentioned mono- or di-methyl ethers of delphinidin yield delphinidin iodide when boiled with concentrated hydriodic acid.

THE GLUCOSIDES (ANTHOCYANINS).

The glucoside members of this group are the pigments producing the reds, purples, and blues which form so noticeable a part of the colourings of flowers, fruit, and autumn leaves. In many instances one pigment may produce all these shades, the colour being dependent on the condition of the cell sap; thus cyanin, as its potassium salt, is the blue of the blue cornflower; as the colour base, it is the purple of the deep purple kinds of the same plant, whereas the same pigment in combination with plant acids gives the red colour to *Rosa gallica*.

Yellow sap pigments, flavone derivatives, being but very faintly coloured unless present as alkali salts, rarely play any great part in the colouration of flowers, except in the production of pale yellows, as in the primrose, or together with anthocyanins, where these are not strong, of pale peach-colour effects; on the other hand, the strongly yellow, or orange, carotinoids produce—beyond the colourations for which they are solely responsible—orange and brown shades when present together with anthocyans.

Owing to the varying sap conditions which occur, and their effect on the pigments, it is not easy, and is often impossible, to obtain, by means of mere observation, any accurate estimation of the quantity of an anthocyan pigment present in a flower; moreover the shades produced by different anthocyanins often resemble one another so closely as to make discrimination between them impossible (*cf.* Willstätter and Mallison Annalen, 408, 147).

Methods of Isolation.

Willstätter and Mallison (*l.c.*) summarise the various methods used for the isolation of anthocyanin pigments thus:—

I. Precipitation and crystallisation of the chloride, *e.g. pelargonin.*

II. Special purification of the pigment followed by crystallisation of the chloride, *e.g.*

(*a*) *Cyanin* (i). from blue cornflower, by purification of the alkali salt by precipitation with alcohol from aqueous solution, followed by conversion to the chloride and fractional purification from alcohol by ether;

(ii.) from rose, or peony, by long standing with a mixture of glacial acetic acid, methyl alcohol, and HCl, whereby impurities are hydrolysed or acetylated.

(*b*) *Myrtillin*, by repeated purification from aqueous solution by HCl.

(*c*) *Delphinin* (i.) by purification of violet colour base from dilute alcohol, soluble by addition of concentrated alcohol;

(ii.) by gently warming with HCl, whereby impurities are hydrolysed, but not the delphinin.

III. Precipitation of the pigment as crystalline picrate, followed by conversion of the pure picrate to chloride, *e.g. Oenin, myrtillin, idaein.*

1. *Derivatives of Pelargonidin.*

Pelargonin, a diglucoside of pelargonidin, the pigment of the scarlet *pelargonium zonale*, was so named by Willstatter and Bolton (Annalen, 1915, 408, 42), to whom we owe our chemical knowledge of this pigment. *Cf.* earlier workers, Griffiths (*l.c.*), Molisch (*l.c.*), and Grafe (*l.c.*). Willstätter and Bolton have also shown that this colouring matter occurs in the pink cornflower, and the cactus dahlia (*ibid.* p. 149).

Pelargonin' chloride $C_{27}H_{31}O_{15}Cl$ crystallises in long red needles, containing $4H_2O$, all of which is lost in vacuum desiccator at room temperature. When anhydrous it softens at 175° C., melts at 180° C. (decomposed). Not very soluble in water, methyl, or ethyl alcohol, its alcoholic solutions show characteristic greenish-yellow fluorescence. It is optically active. W. and B. give $[\alpha]_D = -291°$, $[\alpha]_{614} = -180°$; the salt shows an absorption spectrum consisting of one broad band.

Basic chloride

$$(C_{27}H_{31}O_{15}Cl)_2{\cdot}(C_{27}H_{30}O_{15}){\cdot}12H_2O,$$

deep violet microscopic needles, obtained by boiling the normal chloride with 96 p.c. alcohol for a few minutes. *Acetate*

$$(C_{27}H_{30}O_{15})_2{\cdot}(C_{27}H_{30}O_{15}{\cdot}C_2H_4O_2),$$

fine red needles from a solution of the base (*see* below) in warm glacial acetic acid. *Pelargonin base* $C_{27}H_{30}O_{15}$, amorphous, difficultly soluble in water or alcohol, obtained by the action of a small quantity of water on the normal chloride.

Salvianin (Willstatter and Bolton, Annalen, 1916, 412, 113), as yet only obtained crystalline as picrate, is the pigment of the scarlet *Salvia splendens*, in which it occurs to the extent of *ca.* 6 p.c. The *chloride* (not crystalline) when completely hydrolysed, yields pelargonidin chloride (*ca.* 36 p.c.), glucose (*ca.* 30 p.c.), and malonic acid (*ca.* 25 p.c.). It behaves abnormally in distribution between amyl alcohol and aqueous acid, and it appears possible that the glucose is present in a dehydrated form $C_6H_{10}O_5$. Careful hydrolysis with HCl appears to remove the malonic acid, yielding a new pigment *Salvin chloride*, probably $C_{27}H_{27}O_{13}Cl$ (a diglucoside of pelargonidin $-2H_2O$), which shows the same abnormal distribution as the previous compound; this was obtained in a crystalline condition by W. and B. Further gentle hydrolysis then yields a true diglucoside of pelargonidin which was named *Salvinin chloride* $C_{27}H_{31}O_{15}Cl$; this body shows normal distribution for a diglucoside anthocyanin, whilst by further careful hydrolysis it yields a mono-glucoside of pelargonin and glucose (1 mol.), whilst finally the monoglucoside yields pelargonidin and glucose. W. and B. have not completed their investigation of these pigments, and the names they have used are stated to be tentative.

Callistephin, a mono-glucoside of pelargonin, is present together with asterin (a cyanidin glucoside) in purple-red asters (*Callistephus chinensis* (Nees), syn. *Aster chinensis* (Linn.), from which it was isolated by Willstatter and Burdick (Annalen, 1916, 412, 149). It was separated from asterin by fractional precipitation from alcohol by ether, and recrystallised from aqueous alcoholic hydrochloric acid. *Chloride*

$$C_{21}H_{21}O_{10}Cl,$$

fine orange-red needles containing 2–2½ H_2O; easily soluble in water, alcohol, or dilute acids (HCl, H_2SO_4). Acid solutions become red-violet with alkalis; it gives no ferric chloride reaction; unlike pelargonin it does not show fluorescence in alcoholic solution.

Pelargonenin, a mono-glucoside of pelargonidin, has been prepared by Willstatter and Bolton (Annalen, 1916, 412, 133) by partial hydrolysis of pelargonin with cold concentrated HCl, any pelargonidin produced being removed by means of amyl alcohol, and the chloride crystallised from warm 2 p.c. HCl. *Chloride* $C_{21}H_{21}O_{10}Cl$, scarlet-red needles, probably containing 2½ mols. water, sparingly soluble in water, very difficultly soluble in dilute HCl; its alcoholic solutions show strong fluorescence.

2. *Derivatives of Cyanidin.*

Cyanin, the pigment of blue or purple cornflowers, also occurs in *Rosa gallica*, and deep red dahlia flowers; it is a diglucoside of cyanidin. Willstätter and Everest (Annalen, 1913, 401, 189) first obtained it in a pure condition, as the crystalline chloride, from the blue cornflower; it is, however, more readily prepared from *Rosa gallica* (W. and Nolan, Annalen, 1915, 408, 1), or the deep red dahlia (W. and Mallison, Annalen, 1915, 408, 147). The *chloride* $C_{27}H_{31}O_{16}Cl$, red-brown rhombic leaflets containing 2½ mols. of water can only be completely dried at 105° C. in high vacuum. Air-dried it is very difficultly soluble in water, acetone, or chloroform, difficultly soluble in cold alcohol or dilute HCl, insoluble in benzol. In 7 p.c. sulphuric acid it is fairly soluble, but the sulphate separates out from the solution. Soda added to an acid solution gives a pure blue; ferric chloride gives a fine blue in alcohol, violet in water. It shows a single absorption band covering the green and blue; it is optically active. Willstätter and Nolan give, for white light, $[\alpha] = -258°\ (\pm 10°)$. *Picrate,* red needles, very soluble in water. *Cyanin potassium salt,* the blue pigment of the cornflower, was obtained crystalline, but not free from NaCl, by Willstatter and Everest, after purification by dialysis. It is very soluble in water, insoluble in alcohol; its blue aqueous solutions become colourless on standing owing to formation of *pseudo*- base, whereas in 20 p.c. NaCl solution the colour is stable for months.

Mekocyanin, isolated by Willstatter and Weil (Annalen, 1916, 412, 231), is one of the pigments of the poppy (*Papaver rhœas* (Linn.)), and a diglucoside of cyanidin. Its isolation is difficult, and involves a separation from a second pigment which has not yet been investigated. The *chloride* $C_{27}H_{31}O_{16}Cl$, crystallises in needles containing $3H_2O$, 2 mols. being readily removed, the third only at 105° C. in high vacuum. Very easily soluble in water, dilute HCl, fairly soluble in methyl, difficultly soluble in ethyl alcohol, insoluble in acetone, but soluble in a mixture of acetone and water; its reactions closely resemble those of cyanin chloride. *Ferrocyanide,* fine red-brown needles, prepared by adding potassium ferrocyanide to a solution of the chloride in very dilute HCl; fairly soluble in water, sparingly soluble in alcohol.

Mekocyanin chloride, when carefully hydrolysed, first yields a mono-glucoside (identical with *Chrysanthemin*) and 1 mol. glucose, then by further hydrolysis cyanidin and a further molecule of glucose.

Keracyanin, a rhamno-glucoside of cyanidin, is the pigment of the sweet cherry (*Prunus avium* (Linn.)), and has been isolated by Willstätter and Zollinger (Annalen, 1916, 412, 164) from the skins of that fruit; the purification is tedious, and not final in form. The *chloride* $C_{27}H_{31}O_{15}Cl$ occurs in two forms, fine needles containing $4H_2O$, and short brown-yellow prisms containing $3H_2O$. The salt is easily soluble in methyl alcohol, fairly soluble in ethyl alcohol, difficultly soluble 0·01–0·1 p.c. HCl, but easily soluble 1 p.c. HCl, then less soluble as the concentration of HCl increases.

Prunicyanin, isolated by Willstätter and Zollinger (*l.c.*) from the skins of the sloe (blackthorn, *Prunus spinosa* (Linn.)) is a rhamno-glucoside of cyanidin, closely resembling mekocyanin; its investigation is not yet complete. *Chloride,* not obtained crystalline, but as small spherical particles; yields, on hydrolysis, cyanidin chloride, rhamnose, and a hexose (not yet identified), in approximately molecular proportions.

Asterin, one of the pigments of the purple-red aster (*cf.* Callistephin), has been isolated by Willstätter and Burdick (*l.c.*), it is a monoglucoside of cyanidin. The *chloride* $C_{21}H_{21}O_{11}Cl$, red-brown prisms, containing $1\frac{1}{2}H_2O$, closely resembles chrysanthemin chloride in its reactions, but differs greatly from it in solubilities in dilute acids.

Chrysanthemin, isolated by Willstätter and Bolton (Annalen, 1916, 412, 136), a monoglucoside of cyanidin, is the pigment of the deep red chrysanthemum (*Chrysanthemum indicum* (Linn.)). The *chloride* $C_{21}H_{21}O_{11}Cl$, red-violet leaflets containing $1\frac{1}{2}H_2O$, resembles Idæin chloride in many respects. *Picrate*, thin red prisms, difficultly soluble in water, sinters at 155° C., melts at 165° C. (decomp.).

Idæin, the pigment of the cranberry (*Vaccinium vitis idæa* (Linn.)), has been isolated by Willstätter and Mallison (Annalen, 1915, 408, 15); it is a mono-galactoside of cyanidin. The *chloride* $C_{21}H_{21}O_{11}Cl$, brown-red prisms containing $2\frac{1}{2}H_2O$, melts at 210° C. (frothing). Easily soluble in water or alcohol, almost insoluble in dilute HCl; ferric chloride gives a blue colour in alcohol, a violet in water. It is optically active, W. and M. give: $[\alpha]_C = -219°$ (±15°). *Picrate*, red needles, more soluble in hot than in cold water. *Sulphate*, brown rhombic crystals from 7 p.c. sulphuric acid.

Peonin, a diglucoside of peonidin, the pigment of the deep violet-red peony, has been isolated by Willstatter and Nolan (Annalen, 1915, 408, 136). The *chloride* $C_{28}H_{33}O_{16}Cl$, red-brown needles containing $5H_2O$, m.p. 165° C.; for complete drying 100° C. in high vacuum is necessary. Very easily soluble in water, easily soluble in alcohol, insoluble in acetone; it resembles cyanin in many reactions, but ferric chloride gives no characteristic reaction. It is optically active. W. and N. give, for white light, $[\alpha] = -191°$ (±5°). *Picrate*, red-brown needles, from water.

3. *Derivatives of Delphinidin.*

Delphinin, the pigment of the purple wild delphinium (*Delphinium consolida* (Linn.)), has been isolated by Willstatter and Mieg (Annalen, 1915, 408, 61), and is a complex derivative of delphinidin. Unlike all other known anthocyan pigments, it does not appear to form a *pseudo*-base when its neutral aqueous solution is allowed to stand, or is warmed. Although the free colour base can be isolated by fractional precipitation with alcohol, the compound is best isolated as the *chloride* $C_{41}H_{39}O_{21}Cl$, which appears to crystallise with 12 mols. of water, of which, however, only 10 can be removed even by drying in high vacuum at 130° C. It forms deep-red prismatic tablets or prisms, and dried as above sinters at 150°–160° C., then melts at 200°–203° C. (decomp. and swelling). Easily soluble in methyl alcohol, difficultly soluble in ethyl alcohol, in dilute HCl (over 0·5 p.c.), or in dilute sulphuric acid; water rapidly produces the colour base; ferric chloride gives a blue colouration in aqueous or alcoholic solution; sodium carbonate, to an acid solution, gives a fine blue. The salt is optically active, W. and M. give $[\alpha]_C = -1364°$ (±150°); $[\alpha]_{614} = -2273°$ (±150°); its absorption spectrum consists of one broad band. When hydrolysed it yields delphinidin chloride (1 mol.), glucose (2 mols.), and *p*-oxy-benzoic acid (2 mols.). *Colour base*, produced by the action of water on the chloride, and recrystallised from dilute alcohol by slow increase in the concentration of the alcohol, forms rosettes of violet needles. *Picrate*, red-brown flocculent precipitate, very difficultly soluble in water.

Violanin, isolated by Willstätter and Weil (Annalen, 1916, 412, 178) from the blue-black pansy, and by Everest (Roy. Soc. Proc. 1918, B, 90, 251) from the purple-black viola, is a rhamno-glucoside of delphinidin. The *chloride*, probably $C_{27}H_{31}O_{16}Cl$, forms deep red hexagonal or tetrahedral plates or tablets containing about 16 p.c. of water. Its solubility in aqueous HCl decreases up to *ca.* 12 p.c. HCl, but increases again after *ca.* 20 p.c. HCl is reached; it is almost insoluble in dilute sulphuric acid; with soda an acid solution gives a blue colour; ferric chloride gives pure blue in alcohol, or in water. Hydrolysis yields delphinidin chloride, glucose, and rhamnose in approximately molecular proportions. *Picrate*, cherry-red needles, fairly soluble in water.

Ampelopsin, the pigment of the berries of *Ampelopsis quinquefolia* (Michx.), *Vitis hederacea* (Ehrh.), has been isolated by Willstätter and Zollinger (*l.c.*); it is a mono-glucoside of ampelopsidin. The *chloride* $C_{22}H_{23}O_{12}Cl$ crystallises in prisms containing $4H_2O$; easily soluble in methyl or ethyl alcohol; sodium carbonate gives violet, caustic soda a blue colouration when added to an acid solution; ferric chloride only produces a weak reaction.

Myrtillin, the pigment of the bilberry (*Vaccinium myrtillus* (Linn.)), has received attention from earlier workers—*cf.* Andree (Arch. Pharm. 1879, 13, 90), Heise (*l.c.*), and others—but its isolation is due to Willstatter and Zollinger (Annalen, 1915, 408, 83; and 1916, 412, 205). It is a mono-glucoside of myrtillidin. The *chloride* $C_{23}H_{23}O_{12}Cl$, forms red brown tablets containing $4H_2O$, which is only lost completely in high vacuum at 105° C. It is very soluble in water, or methyl alcohol, but less soluble in ethyl alcohol. Ferric chloride gives a blue in alcohol, violet in water; sodium carbonate produces blue-violet, caustic soda blue when added to an acid solution. Its absorption spectrum shows one band with ill-defined edges. *Picrate*, red needles, difficultly soluble in water.

Althein, the pigment of the black hollyhock (*Althaea rosea* (Cav.)), has been isolated and described by Willstätter and Martin (Annalen, 1915, 408, 100; *cf.* Polyt. Zentralblt. 1860, 1540; Glan, *l.c.*; and Grafe, *l.c.*). The *chloride* $C_{22}H_{23}O_{12}Cl$ which crystallises in brown-red prisms containing $4H_2O$, is easily soluble in water, dilute HCl, dilute sulphuric acid, or in methyl or ethyl alcohol, but almost insoluble in glacial acetic acid; ferric chloride gives a violet-blue colour in alcohol, and violet in water; sodium carbonate produces a blue colour when added to an acid solution. It is optically active. W. and M. give $[\alpha]_{623} = -655°$; $[\alpha C] = -545°$; $[\alpha]_{692} = -291°$. The *picrate* is crystalline and difficultly soluble.

Petunin, the colouring matter of the purple-blue petunia 'Karlsruher Rathaus,' was isolated by Willstätter and Burdick (Annalen, 1916, 412, 217); it is a diglucoside of petunidin. The *chloride* $C_{28}H_{33}O_{17}Cl$ crystallises in prisms containing $2H_2O$, which sinter at 165° C. and melt at 178° C. It is difficultly soluble in dilute HCl, fairly soluble in dilute sulphuric acid, easily soluble in methyl, but less so in ethyl alcohol; ferric chloride gives a poor blue colour in alcohol, or in water; sodium carbonate turns an acid solution blue.

The anthocyanin from the skins of the berries of *Vitis riparia* is a mono-glucoside of a delphinidin mono-methyl ether, but, though obtained in a finely crystalline condition by Willstätter and Zollinger (*l.c.*), it has not yet been completely investigated.

Malvin, isolated by Willstätter and Mieg (Annalen, 1915, 408, 122) from the flowers of the wild mallow (*Malva silvestris* (Linn.)), is a diglucoside of malvidin. The *chloride* $C_{29}H_{35}O_{17}Cl$ forms long red prisms, or bundles of needles, containing $8H_2O$, all of which is lost at room temperature in vacuum desiccator. Difficultly soluble in dilute HCl, or dilute sulphuric acid. it is easily soluble in methyl alcohol, but less so in ethyl alcohol. It gives no ferric chloride reaction; sodium carbonate turns an acid solution blue. *Picrate*, red needles, fairly soluble in water.

Oenin, the pigment of black grapes, and of red wine, has been the subject of many investigations from the time of Berzelius (1837), but Willstatter and Zollinger (Annalen, 1916, 412, 198) first isolated and described this substance, which is a mono-glucoside of oenidin. The *chloride* $C_{23}H_{25}O_{12}Cl$, deep red prisms containing 4 or $6H_2O$, is easily soluble in water, fairly soluble in dilute HCl, easily soluble in dilute sulphuric acid, fairly soluble in ethyl, and more so in methyl alcohol. With ferric chloride it gives no colouration; with sodium carbonate an acid solution becomes blue. It is optically active, and W. and Z. give $[\alpha]_{627} = -542°$ ($\pm 60°$); and $[\alpha]_C = -421°$ ($\pm 30°$); its absorption spectrum shows one band. *Picrate*, bundles of carmine-red needles, difficultly soluble in cold water, easily soluble in hot.

The colour reaction with alum, described by Willstätter and collaborators for many of the pigments of this series, is due to traces of iron in the reagent (A. E. Everest, Proc. Roy. Soc. 1918, B. 90, 260).

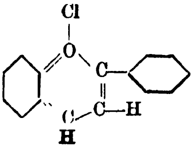
Dyeing Properties of the Anthocyans.

The anthocyanins and anthocyanidins are capable of dyeing not only on mordanted wool, but also on tannined cotton, and indeed some are described by Willstatter as capable of dyeing unmordanted wool.

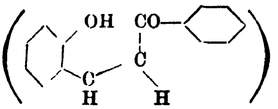
The shades obtained vary from rose to violet and blue, and are fast to light, but very unstable to most reagents, and, owing to pseudo-base formation, even to water.

The substances prepared by Watson, and mentioned above, resemble the natural anthocyans in tinctorial properties, though some of them show very much greater fastness, and in this respect approach the requirements of technical practice.

Everest and Hall (private communication) have confirmed the fact that the affinity of the anthocyans for tin-mordanted wool is connected with the phenolic OH groups present in them. They have also shown that their affinity for tannined cotton is independent of these groups, but dependent upon the presence of the pyrylium ring. Thus the compound:



which is the parent of all the anthocyanidins, has no affinity for tin-mordanted wool, but readily dyes tannined cotton. On the other hand the compound from which the above substance is formed by closing the pyrylium ring



has no dyeing properties.

Further observations have also shown that the compounds which Watson described as dyeing tin-mordanted wool also fall into line in respect of tannined cotton, which they dye very readily.

It is not at all impossible that a new series of technically useful colours for tannined cotton may result from further research in this field.

For fuller details the original papers, or The Natural Organic Colouring Matters, Perkin and Everest (Series of Monographs, Longmans), should be consulted. A. E. E.

ANTHOKIRRIN. The yellow crystalline matter of the flowers of the yellow toadflax (*Linaria vulgaris*). Formerly used as a dyeing material, but the colour is not permanent.

ANTHOKYAN. The expressed juice of the sweet or purple violet (*Viola odorata*), gently heated to 89°, then skimmed, cooled, and filtered. A little rectified spirit is then added, and the following day the whole is again filtered. Used to make syrup of violets, and to colour and flavour liqueurs.

ANTHOPHACIN. A term given by Möbius (Chem. Zentr. 1901, i. 190) to the brown colouring matter of flowers.

ANTHRACENE $C_{14}H_{10}$. Discovered by Dumas and Laurent in the highest boiling portion of coal tar, and termed by them *paranaphthalene* (Annalen, 5, 10); further examined by Laurent, who re-named it *anthracene* (Annalen, 34, 287); first obtained pure, and its composition determined, by Fritzsche (Annalen, 109, 249), and more exactly studied by Anderson (Annalen, 122, 294; Chem. Soc. Trans. 15, 44).

Occurrence.—Anthracene is one of the products of the destructive distillation of coal, and is found in the tar; the average yield of the pure hydrocarbon is about 0·3 p.c. of the tar obtained.

A new source of anthracene has been announced (Dingl. poly. J. 246, 429) in the tar obtained when the residue, left after the illuminating oils have been distilled from Baku petroleum, is allowed to fall on pumice in red-hot iron retorts. 1000 kilos of naphtha residue under these conditions yield 500 c.m. of gas, used to heat the retorts, and 300 kilos. of tar, containing about 0·2 p.c. of pure anthracene. The supply of the naphtha residue is, however, too limited to render anthracene from this source a serious competitor with that from coal tar.

According to Elliott (Amer. Chem. J. 6, 248), the tar obtained in the manufacture of gas by the destructive distillation of light petroleum naphtha boiling below 150° contains 2·63–2·90 p.c. of anthracene. A remarkable production of anthracene, during the distillation of the higher-boiling portions of crude phenol, has been observed by Köhler (Ber. 18, 859).

Anthracene is obtained by the distillation of rhein with zinc-dust (Oesterle and Tesza, Arch. Pharm. 1908, 432), but this production is of no commercial value.

Preparation (Auerbach, Das Anthracen und seine Derivate; Kopp, J. 1878, 1187; Perkin, Journ. Soc. Arts. 27, 572; Lunge, Coal Tar and Ammonia).—Anthracene is obtained from the 'green grease' which forms the last portion of the 'heavy oil' or 'dead oil' of the tar distiller; this at first is greenish-yellow in colour, but turns more brown by the action of the air, and becomes semi-solid on standing, owing to the separation of solid substances. It contains, amongst other substances, naphthalene, methyl naphthalene, anthracene, methyl anthracene, phenanthrene, chrysene, carbazol, and acridine, together with hydrides of anthracene and phenanthrene and other high-boiling liquids. When no further separation occurs, the mass is subjected to filtration, either in a centrifugal machine or a filter press, first in the cold and finally at 40° (Gessert, Dingl. poly. J. 196, 543); or is filtered through strong linen bags, and afterwards submitted to hydraulic pressure in a press so arranged that the plates can be heated with steam and the cake hot-pressed. A notable quantity of anthracene remains dissolved in the expressed oil, and especially in the portions separated when the temperature is raised, and is recovered by redistilling and working up the product as just described. The hard yellowish-green cake obtained, containing 25–40 p.c. of pure anthracene, is ground to a fine powder in mills and heated with coal-tar naphtha (b.p. 80°–100°), solvent naphtha (b.p. 120°–190°), creosote oil, or petroleum spirit (b.p. 70°–100°), in large iron vessels provided with stirrers. Petroleum spirit is to be preferred (Perkin), since it dissolves less anthracene whilst the impurities are sufficiently soluble in it to be removed if the quantity of solvent employed is 2–3 times as great as that of the anthracene to be purified. Solvent naphtha, consisting essentially of xylenes, pseudo-cumene and mesitylene, is extensively employed, as phenanthrene is much more soluble than anthracene in this solvent. It does not, however, remove the carbazole, which is usually present to the extent of 14–18 p.c. When creosote oil is used, it must be free from naphthalene; the advantage of using creosote oil is that it dissolves out the methyl anthracene, the anthracene being practically insoluble therein. The residue contains from 45–50 p.c. of the hydrocarbon, but inasmuch as it is not readily reduced to powder, and unless finely divided is only slowly attacked by oxidising agents, it is sublimed by passing steam, heated at 220°–240°, over the melted product, and condensing the vapours in a chamber by jets of water. The anthracene thus obtained is in leafy masses, containing from 50–60 p.c. of the hydrocarbon, the chief impurities consisting of carbazole (10–12 p.c.), phenanthrene, pyrene, chrysene, and other hydrocarbons, together with small quantities of phenols of high boiling-point, and of acridine; it can readily be ground to a paste, and is now sufficiently pure for conversion into anthraquinone by oxidation. If, however, dichloranthracene is required, further purification is necessary; this can be effected by distillation with caustic potash, whereby impurities such as carbazole and bodies of a phenolic character are retained, and anthracene, together with phenanthrene, distils over with no greater loss than occurs if the 60 p.c. product is distilled alone; caustic soda cannot be substituted for the potash, since it produces no purification of any consequence. Instead of distilling washed anthracene, (100 parts) with caustic potash, Perkin employs a mixture of Montreal potash (30 parts), which usually contains potassium hydroxide in considerable quantities, and caustic lime (6 parts). Unless lime is used, the residue in the retorts forms a hard cake, which can be removed only with difficulty. Hydrogen is evolved during the distillation. The distillate is freed from phenanthrene by washing with coal-tar naphtha, and the residue is a very pure anthracene. This production of phenanthrene, even from anthracene which has been freed from this impurity by extraction with solvents previous to distillation with caustic potash, is noteworthy and points to the probable existence of molecular compounds of phenanthrene with other of the impurities of the washed anthracene, which are destroyed during the distillation with caustic potash. This process of Perkin has been subjected to considerable criticism. According to Auerbach, a loss of anthracene to the extent of 10 p.c. occurs, and this, added to the cost of fuel employed, renders it the most costly method of purification yet devised. The great advantage of the method, however, is that it brings anthracenes of different origins to a similar condition of purity; even pitch anthracene—obtained by the distillation of gas-tar pitch in iron retorts with the aid of super-heated steam, and generally unsuitable for purification owing to the difficulty of removing higher hydrocarbons associated with it—works perfectly well after it has been subjected to this process.

Many modifications in the method of purifying crude anthracene have been introduced. A method based on the far greater solubility of the impurities in mixtures of aniline, pyridine, or quinoline bases, has been patented by the Chemische Fabriks-Actiengesellschaft in Hamburg (D. R. P. 42053 of April 15, 1887). The crude anthracene is dissolved at 100° in 1½–2 times its weight of a dehydrated and rectified mixture of tar bases (pyridines) separated from the light oil obtained in tar distillation (compare D. R. P. 34947 and 36372), and the solution, on cooling, yields a crystalline separation of anthracene almost free from carbazole and its homologues. The patentees state that a 33 p.c. anthracene dissolved in 1·75 times its weight of pyridine bases yields on crystallisation an 82·5 p.c. anthracene, whilst when dissolved in twice its weight of a mixture of equal parts of pyridine bases and benzene, it yields an 80 p.c. anthracene, and in twice its weight of a mixture of equal parts of benzene and aniline a 75 p.c. anthracene. The recovery of the anthracene contained in the mother liquors offers no special difficulty.

Remy and Erhart (D. R. P. 38417 of Jan. 19, 1886) have proposed crystallisation from oleic acid as a means of purification of crude anthracene. The difficulty of recovering the anthracene contained in the mother liquors would seem, however, to deprive this method of technical importance.

Graham (Chem. News, 33, 99, 168) has devised a method for recovering anthracene from the filtered oils used in its purification.

The Farbenfabriken vorm. Friedr. Baeyer & Co. (D. R. P. 68174; Eng. Pat. 6539; J. Soc. Chem. Ind. 1893, 439) employ liquid sulphur dioxide, which dissolves the impurities of crude anthracene, but very little anthracene itself. 600 kilos. crude anthracene is mixed in a wrought iron agitator with 2400 kilos. liquid sulphur dioxide, first exhausting the air and then allowing the sulphur dioxide to enter. The reaction having ceased, the mass is forced by its own vapour pressure into an iron steam-jacketed, filtering tower, where anthracene of 70–80 p.c. remains behind. The mother liquor is distilled, the sulphur dioxide being collected and recondensed by means of an air-compressor.

Another patent of the same firm (D. R. P. 78861; Eng. Pat. 7862; J. Soc. Chem. Ind. 1895, 361) recommends the use of acetone or other fatty ketones as a purifying agent. 560 kilos. crude anthracene is stirred in a steam-jacketed cylinder with 750 kilos. acetone for an hour. After cooling the separated anthracene is filtered and washed with 375 kilos. acetone. The second liquor is used over again, and the first is distilled to recover the acetone. From crude stuff containing 34 or 35 p.c. anthracene, an article of 82 p.c. is easily made, and only a few per cent. anthracene remain in the residue after distilling off the acetone. The acetone may be used in the form of 'raw acetone' or 'acetone oils.'

Welton (Eng. Pat. 27559; D. R. P. 113291; J. Soc. Chem. Ind. 1900, 139) purifies crude anthracene by means of liquid (anhydrous) ammonia, which dissolves out most of the impurities, but not the anthracene itself.

Luyten and Blumer (Eng. Pat. 14892; D. R. P. 141186; J. Soc. Chem. Ind. 1901, 796) state that when anthracene is purified by solvents such as naphtha, acetone, &c., the presence of tar oil in the crude anthracene is beneficial. 25 parts of drained crude anthracene are heated with 35 parts of naphtha until the temperature is near that of the solvent. On cooling, the anthracene crystallises out and is filtered and washed with a little of the solvent. It is dried by heating to fusion, and distilling off the solvent; 80 p.c. anthracene is obtained by this method.

The Aktien Gesellschaft für Theer und Erdöl Industrie (D. R. P. 111359; Eng. Pat. 7868; J. Soc. Chem. Ind. 1899, 750) heat crude anthracene to fusion, and allow it to cool until 50 p.c. has crystallised, when the mother liquor is run off and again allowed to crystallise. The second crop can be raised to the value of the first (45–50 p.c.) by another fusion. This product is again fused and treated with caustic potash lye (50 p.c.) in quantity sufficient to react with the carbazole present. When the reaction is complete, the mass separates into two layers, the lower part being potassium carbazole. The upper anthracene layer is run into its own volume of 90's benzol, which dissolves any phenanthrene. The anthracene is pressed or centrifuged, and again washed with the same solvent, and is obtained as a pale-brown powder. By this means 30 p.c. anthracene is raised to 90 p.c. (*v.* also Scholvien, Fr. Pat. 335013; J. Soc. Chem. Ind. 1904, 113).

The Aktien Gesellschaft fur Anilinfabrik (D. R. P. 178764; J Soc. Chem. Ind. 1907, 1193) add potassium hydroxide to the melted crude anthracene, which is then distilled *in vacuô*, the anthracene distilling over being passed into some solvent in which it is soluble at the temperature of the reaction, and from which it crystallises on cooling. It is stated that 95–96 p.c. of the anthracene is recovered as a product containing 95–98 p.c. of pure anthracene.

Wirth (Eng. Pat. 14462; J. Soc. Chem. Ind. 1901, 464) separates the carbazole by means of its easily soluble nitroso- compound. Crude anthracene is mixed in a vessel provided with a stirrer with light coal-tar oil and sodium nitrite. Dilute sulphuric acid is added gradually, and the sodium sulphate which is formed is dissolved in water and separated from the light-oil layer. The anthracene is filtered from the light coal-tar oil, washed with benzene, and dried. It contains 75–95 p.c. anthracene, according to quality of the crude material.

Catchpole (Eng. Pat. 16641; D. R. P. 164508; J. Soc. Chem. Ind. 1903, 1190) places the crude product in the form of blocks or slabs on a perforated or channelled surface in a chamber suitably heated to a temperature not exceeding 200°, whereby the impurities are 'sweated' out. A slight washing with acid and distillation complete the process.

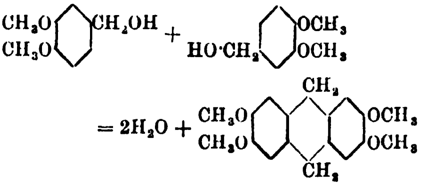
Vesely and Votocek (Eng. Pat. 27596; J. Soc. Chem. Ind. 1905, 191) find that concentrated sulphuric acid extracts the whole of the basic impurities of anthracene from a solution of crude anthracene in a solvent immiscible with sulphuric acid. The most suitable solvents are mineral and coal-tar oils, but carbon disulphide and chloroform may be used; 100 parts of crude anthracene (35 p.c.) are dissolved in 300 parts of solvent naphtha, 100 parts of concentrated sulphuric acid are added, and the mixture is heated and at the same time vigorously agitated for a few minutes. The sulphuric acid having been drawn off, the solution is freed from acid by agitation with calcium carbonate, filtered, and then allowed to crystallise. By this process it is stated to be possible to obtain an 85–90 p.c. anthracene, perfectly free from carbazole.

A troublesome impurity in anthracene is

a peculiar paraffin, which has a high melting-point, and is only sparingly soluble either in light petroleum or coal-tar naphtha; it is dissolved to a certain extent by these solvents when hot, but on cooling is almost entirely deposited again. A small quantity left in the anthracene frequently impedes succeeding operations, and, owing to its stability, passes through most of the processes without change.

Syntheses.—From orthotolylketone, by heating with zinc-dust (Behr and Van Dorp, Ber. 7, 17); from orthobromobenzylbromide, by the action of sodium (Jackson and White, Ber. 12, 1965); from a mixture of benzene, acetylene tetrabromide, and aluminium chloride (Anschütz, Annalen, 235, 156); from benzene and aluminium chloride under the influence of nickel carbonyl at 100° (Dewar and Jones, Chem. Soc. Trans. 1904, 213); and by treating pentachlorethane in benzene with aluminium chloride, when anthracene is formed through the intermediate formation of perchlorethylene (Mouneyrat, Bull. Soc. chim. 19, [3] 557). An interesting synthesis resulting in the production of methyl anthracene (m.p. 200°) is that of Kraemer and Spilker (Ber. 1890, 3174). By the interaction of xylene and cinnamene, phenyltolylpentane is formed, which when passed through a red-hot tube forms methyl anthracene (m.p. 207°), hydrogen and methane being evolved. This synthetical production of methyl anthracene is of importance in its relation to the present theories of the mode of formation of anthracene in coal tar.

The following syntheses in the anthracene group have been carried out in recent years. Mineral acids convert homopiperonyl and homoveratryl alcohols into derivatives of 2.3.6.7.-tetrahydroxy-9.10-dihydroanthracene



the tetramethoxy compound being obtained in quantitative yield by the condensation of veratrole with formaldehyde in the presence of 60 p.c. sulphuric acid (Robinson, Chem. Soc. Trans. 107, 267). Magnesium phenyl bromide reacts with ortho-phthalaldehydic acid in boiling anisole solution to produce ortho-*α*-benzhydrylbenzhydrol $HO{\cdot}CH(C_6H_5){\cdot}C_6H_4{\cdot}C(C_6H_5)_2{\cdot}OH$, and this, when boiled with hydrobromic acid, is converted into 9.10-diphenylanthracene (Simonis and Remmert, Ber. 48, 406). Purpurin (1.2.4-trihydroxyanthraquinone) may be synthesised by condensing phthalic anhydride with hydroxyquinol, whilst by using 4-hydroxy-phthalic anhydride, hydroxyflavopurpurin (1.2.4.6-tetrahydroxyanthraquinone), identical with the oxidation product of flavopurpurin, is obtained (Dimroth and Fick, Annalen, 411, 315).

Properties.—Anthracene crystallises in glistening white scales. It melts at 213°, and boils at 360° (Ullmann, Enzykl). When pure it shows a bluish-violet fluorescence, but this is concealed if small quantities of yellow impurities (Fritzsche's chrysogen) are present. Yellow-coloured anthracene, on exposure to sunlight, is bleached, and becomes fluorescent, but under these conditions the hydrocarbon undergoes conversion into paranthracene $(C_{14}H_{10})_2$—a peculiar modification, which is much less soluble than anthracene, is unattacked by bromine and nitric acid at 100°, and does not combine with picric acid; it melts at 244°, and is thereby converted into ordinary anthracene (Fritzsche, J. pr. Chem. 101, 333; Graebe and Liebermann, Annalen, Suppl. 7, 264; Schmidt, J. pr. Chem. [2] 9, 248). According to Luther and Weigert (Ch. Ztrbl. 1904, ii. 117; 1905, i. 1152), anthracene in the solid state, as well as in solution, yields para-anthracene. The fluorescence of anthracene and certain of its derivatives has been referred by Liebermann to a particular molecular grouping (Ber. 13, 913). Meyer (Zeitsch. physikal. Chem. 1897, 468) attributes fluorescence to the presence of what are known as fluorphoric groups, which must be situated between two heavy atomic groups, usually benzene nuclei. For a discussion of the cause of fluorescence in anthracene, *see* Stevenson (J. Physiol. Chem. 1911, 15, 845). The solubility of anthracene in 100 parts of various solvents has been determined by Versmann (Jahresbericht. 1874, 423), Perkin (Journ. Soc. Arts, 27, 598: v. Becchi, Ber. 12, 1978), Findlay (Chem. Soc. Trans. 1902, 1221) with the following results:—

According to Hildebrand, Ellefson, and Beebe (J. Amer. Chem. Soc. 1917, 39, 2301), the solubilities of anthracene at 25°, in grams per 100 grams of the solvents, are as follows:—

Alcohol	0·328
Benzene	1·86
Carbon disulphide . . .	2·58
Carbon tetrachloride . .	0·732
Ether ,, . .	1·42
Hexane ,, . .	0·37

When introduced into an alcoholic solution of picric acid saturated at 30°–40°, anthracene forms a picrate $C_{14}H_{10},C_6H_3(NO_2)_3O$, crystallising in glistening red needles which melt at 138°; it is decomposed into its constituents by alcohol, water, and dilute alkalis, even in the cold. The formation of the picrate is best obtained by warming molecular quantities of anthracene and picric acid on the water-bath in chloroform solution. On oxidation with potassium dichromate or manganese dioxide and sulphuric acid, anthracene is converted into anthraquinone, whilst strong nitric acid oxidises it to anthraquinone and dinitroanthraquinone; nitro- derivatives of anthracene can, however, be prepared by the action of strong nitric acid on the hydrocarbon, if care is taken to decompose any nitrous acid which may be formed during the reaction (Perkin, Chem. Soc. Proc. 1889, 13). Electrolytic oxidation in acetone yields anthraquinone (Fontana and Perkin, Chem. Zentr. 1904, ii. 708); the same product results by the electrolytic oxidation of a suspension of anthracene in a 2 p.c. solution of cerium sulphate in 20 p.c. sulphuric acid at 80°-90° (Farb. vorm. Meister, Lucius, and Brüning, D. R. P. 152063; Chem. Zentr. 1904, ii. 71); or by the oxidation of anthracene by cerium oxide in sulphuric acid (Farb. M. L. & B.; D. R. P. 158609; Chem. Zentr. 1905, i. 840); or by heating anthracene with charcoal at 150°-300° (Dennstedt and Hassler, D. R. P. 203848; Chem. Zentr. 1908, ii. 1750).

Concentrated sulphuric acid converts anthracene into sulphonic acids. Anthracene monosulphonic acid is obtained by the direct sulphonation of anthracene with sulphuric acid of 53° or 54°B., and about 60 p.c. of the anthracene employed is thus converted. If sulphuric acid of 66°B. is used, two isomeric disulphonic acids are obtained, and these, on oxidation, yield two anthraquinonedisulphonic acids, which are isomeric with the two acids obtained by the direct sulphonation of anthraquinone. The *β*-anthracene disulphonic acid, after oxidation with chromic or nitric acids, and subsequent fusion with alkali, yields *alizarin* (*q.v.*), and the monosulphonic acid similarly treated yields *anthrapurpurin* (*q.v.*) (La Société Anonomye des Matières Colorantes et Produits Chemiques de St. Denis, Eng. Pat. 1280; J. Soc. Chem. Ind. 1894, 32).

The same acids are obtained by heating anthracene with alkali bisulphate to 140°-150° (D. R. P. 77311). Anthracene is readily attacked by chlorine and bromine, and yields with each element a series of additive and substitution derivatives; additive compounds, apparently, are the first products of the action, and these either decompose during the reaction or can be decomposed by boiling with alcoholic potash into the corresponding substitution derivatives, which also form additive compounds by the further action of the halogens. The chloranthracenes are now prepared on a large scale (Clayton Aniline Co., Eng. Pat. 8744; J. Soc. Chem. Ind. 1906, 64). Dry chlorine reacts with anthracene in the presence of lead peroxide at a high temperature. Fifty parts by weight of anthracene and 10 parts of dry powdered lead peroxide are treated with dry chlorine at 220° until the weight has increased to 120 parts. The temperature, however, may be varied between 180° and 260°, and the composition of the product varies with the temperature employed and the amount of chlorine absorbed. The product consists mainly of *β*-tetrachloranthracene (m.p. 152°), which is readily soluble in benzene and crystallises out in yellow needles, and another part much less soluble in benzene and more highly chlorinated. This latter consists of two products: hexachloranthracene (m.p. 277°), which crystallises from nitrobenzene, and heptachloranthracene (m.p. 232°), which is more soluble in benzene than the former. Oxidation converts these compounds into chloranthraquinones, containing 2 atoms of chlorine less than the original compound. Treatment with a mixture of nitric and sulphuric acids results in the formation of chlornitroanthraquinones which yield dyestuffs on treatment with fuming sulphuric acid. The chloranthraquinones on treatment with fuming sulphuric acid in the presence or absence of boric acid, yield hydroxy- compounds; *e.g.* 1:4 dichloranthraquinone yields *quinizarin* (*q.v.*) (Farb. vorm. F. Baeyer & Co., Fr. Pat. 385358; J. Soc. Chem. Ind. 1908, 557). Reducing agents, such as sodium amalgam or phosphorus and hydrogen iodide, convert anthracene into the dihydride (Graebe and Liebermann, *l.c.*; Liebermann and Topf., Annalen, 212, 5); hydrogen and nickel oxide at 260°-270° and 100-125 atmos. convert anthracene first into tetrahydro-, then decahydro-, and finally perhydroanthracene (Ipatieff, Jokowleff, and Rakitin, Ber. 1908, 996).

Estimation.—Luck (Ber. 6, 1347); Meister, Lucius, and Bruning (Dingl. polv. J. 224, 559); Nicol (Chem. Soc. Trans. 1876, 2, 553); Bassett (Chem. News, 73, 178; 79, 157). The percentage of anthracene in a sample of the commercial product is determined by oxidising it to anthraquinone with chromic acid, dissolving the product in sulphuric acid, and precipitating with water, since the associated impurities are either destroyed during the oxidation or are converted into sulphonic acids soluble in water. The details of the process are as follows: 1 gram of anthracene is introduced with 45 c.c. of acetic acid into a flask connected with a reversed condenser, and heated to boiling; a solution of 15 grams of chromic acid in 10 c.c. of acetic acid and 10 c.c. of water is then added, drop by drop, to the boiling solution during a period of 2 hours; and the product is boiled for 2 hours longer, allowed to stand for 12 hours, then poured into 400 c.c. of water, and, after standing for 3 hours longer, is filtered. The anthraquinone on the filter is washed with water, with hot dilute alkali, and then with hot water; afterwards it is placed in a small dish dried at 100°, and digested for 10 minutes with 10 times its weight of pure concentrated sulphuric acid at 100°. The solution of anthraquinone in sulphuric acid is then allowed to remain for 12 hours in a moist atmosphere, mixed with 200 c.c. of water, and the precipitated anthraquinone filtered off and washed first with water, then with dilute alkali, and finally with water; it is then dried at 100° in a dish, weighed, ignited, and the ash deducted from the first weighing. The difference gives the weight of anthraquinone corresponding to the amount of anthracene present in the sample.

Impurities.—Paraffin is usually present in crude anthracene, and is estimated by treating the material with fuming nitric acid, keeping the mass cold. When all the acid has been added, the mixture is kept at the ordinary temperature until the anthracene has dissolved, and then heated until the paraffin has melted. The solution is filtered and the precipitate washed with fuming nitric acid until the filtrate dissolves in water without turbidity, and then with water until neutral. Finally, the paraffin is washed with alcohol, dissolved in warm ether and the filtrates collected in a weighed porcelain dish; the filtrates are evaporated and the paraffin dried at 105°–110° for half an hour (Heusler and Herde, J. Soc. Chem. Ind. 1895, 828). Kraemer and Spilker (Muspratt-Bunte, vii. 70) use the following method: 10 grams finely-powdered anthracene are shaken with 100 c.c. ether for ten minutes and mixture then allowed to settle. 50 c.c. of the clear solution are then evaporated and the residue dried at 100° for half an hour. After cooling, the residue is finely ground, 8 c.c. fuming sulphuric acid (20 p.c. SO_3) added, well mixed, and the whole heated to 100° for three hours, with frequent stirring. Contents of dish are then washed by means of 500 c.c. hot water into a beaker, filtered through a dry filter and the whole washed with cold water, until filtrate is free from sulphuric acid. Moisten filter with absolute alcohol and wash the paraffin into a weighed dish by means of ether, removing last traces of paraffin from the beaker in the same manner. Evaporate ether solutions and dry residue for half an hour at 105°; and weigh as pure paraffin The detection of carbazole and phenanthrene in the purified product is carried out as follows:—

Carbazole. Sample is extracted in cold with ethyl acetate, solution allowed to evaporate, and residue transferred by a few drops of same solvent to a watch-glass. On evaporation, carbazole is left behind; when treated with a drop of nitrobenzene and phenanthraquinone, it yields characteristic small copper-coloured plates.

Phenanthrene. Sample is extracted with benzene, and the evaporation residue treated with α-dinitrophenanthraquinone in nitrobenzene. In this case mixed crystals are obtained having the form and colour of the brown needles of the phenanthrene compound, but containing a large quantity of anthracene.

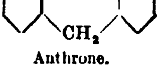
ANTHRANOL. 9-*Hydroxyanthracene*

$$C_6H_4\left\langle\begin{matrix}C\cdot(OH)\\ |\\ CH\end{matrix}\right\rangle C_6H_4$$

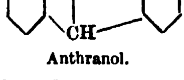
is prepared by the reduction of anthraquinone with hydriodic acid and phosphorus (Liebermann and Topf, Annalen, 212, 6; Ber. 1876, 1201), or with tin and acetic acid (Liebermann and Gimbel, Ber. 1887, 1854). Another method is to add copper or aluminium powder to anthraquinone dissolved in concentrated sulphuric acid at 30°–40°, and pour the product into water. The crude substance is recrystallised from glacial acetic acid containing a trace of aluminium and a little hydrochloric acid (Baeyer & Co. D. R. P. 201542: Chem. Zentr 1908, ii. 1218, Bezdizk and Friedlander, Monatsh. 30, 871). It is also obtained when 50 parts of finely divided anthraquinone are mixed with 10 parts of iron and 1000 parts ferrous chloride, and the mixture heated to 200° C. or higher, until it dissolves in sodium hydroxide solution with a yellow colour. The product is then cooled and washed with water, the residue dissolved in sodium hydroxide solution, and filtered into hydrochloric acid (D. R. P. 249124). Anthranol has been synthesised by heating 1 part of *o*-benzylbenzoic acid with 2 parts of sulphuric acid at 100° (Fischer and Schmidt, Ber. 1894, 2789). It crystallises in colourless needles, m.p. 165°, with decomposition. It dissolves in alkalis, and then behaves as its tautomeride anthrol (*q.v.*); *e.g.* it condenses with benzaldehyde to form benzilidine anthrol (Haller and Padova, Compt. rend. 141, 857; *v.* also Bad. Anil. und Soda Fab. D. R. P. 172930; Chem. Zentr. 1906, ii. 834). By heating the alkaline solution of anthranol for some time, it becomes oxidised to anthraquinone; hydroxylamine hydrochloride converts it into anthraquinonedioxime (Nietzki and Kehrmann, Ber. 1887, 613). Anthranol yields a benzoyl derivative (m.p. 164°) with benzoyl chloride in pyridine (Padova, Compt. rend. 143, 121; Ann. Chim. Phys. [8] 19, 353), and a diiodide with iodine in benzene solution (Liebermann, Glawe, and Lindenbaum, Ber. 1904, 3337)

Kurt Meyer (Annalen, 1911, 379, 37) has obtained the two desmotropic forms of anthranol, namely, anthrone and anthranol:



Anthrone.

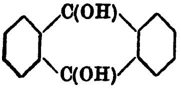
and



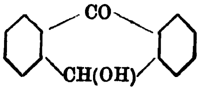
Anthranol.

The keto-form is prepared by reducing anthraquinone with tin and hydrochloric acid, and subsequent precipitation with water. It melts at 154°, and is almost completely insoluble in cold alkali solutions. On solution in boiling dilute sodium hydroxide, rapid cooling and precipitation with dilute well-cooled sulphuric acid, the yellow anthranol is obtained. It melts at about 152°, dissolves readily in most solvents, being converted into anthrone. Solutions of anthranol show a strong fluorescence, those of anthrone no fluorescence. Thiele's assumption that the high reactivity of phenols is due to a change to the keto-type seems to be contradicted here, for in the above pair of compounds the hydroxylic form is the more active isomeride.

Bromo-anthrone is obtained when bromine is added to a cold saturated solution of anthrone in CS_2. It crystallises in yellow needles, and melts at 148°. On boiling with aqueous acetone it yields oxanthrone, which crystallises in colourless needles, melting at 167°. Solutions of oxanthrone are colourless and do not fluoresce. On boiling with aqueous alkali it passes into the desmotropic form anthraquinol, which is also formed when anthraquinone is reduced by zinc-dust and alkali. It crystallises in brown leaflets, which dissolve in solvents with a yellow colour and an intense green fluorescence.



Anthraquinol.



Oxanthrone.

By the oxidation of anthracene in glacial acetic acid solution with lead peroxide (1 mol. $C_{14}H_{10}$; 1 mol. PbO_2) anthranol acetate is produced, but if in the proportions of 1 mol. $C_{14}H_{10}$; 2 mols. PbO_2, then oxanthrone acetate results. The former melts at 127°, and is readily hydrolysed to anthranol, the latter melts at 108°–109°. Again, by dissolving anthracene in glacial acetic acid, pouring into water and passing chlorine, oxanthrone is obtained in about 75 p.c. yield (K. Meyer, *l.c.*). Oxanthrone is also obtained by the following method (D. R. P. 250075), 3·4 parts of anthracene are dissolved in 200 parts acetone, and then precipitated by the addition of 200 parts ice-cold water. 6·4 parts of bromine are added, with continual shaking, all goes into solution, much cold water is added, and the oxanthrone is precipitated. It crystallises from toluene in long yellowish needles.

Dianthranol $C_{28}H_{18}O_2$ is formed, together with a little anthraquinone, when anthranol dissolved in benzene is exposed to sunlight for some weeks, or when the benzene solution is boiled for some hours. It is also obtained by oxidising anthranol with ferric chloride, in glacial acetic acid solution, or (D. R. P. 223209) by heating 100 parts anthraquinone, 500 parts of water, 50 parts sodium hydroxide, and 50 parts zinc-dust in an autoclave for six hours at 160° C. The reaction mixture is then precipitated by the addition of acid, and recrystallised from methyl alcohol. On oxidation with potassium permanganate it yields dianthrone $C_{28}H_{16}O_2$, a yellow crystalline solid which blackens at 300° C. Dianthranol crystallises in colourless tabular crystals (m.p. 250°) (Orndorff and Bliss, Amer. Chem. J. 1896, 453; Orndorff and Cameron, Amer. Chem. J. 1895, 658).

ANTHRAQUINONE

$$C_6H_4\left\langle\begin{matrix}CO\\CO\end{matrix}\right\rangle C_6H_4.$$

Obtained by the oxidation of anthracene with chromic acid (Kopp, Jahresbericht. 1878, 1188; Laurent, Ann. Chim. Phys. [2] 60, 220; 72, 415; Annalen, 34, 287; Anderson, Annalen, 122, 301; Graebe and Liebermann, Annalen, Spl. 7, 285); by the distillation of calcium benzoate (Kekulé and Franchimont, Ber. 1872, 908); by the distillation of benzoic acid with phosphorus pentoxide; by the distillation of *o*-benzoylbenzoic acid with phosphorus pentoxide, or by heating it alone (Ullmann, Annalen, 291, 24; Behr and Dorp, Ber. 1874, 578; Liebermann, Ber. 1874, 805; Perkin, Chem. Soc. Trans. 1891, 1012); by the dry distillation of calcium phthalate (Panaotovits, Ber. 1884, 13). Heller (Zeitsch. angew. Chem. 1906, 19, 669) heats 1 part of phthalic anhydride with 3·5 parts of benzene and 1·8 parts of aluminium chloride in a lead vessel at 70° until the evolution of hydrogen chloride ceases. After cooling, water is added and the excess of benzene removed by steam distillation. The solution is made alkaline and boiled, and then on addition of acid benzoyl benzoic acid is precipitated. On heating this for one hour at 150°, anthraquinone is obtained (*cf.* Piccard, Ber. 1874, 1785; Friedel and Crafts, Ann. Chim. Phys. [6] 1, 523; Müller, J. 1863, 393). Phenyl-*o*-tolylketone gives anthraquinone on heating with lead oxide or on oxidation with manganese dioxide and sulphuric acid (Behr and Dorp, Ber. 1873, 754; 1874, 16; Thörner and Zincke, Ber. 1877, 1479).

Industrial preparation.—Crude anthracene (55-60 p.c.) is slowly added to a hot solution of sodium dichromate in a large wood vat lined with lead. The solution is kept well stirred and heated with steam until all the anthracene has been added. The steam is then cut off and sulphuric acid is run into the mixture in the form of a fine spray; the heat generated by the reaction keeps the solution boiling. The crude anthraquinone is then separated by filtration and dried. It is dissolved in sulphuric acid without applying any heat, and, when solution is complete, transferred to a large vat lined with lead and boiled with water. The precipitated anthraquinone is at once separated by means of filter presses from the soluble compounds; the pressed cakes are boiled with a solution of soda, and then again filtered, pressed, dried, and finally sublimed (Levinstein, J. Soc. Chem. Ind. 1883, 219; Kopp, *l.c.*). Poirrier and Rosenstiehl (Eng. Pat. 8431; J. Soc. Chem. Ind. 1887, 595) oxidise anthracene in a closed lead-lined vessel by means of ferric sulphate. The vessel is heated to 120°–150° during 72 hours, compressed air being injected into the vessel. By this means the anthracene is virtually oxidised by the air, the ferric sulphate acting as a carrier for oxygen. The Farbenfabrik vorm. Meister, Lucius und Brüning, state that an almost quantitative yield of anthraquinone is obtained by the electrolytic oxidation of anthracene in 20 p.c. sulphuric acid, in the presence of cerium sulphate (D. R. P. 152063; Eng. Pat. 19178, 1902). Another process consists in the absorption of nitric oxides diluted with air, by zinc oxide, copper oxide, or a similar oxide of low basicity. Anthracene is mixed with this, and a stream of air or oxygen is passed through the mixture at 250°–350°, anthraquinone being produced (Ch. Fabr. Grünau, Landshoff und Meyer, D. R. PP. 207170, 215335; J. Soc. Chem. Ind. 1909, 360, 1310). On the use of oxides of nitrogen and nitric acid for oxidising anthracene, *see* D. R. PP. 234289, 254710, 256623. Meister, Lucius, and Brüning (D. R. P. 292681) make a mixture of 100 parts 30 p.c.

aqueous anthracene paste, with 3000 parts water, 250 parts 25 p.c. ammonia, and 5 parts copper oxide. Oxygen corresponding to 3 molecules per molecule of anthracene is forced in and the whole stirred and heated for two hours at 170° C. Darmstädter (Chem. Zentr. 1900, ii. 151; D. R. P. 109012) prepares anthraquinone by the electrolytic oxidation of anthracene in a chromic-acid bath. Various processes have been patented for purifying the crude anthraquinone thus produced. Bronner (J. Soc. Chem. Ind. 1882, 499; 1883, 410; Eng. Pat. 759; D. R. P. 21681) dissolves out the impurities on a specially constructed circular shelf. The method depends on the continuous extraction of the impure product with an amount of solvent insufficient to keep in solution the whole of the anthraquinone and the easily soluble impurities. Bayer & Co. (D. R. P. 68474; Eng. Pat. 5539; J. Soc. Chem. Ind. 1893, 439) dissolve out the impurities with liquid sulphur dioxide; Sadler & Co., Ltd. and Driedger (Eng. Pat. 17635; J. Soc. Chem. Ind. 1902, 1072) recrystallise the crude anthraquinone from hot aniline. The chromium liquors may be recovered and used again, by a process of electrolytic oxidation in iron cells which are lined with lead. Strips of lead, hanging in the cells, act as cathodes, and the liquor is circulated through a series of cells.

Properties.—Anthraquinone, as usually prepared, forms a felted mass of crystals of a pale-yellow or buff colour; by sublimation it can be obtained in the form of lemon-yellow needles or golden-yellow prisms; m.p. 285°-286° (corr.); b.p. 379°-381° (corr.) (Recklinghausen, Ber. 1893, 1515); sp.gr. 1·438-1·419 (Schroeder, *ibid.* 1880, 1071; Phillipi, Monatsh. 1912, 33, 373). Sparingly soluble in alcohol and ether, somewhat more soluble in hot benzene. According to Hildebrand, Ellefson, and Beebe (J. Amer. Chem. Soc. 1917, 39, 2301), the solubilities of anthraquinone at 25°, in grams per 100 grams of the solvents, are as follows:—

Alcohol	0·437
Ether	0·104

It is neutral in its reactions, and is insoluble in dilute acids or alkalis. Anthraquinone is very stable; it is not affected by hot hydrochloric acid, or by boiling with caustic potash or calcium hydroxide solutions; it dissolves in hot nitric acid (sp.gr. 1·4), and is deposited in crystals on cooling or on dilution; it dissolves unchanged in concentrated sulphuric acid at 100°, and is precipitated in fine crystals on pouring into water. Strongly heated with sulphuric acid, it is converted into mono- and di-sulphonic acids (*v.* ALIZARIN). Anthraquinone is of great commercial importance, as it is used in the preparation of alizarin, quinizarin, purpurin, &c. (*v.* ALIZARIN). Fusion with zinc or treatment with sodium methoxide converts it into anthracene (Haller and Minguin, Compt. rend. 120, 1105); fusion with caustic soda converts it into sodium benzoate (Graebe and Liebermann, Annalen, 160, 129), and by distilling it over lime benzene is formed; reduction with zinc and caustic soda, or with sodium amalgam yields oxanthranol $C_{14}H_{10}O_2$ and dianthranol (Diels and Rhodius, Ber. 1909, 1076; Meyer, Ber. 1909, 143); zinc and amyl alcohol convert it into dianthrol (Meyer, Monatsh. 30, 165). Phosphorus pentachloride and phosphorus oxychloride convert it into trichloranthracene and other chlorinated products (Radulescu, Chem. Zentr. 1908, ii. 1032). A delicate test for anthraquinone consists in reducing it with sodium amalgam in dry ether. On adding a drop of water, a red colouration is produced; if alcohol is used instead of ether, addition of water gives a green colouration (Claus, Ber. 1877, 927).

The following method serves to estimate anthraquinone in presence of anthracene, and not more than 10 p.c. of phenanthraquinone, with an error not exceeding 0·3 p.c. One part of the crude anthraquinone is wetted with alcohol, mixed with 2 parts of zinc-dust, and about 50 parts of hot 5 p.c. sodium hydroxide solution. The mixture is heated just below boiling-point for five minutes, and then rapidly filtered and washed once with water. The filter with the residue is heated with another equal portion of sodium hydroxide solution and filtered into the same flask. The residue is again treated with sodium hydroxide solution, and if it imparts no red colour to this on boiling, is rejected. Otherwise the liquid is filtered off, and the residue treated with sodium hydroxide repeatedly until anthraquinone is shown to be completely reduced to oxanthranol and removed, by the failure of the residue to impart a red colour to boiling sodium hydroxide solution. The united filtrates are cooled and reoxidised by shaking until the red colour disappears. The anthraquinone is filtered off on asbestos, dried at 110°, and weighed. The following precautions are necessary: Boiling with alkali must not be unduly prolonged, or reduction may proceed so far that anthraquinone is not reconstituted on mere shaking with air, and filtration of the reduced solution must be rapid to prevent reoxidation on the filter (Lewis, J. Ind. and Eng. Chem. 1918, 10, 425; Analyst, 1918, 297).

Condensation products.—With phenols: Scharwin and Kusnezof, Ber. 1903, 2020; 1904, 3616; Deichler, D. R. P. 109344; Chem. Zentr. 1900, ii. 360. With amines: Bayer & Co. D. R. PP. 86150, 107730, 136777, 136788, 148079; Chem. Zentr. 1902, ii. 1272; Chem. Soc. Abst. 1904, i. 326. Aryl ethers, aryl- and alkylamino- derivatives: Bayer & Co. D. R. P. 158531; Fr. Pats. 354717, 362140; J. Soc. Chem. Ind. 1905, 885, 1105; 1906, 752. Thiocyanates: Bayer & Co. D. R. P. 206054; J. Soc. Chem. Ind. 1909, 239. Mercaptans: *ibid.* 469.

A cooled solution of anthraquinone in concentrated sulphuric acid, when treated with aluminium powder with constant stirring, yields anthraquinol and anthrone.

1.2- and 1.4-anthraquinones have been prepared from α-anthrol and 1.2-anthraquinone from β-anthrol (*v.* Dienel, Ber. 1906, 926; Liebermann, Ber. 1906, 2089; Harlinger, Ber. 1906, 3537; Lagodzinski, Ber. 1894, 1483; 1895, 1422; 1906, 1717).

ANTHRAQUINONE RED *v.* ALIZARIN AND ALLIED COLOURING MATTERS.

ANTHRAQUINONE SULPHONIC ACIDS *v.* ALIZARIN AND ALLIED COLOURING MATTERS.

ANTHRAROBIN *v.* CHRYSAROBIN.

ANTHRARUFIN *v.* ALIZARIN AND ALLIED COLOURING MATTERS.

ANTHRASOL. A trade name for a preparation of coal-tar with the colour and consistence of olive oil.

ANTHROL

$$C_6H_4\begin{matrix}CH\\|\\CH\end{matrix}C_6H_3(OH)$$

Two isomeric anthrols are known, α- or 1-hydroxyanthracene and β- or 2-hydroxyanthracene.

α-Anthrol is prepared by fusing 1-anthracenesulphonic acid with 5 parts of caustic potash at 250°, dissolving the mass in water, and filtering off the yellow flocks which separate out. The crude product is recrystallised from acetic acid and water. It forms yellow plates, m.p. 152°. α-Anthrol dissolves in the ordinary solvents with a blue fluorescence, and is more soluble than β-anthrol (Schmidt, Ber. 1904, 66; Dienel, Ber. 1905, 2862; *v.* also Linke, J. pr. Chem. [2] 11, 227). It is used in the preparation of alizarin-indigo G, which is obtained from dibromo-isatin chloride and α-anthrol (D. R. P. 237199).

β-Anthrol is prepared by fusing 2-anthracenesulphonic acid with potash and recrystallising the crude product from acetone (Liebermann and Hörmann, Ber. 1879, 589; Linke, J. pr. Chem. [2] 11, 222). It can also be obtained by reducing hydroxyanthraquinone with hydriodic acid and phosphorus (Liebermann and Simon, Ber. 1881, 123). It forms yellow plates melting with decomposition at 200°, and is soluble in the common organic solvents with a violet fluorescence. By reduction with sodium in alcoholic solution, dihydroanthrol is obtained (Bamberger and Hoffmann, Ber 1893, 3069), and by heating with acetamide at 280° *anthramin* is obtained. Azo- dyestuffs have been obtained from β-anthrol (Act. Ges. f. Anilinf. D. R. P. 21178; Frdl. i. 538) It possesses a somewhat phenolic character, but more resembles the naphthols in that on heating with ammonia to 200° C. it yields the corresponding anthramine. If, however, it be reduced to the dihydroanthrol, this is the complete analogue of phenol, and does not condense with ammonia to the amine.

ANTIAR RESIN or **UPAS ANTIAR.** A green resin which exudes from the upas tree (*Antiaris toxicaria* (Lesch.), order Maraceæ). Light petroleum and benzene extract from it a substance analogous to caoutchouc, a fatty matter, and two resinous substances; alcohol extracts from the residue a very poisonous glucoside, *antiarin* (De Vrij and Ludwig, J. pr. Chem. 103, 253).

ANTIARIN *v.* DIGITALIS; GLUCOSIDES.

ANTIARTHRIN. A trade name for a condensation product of saligenin and tannin.

ANTI-CHLOR. Linen and cotton fibres and paper pulp are apt to retain some free chlorine from the hypochlorite used in bleaching, and as this causes the material to rot slowly, the manufacturers use certain reagents known as 'anti-chlors' to remove the last traces of chlorine. The first substances employed were the neutral and acid sulphites of soda (sodium sulphite and bisulphite); these were superseded in 1853 by sodium hyposulphite, which is now very largely employed. Calcium sulphide, made by boiling milk of lime with sulphur; stannous chloride in hydrochloric acid with subsequent treatment with sodium carbonate to neutralise any free acid; ammonia and sodium nitrite have also been recommended.

ANTIDIABETINE. Trade name for a preparation said to be composed of saccharin and mannite.

ANTIDIN. Phenyl ether of glycerol

ANTI-FEBRIN. A trade name for *acetanilide* or *phenylacetamide* $C_6H_5{\cdot}NH{\cdot}CO{\cdot}CH_3$. Discovered by Gerhardt in 1853, and investigated as an antipyretic by Kussmaul in 1886 (*v.* ACETANILIDE).

ANTIFORMIN. Trade name for the alkaline liquid prepared by adding caustic soda to a solution of sodium hypochlorite. Used as a disinfectant, the active ingredient being the chlorine, of which 4 p.c. is liberated on treatment with hydrochloric acid. Solutions of sodium hypochlorite are prepared in Germany by the electrolysis of 5 p.c. salt solution. A current of 110 volts and 100 amperes furnishes nearly 6000 litres daily of a disinfecting or bleaching solution containing 1 p.c. of available chlorine.

According to H. Will (Zeitsch. Ges. Brauw. 1903, 865; J. Soc. Chem Ind. 1904, 125), it is one of the best disinfectants for brewery work It rapidly softens organic impurities and facilitates their removal by scouring, in addition to its oxidising action, and it also dissolves incrustation. Its germicidal power is high, and a 5 p.c. solution is sufficient for most purposes. It is used cold, and may be safely applied to varnished surfaces with a brush, provided care is taken to prevent prolonged contact.

ANTIFUNGIN. Trade name for magnesium borate, employed as a fungicide.

ANTIGERMIN. Trade name for a preparation of a copper salt of a phenol-carboxylic acid mixed with lime. It is used as a fungicide.

ANTIHYPO. A solution of potassium percarbonate, used for destroying sodium thiosulphate in photographic negatives and prints.

ANTILEPROL. Syn. for chaulmoogra oil as used in pharmacy.

ANTILUETIN. Potassium-ammonium antimonyltartrate.

ANTIMONIALS, ORGANIC.

Historical. The first organic derivative of antimony was synthesised by Löwig and Schweitzer, who prepared triethylstibine in 1850 (Mitth. d. Züroh. Naturforsch. Gesellschaft. 1850, 45, 1; Annalen, 1850, 75, 315, 327).

This synthesis was immediately extended by H. Landolt (Annalen, 1851, 78, 91), and further investigations of aliphatic antimonials were made by Hofman (1857) and by Buckton (1860). The first aromatic antimonials were prepared about 30 years later by Michaelis, who, in collaboration with Reese, Hasenbäumer and others, developed a general method for the synthesis of antimony derivatives containing one, two, or three acyl groups.

In 1910 these researches were revised by Morgan and Micklethwait (Chem. Soc. Trans. 1911, 99, 2293), who showed that triphenylstibine on heating with antimony chloride yields both mono- and diphenylstibine chlorides, and who determined the effect of the antimony complex on the orientation of a nitro group. Similar investigations were made independently by P. May, who also studied the reduction of the nitrated arylantimony compounds and arrived at concordant results (Chem. Soc. Trans. 1912, 101, 1033).

The diazo synthesis of aryl antimony compounds was first employed by the Chemische Fabrik von Heyden of Dresden, and this led to the synthesis of antimony atoxyl and antimony salvarsan (Fabr. Heyden. D. R. P. 254421)

Syntheses of aliphatic antimonials are few compared with those in the arsenic series, and are attended by greater experimental difficulties Syntheses are successful only when the more energetic reagents are employed, owing to the feebler affinity of antimony for hydrocarbon radicals.

Antimony analogues of certain of the therapeutic organic arsenicals have been prepared, but although when tested therapeutically they show trypanocidal power, and sometimes confer immunity to trypanosomes, yet so far nothing comparable with the specific action of aromatic arsenicals has been observed. Local irritation has been found to accompany subcutaneous introduction, but possibly this disagreeable effect might be overcome by intravenous injection

Stibacetin, the antimonial analogue of arsacetin, has been tried successfully in rendering mice immune against various strains of trypanosomes, the immunising dose being one-tenth of the lethal proportion. Uhlenhuth has reported on the effect of this drug on the growth of experimental tumours in rats and mice (Medizinische Klinik, 1912, 37) Sulphoform (triphenylstibine sulphide) has been employed medicinally as a remedy in skin diseases.

SYNTHESES OF ALIPHATIC ANTIMONIALS.

I. Interaction of an Alkyl Halide with an Alloy of Antimony.

Ethyl iodide, chloride or bromide reacts with an alloy of potassium and antimony (12 p.c. potassium), yielding triethylstibine and tetraethylstibonium halide. These products are not accompanied by any antimonial analogue of ethylcacodyl.

II. Interaction of an Alkyl Halide with Antimony.

Methyl iodide heated with antimony in a sealed tube at 140° yields *trimethylstibine diiodide* $Sb(CH_3)_3I_2$ (Buckton, Journ. Chem. Soc 1860, 13, 120; Jahresber, 1860, 374)

III. Interaction of a Metallic Alkyl with an Antimony Halide.

Zinc dimethyl reacts with antimony trichloride, giving trimethylstibine (Hofmann, Jahresber. 1857, 103, 357).

The Grignard reaction may also be employed. Antimony trichloride treated with Grignard reagent (*magnesium methyl iodide*) gives a 60-70 p.c. yield of trimethylstibine (Hibbert, Ber., 1906, 39, 160).

ALIPHATIC ANTIMONIALS.

Trimethylstibine $Sb(CH_3)_3$. Synthesised by method I. (above), and is ordinarily prepared in the same manner.

Colourless liquid, b.p. 80·6°, D 1·523/15°; odour of onions, soluble in ether, slightly soluble in water or alcohol; spontaneously inflammable in air or chlorine (Landolt, Annalen, 1851, 78, 91; Jahresber. 1861, 569).

The *dichloride* $Sb(CH_3)_3Cl_2$, and the corresponding *dibromide* are produced by direct addition of the halogen.

Tetramethylstibonium iodide $Sb(CH_3)_4I$ Formed by direct combination of trimethylstibine and methyl iodide Hexagonal plates, very soluble in water or alcohol, less so in ether; bitter saline taste

Tetramethylstibonium hydroxide, deliquescent crystalline mass obtained by treating the iodide with moist silver oxide; resembles caustic potash; its salts are crystalline and devoid of emetic action.

Triethylstibine $Sb(C_2H_5)_3$. Synthesised by method I (above), and ordinarily prepared in the same manner or by method III. (above) Colourless liquid, b p 158 5/730 mm. D 1 3244/16°, odour of onions, soluble in ether or alcohol, insoluble in water, spontaneously inflammable (Lowig and Schweitzer, Annalen, 1850, 75, 315; Hofmann, Annalen, 1857, 103, 357, Buckton, Quart. J. Chem. Soc, 1863, 13, 116, 118).

Tetraethylstibonium iodide $Sb(C_2H_5)_4I,1\frac{1}{2}H_2O$. Hexagonal prisms, fairly soluble in water, more so in alcohol and less so in ether.

Tetraethylstibonium hydroxide, prepared from the iodide and moist silver oxide, is oily, miscible with water or alcohol, and forms crystalline but hygroscopic salts.

Triamyl stibine $Sb(C_5H_{11})_3$, prepared by method I. (above). Fuming liquid heavier than water, oxidising to *triamylstibine oxide*

$$Sb(C_5H_{11})_3O$$

SYNTHESES OF AROMATIC ANTIMONIALS.

I. Interaction of sodium with chlorobenzene and antimony trichloride in benzene solution.

The mixture heated for 24 hours yields triphenylstibine, triphenylstibine dichloride and diphenylstibine trichloride. Triphenylstibine heated under pressure with antimony trichloride gives phenylstibine dichloride and diphenylstibine chloride, the sodium condensation thus leading from tertiary to primary and secondary antimonials

II. Grignard reaction. Antimony trichloride heated with magnesium aryl bromide or iodide gives triarylstibine as chief product, but the diaryl and monaryl antimony compounds may be obtained from the tertiary stibine by heating with antimony trichloride (Morgan and Micklethwait, *l.c*, *cf* Pfeiffer, Ber 1904, 37, 4621)

III. **Diazo-synthesis.** This method was discovered by the Chemische Fabrik von Heyden, who in 1911 showed that the stibinic group could by this means be introduced into aromatic nuclei *Phenylstibinic acid* is prepared by diazotising aniline, which is then treated with a cooled solution of antimony trichloride in aqueous sodium hydroxide. After some hours the mixture is almost neutralised with dilute sulphuric acid, and the phenylstibinic acid is precipitated from the filtered solution by hydrochloric acid. As thus prepared, phenylstibinic acid differs appreciably from specimens obtained *viâ* phenylstibinic chloride, showing decided tendency to form salts with ammonia and sodium hydroxide.

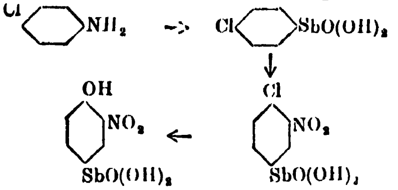
p-*Hydroxyphenylstibinic Acid*

$HO{\cdot}C_6H_4{\cdot}SbO(OH)_2$

and p-*Aminophenylstibinic Acid* (p-*Stibanilic Acid*) $NH_2{\cdot}C_6H_4{\cdot}SbO(OH)_2$ are both prepared by analogous methods. The sodium salt of the latter is the antimonial analogue of atoxyl (*q.v.*), and has similar therapeutic properties. Acetyl-*p*-phenylenediamine is diazotised and converted into acetyl-*p*-aminophenylstibinic acid by treatment with alkaline solution of antimony trichloride. The product is hydrolysed into *p*-aminophenylstibinic acid.

The sodium salt of acetyl-*p*-aminophenylstibinic acid is 'stibacetin,' the antimony analogue of 'arsacetin.'

When acetyl-*p*-aminophenylstibinic acid is successively nitrated and hydrolysed with caustic alkali so as to replace the acetylaminocomplex by hydroxyl, the scarlet alkali salt of 3-*nitro*-4-*hydroxystibinic acid* separates. This salt is also produced by converting *p*-chloroaniline into *p*-chlorophenylstibinic acid (by the above diazo reaction). This chloro- compound is nitrated to 3-nitro-4-chlorophenylstibinic acid, which on treatment with alkali exchanges its chlorine atom for a hydroxyl group.



AROMATIC ANTIMONIALS.

Phenylstibine dichloride $C_6H_5{\cdot}Sb{\cdot}Cl_2$, colourless crystals, m.p. 58°; b.p. 290°; very soluble in alcohol, ether, benzene, or light petroleum On warming, the odour, which is at first faint, becomes very pungent and irritating (Hasenbaumer, Ber 1898, 31, 2912)

Phenylstibinic chloride $C_6H_5\,SbCl_4$, is prepared by saturating an ethereal solution of phenylstibine chloride with chlorine, and is obtained as a hygroscopic crystalline mass. It is hydrolysed by water into *phenylstibinic acid*

$C_6H_5{\cdot}SbO(OH)_2$

a white powder decomposing above 200°; insoluble in water; soluble in aqueous alkalis and in glacial acetic acid.

Diphenylstibine chloride $(C_6H_5)_2Sb{\cdot}Cl$, colourless crystals, m.p. 68° (Michaelis and Günther, Ber. 1911, 44, 2316; Morgan and Micklethwait, *l.c.*; Gruthner and Wiernik, Ber. 1915, 48, 1749).

Diphenylstibine trichloride. Colourless needles with one molecule of water, m.p. 180°. Formed as by-product in synthesis I., being extracted with hot dilute hydrochloric acid from the concentrated mother liquors from this reaction. Treated successively with (*a*) alcohol and dilute ammonia, or with (*b*) aqueous sodium hydroxide and acetic acid, the trichloride yields

Diphenylstibinic acid $(C_6H_5)_2SbO{\cdot}OH$, a granular precipitate insoluble in ammonia or sodium carbonate, as produced by the first method, or in a form soluble in these reagents when obtained by the second method.

Triphenylstibine $(C_6H_5)_3Sb$. Colourless, triclinic plates, m.p. 48°; b.p. 231–232°/16–18 mm., above 360°/760 mm. (with partial decomposition); D 1·4998/12° (Ghira, Gazzetta, 1894, 24 (i), 317). Synthesised by method I. (above). The product of this reaction is successively extracted with alcoholic hydrochloric acid and light petroleum, the latter removing the required stibine, which is then precipitated by chlorine in the form of its dichloride, this being reduced by hydrogen sulphide. The product is recrystallised from light petroleum (Michaelis and Reese, Annalen, 1886, 233, 45). An almost quantitative yield can be obtained by employing the Grignard reaction (Morgan and Micklethwait, Chem. Soc. Trans., 1911, 99, 2290).

Triphenylstibine dichloride $(C_6H_5)_3Sb{\cdot}Cl_2$. Formed as a by-product in Method I. (above). Colourless needles, m.p. 143°.

Triphenylstibine sulphide, 'Sulphoform,' $(C_6H_5)_3SbS$. White needles, m.p. 119–120°. Soluble in benzene, chloroform, or glacial acetic acid, less soluble in alcohol, slightly soluble in ether. It has been used successfully in the treatment of eczema and other skin diseases. It is prepared by the carefully regulated action of hydrogen sulphide on the alcoholic ammonia solution of the stibine chloride (Kaufmann, Ber. 1908, 41, 2761)

TERVALENT ANTIMONY DERIVATIVES.

The members of this series of antimonials contain the stibino-group, $-Sb{=}Sb-$, and were discovered in 1911 by the Chemische Fabrik von Heyden, who succeeded in reducing the aromatic stibinic acids.

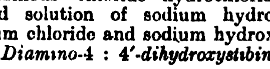
Stibinobenzene $C_6H_5{\cdot}Sb:Sb{\cdot}C_6H_5$. Pale yellow powder, insoluble in water, soluble in glacial acetic acid and chloroform. Phenylstibinic acid in caustic soda solution is cautiously reduced with sodium hydrosulphite, and the resulting crude product extracted with a mixture of alcohol and benzene containing copper-powder. The filtered solution contains the purified product.

3 : 3′-*Diaminostibinobenzene*

$NH_2{\cdot}C_6H_4{\cdot}Sb:Sb{\cdot}C_6H_4{\cdot}NH_2$

Yellow powder, insoluble in water, soluble in glacial acetic acid, soluble with pronounced decomposition in mineral acids. Prepared by treating a dilute alkaline solution of *m*-aminophenylstibinous chloride-hydrochloride with a filtered solution of sodium hydrosulphite magnesium chloride and sodium hydroxide.

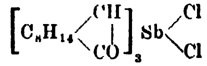
3 : 3′-*Diamino*-4 : 4′-*dihydroxystibinobenzene*



the antimonial analogue of Salvarsan base is prepared by reducing 3-nitro-4-hydroxyphenylstibinic acid with alkaline sodium hydrosulphite. The red colour of the sodium salt of this acid disappears, and the stibinic compound separates as a reddish-brown precipitate, soluble in aqueous alkalis or acids. It is easily acylated, and it condenses with aldehydes. It can be diazotised and yields a colouration with ferric chloride. When oxidised with alkaline hydrogen peroxide it is converted into colourless 3-amino-4-hydroxyphenylstibinic acid (D. R. P. 268451).

MISCELLANEOUS ORGANIC DERIVATIVES OF ANTIMONY.

Tricamphorylstibinic chloride



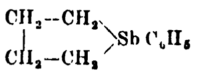
$$\left[C_8H_{14}\begin{matrix}\diagup CH\\ \mid\\ \diagdown CO\end{matrix}\right]_3Sb\begin{matrix}\diagup Cl\\ \diagdown Cl\end{matrix}$$

This is the main product of the condensation of the sodium derivative of camphor with antimony trichloride. It is soluble in benzene, from which it is obtained in colourless crystals, melting with decomposition at 244°; it is resolved by water into the unstable *tricamphorylstibinic acid* $(C_{10}H_{15}O)_3Sb(OH)_2$, decomposed by dilute aqueous sodium hydroxide, and by boiling water (Morgan, Micklethwait and Whitby, Chem Soc. Trans. 1910, 97, 35).

Phenylcyclopentamethylenestibine (I) is prepared by the Grignard method from phenylstibine dichloride and the magnesium compound of αε-dibromopentane, and is a colourless, viscous, unpleasant smelling oil, b.p. 169–171°/18–20 mm. (in CO_2); oxidises on exposure to air.

$$CH_2\begin{matrix}\diagup CH_2\cdot CH_2\diagdown\\ \diagdown CH_2\cdot CH_2\diagup\end{matrix}Sb\cdot C_6H_5$$

I.



II.

When αδ-dibromobutane is employed in this condensation *phenylcyclotetramethylenestibine* (II.) is obtained as a colourless oil of unpleasant odour, b.p. 156–158°/20-22 mm., yielding crystalline dichloride and dibromide (Gruttner, Wiernik and Krause, Ber. 1915, 48, 1473; 1916, 49, 437).

Bibliography.—Organic Compounds of Arsenic and Antimony (Morgan, London, 1918).

G. T. M.

ANTIMONIN. Trade name for antimony calcium lactate, used as a tannin-fixing mordant.

ANTIMONITE. Native antimony sulphide (*v.* ANTIMONY).

ANTIMONY. (*Antimoine*, Fr.; *Antimon*, Ger.) *Stibium.* Sym. Sb. At.wt. 120·2.

Occurrence.—Antimony occurs native in small quantities, occasionally in rhombohedral crystals, at Andreasberg in the Hartz, Przibram in Bohemia, Sala in Sweden, Allemont in France, in the United States, New South Wales, and Quebec. It occurs in large masses in Sarawak, Borneo.

Combined with *oxygen* as the sesquioxide Sb_2O_3, it occurs in *antimony bloom, white antimony*, or *valentinite*, and in *senarmontite*, being found in workable quantities in the Algerian province of Constantine. In *antimony ochre* or *cervantite*, and in *stibiconite* and *volgerite*, it occurs as antimonite of antimony Sb_2O_4.

Combined with *sulphur*, it occurs as *stibnite, antimonite*, or *grey antimony ore* Sb_2S_3. In union with *sulphur* and *oxygen* together, it forms *red antimony, antimony blende* or *kermesite* $Sb_2O_32Sb_2S_3$.

With *arsenic*, antimony is found in *allemontite* or *arsenical antimony*. With *silver*,

With sulphur and metals, antimony forms a number of *sulphantimonites*, among which may be mentioned *zinkenite, jamesonite, boulangerite* and *feather ore*, containing antimony, sulphur and lead; *miargyrite, pyrargyrite*, and *stephanite*, containing silver; *berthierite*, containing iron, and *antimonial copper glance*. Antimony is found in certain ferruginous waters.

The antimony minerals of commercial importance as ores are *stibnite*, and the decomposition products which are usually associated with it and sometimes entirely replace it, viz. *kermesite, valentinite, senarmontite*, and *cervantite*.

Antimony ores occur in workable quantities in Mexico, California, North and South America, Canada, Australia, Japan, Borneo, Cape of Good Hope, New Zealand, Asia Minor, Austria Hungary, France, Russia, Siberia, Serbia, Algiers, Italy, Spain, Portugal, Corsica, and Sardinia. Small deposits of antimony sulphide have been discovered in Cornwall, Cumberland and Scotland.

Antimony ores occur in the south of Hupeh and part of Sze-chuen province and in the provinces of Hu-nan Kwei-chow, Kwang-si, and Yun-nan. Roughly speaking, this vast antimony belt comprises the entire western half of China south of the Yang-tse-Kiang. There are smelting and refining works at Woo-chow which reduce the ore mined in the province of Kwang-si, exports from which are shipped to Canton and Hong-Kong. There are also important works at Chang-sha, the capital of Hu-nan province, exports from which are shipped *viâ* Hankow and Shanghai (Schoeller J. Soc. Chem. Ind. 1913, 32, 260).

For a list of antimony-producing countries *see* J. Soc. Chem. Ind. 1915, 34, 1148.

The veins in which stibnite is found are usually 4–6 inches in width, but in some rich mines, as in Nevada, they are several feet across. The gangue materials are quartz, with some brown-spar and heavy spar, and from these the sulphide can only be separated by hand picking or liquation. It is occasionally found in pockets, when it is usually very pure.

By far the most general ore of antimony is the sulphide, but in some cases, as in Algeria, the oxide is found in workable quantities, and in other cases both oxide and sulphide occur together.

Extraction.—Metallic antimony and its compounds are nearly always extracted from the ores by dry methods. According to their suitability for the several methods of treatment the ores fall into two broad classes:

(*a*) Sulphide ores containing over 40 p.c. stibnite.

(*b*) Sulphide ores containing less than 40 p.c. of the sulphide, and oxide ores of any grade. In this class also may be included liquation residues and flue deposits, &c.

Preliminary treatment of Ores.—Ores of class (*a*) are used for the production of the metal by the English process. If the content of sulphide is over 90 p.c., the ore requires no preliminary treatment, but less pure ore is subjected to a process of *liquation*, in which the sulphide is melted and allowed to run away from the gangue.

formerly used where fuel is plentiful, as at Malbosc, in the Department of Ardèche, Wolfsberg in the Hartz, and in Hungary. The ore was placed in small lumps in a number of conical pots of 45 kilos capacity, each perforated below and standing on a perforated plate over a sunken receiver. The pots were surrounded by fuel which continued to burn for 10 hours, the melted sulphide, known as crude antimony, collecting in the receivers.

At La Lincouln, Wolfsberg, and Haute Loire, the pots were contained in a reverberatory furnace. At Schmöllnitz, in Hungary, the melted sulphide ran through channels into receivers outside the furnace.

At Malbosc, the pots are replaced by cylindrical tubes, perforated below and standing on similarly perforated plates above the receivers. Each cylinder has a capacity of 500 lbs. of ore, four being heated in one furnace. Each has a hole at the side, through which the residues are removed, these holes being closed during the heating. The receivers are of clay, or of iron coated with clay.

At Chang-Sha, and also in other parts of the province, crude antimony is obtained from high-grade (58 p.c.) ores by liquation. The process is carried out in furnaces each of which holds two clay crucibles, the charge for each crucible being 50 lbs. of ore. The crucibles are inclined and perforated at the bottom; they are fired for two hours, the liquated sulphide collecting in a cavity at the back of the furnace, whence it is ladled into iron moulds and allowed to solidify. The pasty liquation residue is dumped into loose iron frames formed of two L-shaped pieces in which it cakes together on cooling (Schoeller, *l.c.*).

The method of liquation in reverberatory furnaces is used in some places where ore can be mined cheaply but fuel is dear. The consumption of fuel per unit of sulphide liquated is least with this type of furnace, but there is a considerable loss of antimony by volatilisation. This loss, however, can be prevented by the use of suitable condensing apparatus such as Herrenschmidt's (*v.i.*).

In any process of liquation the temperature must be carefully regulated, as too low a temperature results in a low yield of sulphide, the residues containing too much antimony, while too high a temperature increases the loss by volatilisation.

The liquated stibnite contains much less sulphur than is required by the formula Sb_2S_3, and Schoeller has shown that this is due to the presence of oxygen.

Ores of class (*b*) are either roasted to the non-volatile tetroxide, or to the volatile trioxide, or are subjected to one of the direct reduction processes.

The oxidation of the sulphide to tetroxide takes place at temperatures between 350° and 400° in presence of excess of air. If the ore is impure, antimonates of the metallic impurities are formed at the same time. During the roasting there is a great tendency for the ore to frit, and this necessitates the constant rabbling of the charge. The presence of gangue renders the ore less liable to fuse, so that the process is most easily carried out with poor ores, *e.g.* ore-dust, for the treatment of which it is largely used. The furnaces employed are of two classes:

(*a*) Hand rabbled reverberatory furnaces, having an egg-shaped flat bed, with a fireplace on either side and a working door at the front. With these the process is intermittent.

(*b*) Long bedded furnaces, in which the roasting is carried on continuously. These furnaces are 40–45 feet long, by 8 feet wide, by 2 feet high, and have 10 working doors on each side. The ore is charged in at one end, and is then gradually worked along the bed during about 40 hours, and finally discharged at the other end. Fresh ore is continually charged into the furnace at the rate of 6 cwts. every 8 hours.

The oxidation of the sulphide to volatile trioxide takes place at about 400° with a carefully regulated amount of air. This process, provided suitable condensation apparatus is installed, presents marked advantages, and is finding an increasing application, especially in dealing with poor ores. It may be noted that arsenic is completely separated as the more volatile trioxide, that any gold or silver present is left in the residue and can afterwards be extracted, that the loss of antimony and the consumption of fuel are low. Many different forms of plant have been used for this process, but in most the roasting takes place in a furnace of cupola type, the most important processes being the Chatillon and Herrenschmidt. The forms of condensing apparatus are of two classes:

(*a*) In which the vapours are passed through a series of flues and chambers and finally through water-tanks in which the last traces of oxide are deposited.

(*b*) In which the furnace gases are cooled below 100° in flues and then filtered through canvas or other coarse fabric.

In the Herrenschmidt process the roasting furnace is built of brick, and is provided with a hopper through which the ore, mixed with 4–5 p.c. of gas-coke or 6–7 p.c. charcoal, is introduced. The gases pass from the furnace into a chamber, and then through a series of cast-iron tubes placed nearly vertical and air-cooled, in which the main portion of the trioxide is deposited. The last traces are removed by forcing the gases up a tower filled with coke over which water flows. The draught is maintained by two centrifugal fans, working tandem. It is stated that 6 tons of ore, containing 10–15 p.c. antimony, can be treated in 24 hours, with a yield of over 90 p.c.

Smelting of the metal.—Antimony is prepared from 'crude antimony' or high-grade stibnite ores by the 'English' or 'precipitation' method. The ore, of which the composition has been determined by analysis, is ground under edge-runners to the size of a hazel-nut, or smaller, and is subjected to three operations:

Singling. This process is carried out in crucibles of which about forty are arranged in a double row on the hearth of a long reverberatory furnace having a grate at each end, and a flue, leading to condensing chambers, in the middle. The crucibles are about 20 inches high and 11 inches across, and are made of a mixture of 6 parts fire-clay and 1 part plumbago. The charge for each pot is 42 lbs. ore, 16 lbs. iron, 4 lbs. salt, and 1 lb. slag from 'doubling' (*v.i.*). These materials are introduced into the red-hot crucible, and kept in a state of fusion for 2–3 hours, at the end of which time the contents are poured into moulds, and the antimony is removed from beneath the slag. The product, known as *singles*, usually contains about 91 p.c. antimony.

Doubling is carried out in crucibles arranged in a furnace as previously described. The charge for each pot is 84 lbs. broken singles, 7–8 lbs. liquated sulphide, and 4 lbs. salt, and the fusion, which takes about 1½ hours, is closely watched, the workman judging from the nature of the slag when the operation is complete. The slag is then removed with an iron ladle, and the metal poured into moulds. This product is called *bowl metal* or *star bowls*, and sometimes contains over 99 p.c. antimony.

Starring, or *melting for star metal* (*v.i.* under *Refining*).

In the English process the loss due to slagging and volatilisation is small, being only 2–5 p.c.

It is possible also to reduce the sulphide on the hearth of a reverberatory furnace. The partially roasted ore, which contains the sulphide and oxides of antimony, is mixed and fused with 8–13 p.c. of coal and 9–11 p.c. of soda, frequently with the addition of iron, in which case the slag produced is much less fusible and does not entirely cover the bath of metal; the antimony produced also contains much iron (Dingl. poly. J. 162, 449). Where carbonate of soda is used for the fusion the mass froths considerably and attacks the furnace hearth.

The metal is prepared from either of the oxides by one of the numerous reduction processes now in use.

(*a*) Reduction in reverberatory furnaces is carried out at Bouc, Septêmes, New Brunswick, &c. The furnace-bed is egg-shaped, deep in proportion to its width, and is provided with a tap-hole at the lowest point. The furnace gases are passed through a long series of condensing chambers. First 90–110 lbs. flux (chiefly salt, with some soda and sodium sulphate) and 220–230 lbs. of slag from a previous operation are melted on the hearth, and then 400–500 lbs. of roasted ore and 67–75 lbs. of charcoal are added, and the whole kept in a state of fusion till reduction is complete. At New Brunswick the reduction and refining are carried out consecutively in the same operation.

(*b*) Some French smelters reduce an oxidised ore containing 30–40 p.c. of antimony in a 3-tuyered shaft furnace at the rate of 2–2½ tons per 24 hours, with the consumption of about half that weight of coke. The regulus contains 92–95 p.c. of antimony, and is subsequently refined.

At Bánya, Hungary, antimony ores are mixed with silicious material and smelted in a blast-furnace for impure regulus, which is then refined in a reverberatory furnace. The blast-furnace used is a round stack 6 m. high and 1·4 m. diameter at the throat. The hearth, which is 1 m. across, is fitted with five water-jacketed tuyeres, and has two outlets for slag and metal respectively; a third opening is used for blowing out. A blast of 15 c.m. per minute is used, and the gases are collected by a tube at the throat and passed through a condensing apparatus. Such a furnace will run for 3 weeks continuously, smelting about 20 tons of material daily (Berg. u. Hütt. Zeit. 1886, p. 102).

(*c*) Reduction in crucibles is only used when rich ore or the trioxide is available. The reducing agent for the trioxide is carbon (charcoal or anthracite), and sodium sulphate and carbonate are added to form a slag.

Considerable quantities of antimony ore are now treated directly for the production of the metal. One such process which has been successfully used for some time depends on the reduction of the sulphide in a bath of molten ferrous sulphide containing iron (*v.* T. C. Sanderson, U.S. Pat. 714040, 1902; Cookson, Fr. Pat. 324864 1902; and Herrenschmidt, Fr. Pat. 296200, 1900).

Another method consists in the reduction of the sulphide with carbon in water-jacketed blast-furnaces. This has been used by Hering for the treatment of liquidation residues.

W. R. Schoeller (Bull. Inst. Min. and Met. Feb. 1918) describes the blast-furnace smelting of antimony ores direct in water-jacketed blast furnaces, the charge consisting of ore, basic slag, chalk and coke. In this method, no iron is added to the charge and no reduction of iron takes place in the furnace. The antimony is obtained as a high grade metal, practically free from iron. The best conditions for working the furnace are found to be about 10 p.c. coke, low blast pressure, low metal content of charge (about 10 p.c.), high smelting column (over 15 feet), and provision of a heated forehearth for the separation of metal and slag.

Methods of treating antimony ores have also been proposed by which the antimony is converted into the volatile chloride, as in Lyte's process of roasting the ore with salt. The ore may also be subjected to the action of hydrochloric acid gas in a reverberatory or muffle furnace, the volatilised chloride being condensed in a solution of hydrochloric acid (Dingl. poly. J. 250, 79–88, and 123–133).

Among processes allied to the smelting of antimony there need only be mentioned that of Herrenschmidt for the extraction of gold from antimony (Fr. Pat. 350013, 1904). This depends on the fact that when a small quantity of antimony is melted with or reduced from auriferous stibnite, all the gold present in the sulphide passes into the metal.

Many proposals have been made for the extraction of antimony by wet or electrolytic methods, but they have not been a success commercially. Reference may be made to Hering (Dingl. poly. J. 230, 253), and Borchers (Electrolytische Gewinnung des Ant. Chem. Zeit. xi. 1883, 1023).

Refining of Antimony.

Unrefined antimony contains sulphur, iron, arsenic, and sometimes copper, gold, and lead. The following analyses show the composition of typical samples, I. and II. being metal made with scrap iron; III. and IV. metal from roasted ore smelted in a blast furnace; V. Chinese:—

	I.	II.	III.	IV.	V.
Antimony .	94·5	84·0	97·2	95·0	98·20
Iron . .	3·0	10·0	2·5	4·0	0·146
Sulphur .	2·0	5·0	0·2	0·75	0·37
Arsenic .	0·25	1·0	0·1	0·25	0·148
Gold .	traces	—	—	—	—

All these impurities, except lead, can be removed by slagging with oxidising, sulphurising, or chlorinating agents. The usual fluxes are: Glauber salt and charcoal, which remove copper and iron as sulphides, and arsenic as sodium arsenate; and antimony glass (antimony oxysulphide) which eliminates sulphur. Chlorides, such as salt or carnallite, must be used with caution, or great loss by volatilisation may result.

Refining in crucibles finds its chief application in the English process. The 'star bowls' (*v.s.*) are cleaned from slag by chipping with sharp hammers, and the metal is then broken small and melted with 2–3 p.c. of antimony flux, prepared by melting together American potashes and powdered stibnite in varying proportions (approximately 3 parts potashes and 2 parts stibnite) until, by experiment, the correct composition is found. The refining is carried out in the pots nearest the grates, and takes 30 minutes to 1 hour, the charge for each crucible being 84 lbs. The finished product is run into 8-lb. ingots, which are carefully covered with slag and allowed to cool without disturbance. The coal consumption is large, but is compensated by a much smaller loss by volatilisation than occurs in other processes.

Refining in reverberatory furnaces is used at Milleschau, Bánya, Siena, and Oakland. It is imperative that the bed of the furnace should be tight and able to withstand the action of the alkali flux, and this is best attained by making it of one solid piece of soft, weathered granite. A fairly good substitute for the granite is a mixture of burnt and raw clay well rammed into an iron box. An example of such a process is that recommended by Helmhacker and used at Milleschau (Berg. u. Hütt. Zeit. 1883, 191; and Dingl. poly. J. 250, 123).

A 'glass of antimony' is prepared by fusing a mixture of the crystalline antimony oxide which collects on the hotter portions of the flues with sulphide of antimony, until it forms a glassy dark grey or brown mass; this is mixed with the carbonate for the purification of the metal, and is occasionally used alone where the metal is but slightly impure

The bed of the furnace is heated to a cherry red and 600 to 700 kilos. of crude antimony placed on it; a quantity of oxide and some arsenic escape, and in from 30 to 60 minutes the metal has run down. From 3 to 7 p.c. (according to the purity of the metal) of carbonate of soda, sometimes mixed with coal or coke, is then added The metal is thus covered and fumes less, small jets of flame appearing occasionally on its surface; the temperature is raised, the metal remaining under the slag for from 1 to 3 hours (determined by the workman), the slag then becomes thick, and is removed by drawing it through the door with a long-handled flat transverse iron.

Three p.c. of antimony sulphide and 1½ p.c. of oxide are then thrown on the surface of the metal, and when melted 4½ p.c. carbonate of potash, or of a mixture of carbonate of potash and soda, are added. By this means the iron and last traces of sulphur are removed; in less than 15 minutes the refining is complete, and the critical operation of ladling is performed. A cast-iron hemispherical ladle, holding 15–20 kilos., is riveted to a chain hanging from the roof exactly in front of the working door, before which the cast-iron moulds for receiving the metal are arranged on a stone table. The workman dips his ladle obliquely, removing some slag with the metal; part of this is first poured into the mould to prevent the metal from actually touching the mould, and the metal is well covered with the slag and left at rest. Unless this be done the 'starring' will be imperfect, and, as this is considered a test of purity, its value will be lowered in the market. The slag may generally be used again. The oxide condensing in the flues is removed as seldom as possible, as this operation, as well as the furnace work, is very injurious to the workers.

Star antimony usually contains small amounts of iron, lead, sulphur, and arsenic, but can be further purified by Liebig's method, which consists in fusing the metal successively with 12 p.c. sodium carbonate and 6 p.c. antimony sulphide, and again with sodium carbonate to which a little nitre has been added.

The following are typical analyses of commercial antimony (*v.* Min. and Sci. Press, July 10, 1915).

	Cookson's	Hallett's.	Japanese.	Chinese.
Lead .	0·041	0·669	0·424	0·018
Tin .	0·035	0·175	0·012	0·035
Arsenic .	trace	trace	0·095	0·017
Copper .	0·040	0·038	0·043	0·008
Iron .	0·010	0·014	0·007	0·007

When 'pure,' and cast under correct conditions, a beautiful fern leaf or 'star' appears upon the surface of antimony, and according to the length and form of this 'star' on the ingot its quality is decided. Although the 'star' is accepted as a criterion for the purity of the metal, it is really only a rough guide. It is no guarantee that the metal is more than 99 p.c. pure, as it may be produced with inferior metal, while the very best metal may show an imperfect star or none at all if not properly cast. It is this peculiar characteristic of pure antimony to crystallise on the ingot in the fern-leaf or star form when cooling, which originates the trade term of 'star antimony' for good quality of antimony.

For pharmaceutical purposes it is important to prepare antimony quite free from arsenic. This may be accomplished by Wöhler's method. A mixture of 4 parts powdered commercial antimony, 5 parts sodium nitrate, and 2 parts sodium carbonate (to prevent the formation of insoluble antimony arsenate) is thrown into a red-hot crucible. Combustion takes place quietly, the mass is pressed together and more strongly heated for half an hour, so as to become pasty without fusion, being pressed down as it rises from evolution of gas. While still hot and soft, it is removed, reduced to powder, and boiled with frequent stirring in water, the finer powder is poured off with the water, and the residue again treated, the washings being mixed with that first obtained. The water, which contains the whole of the arsenic but no antimony (Meyer), is removed from the insoluble portion by subsidence, decantation, and filtration. The residue of sodium antimonate should be white but the presence of lead imparts a yellow colour It is dried and fused with half its weight of cream of tartar at a moderate heat, cooled, broken into small lumps, and the potassium and sodium removed by digestion in water. The powdered metal is then fused into a button.

This method may be used quantitatively for the separation of antimony from arsenic. If the sodium nitrate be replaced by potassium nitrate, a portion of the antimony will enter into solution with the arsenic as potassium antimonate (*v.* C. Meyer, Annalen, 46, 236; Chem. Zentr. 1348, 828). Arsenic may also be completely removed by fusing the antimony in succession with 1st, potassium carbonate; 2nd, potassium nitrate; 3rd antimonic oxide; 4th, potassium carbonate (Th. Martins, Kastn. Arch. 24, 253), or by fusing three times with fresh portions of sodium or potassium nitrate.

Duflos (Kastn. Arch. 19, 56) recommends a process in which the arsenic is driven off as fluoride by means of sulphuric acid and fluorspar. (*See* further Schw. 42, 501; also Buchner and Herberger, Repert. 38, 381, 256.)

Pure antimony may be obtained by heating tartar emetic to low redness and digesting the resultant mass in water to remove the potassium. The powder thus obtained may be then dried and fused into a button.

Groschuff (Zeitsch. anorg. Chem. 1918, 103, 164) describes the following method of preparing chemically pure antimony. Antimony trichloride or pentachloride is purified by distillation and converted into chloroantimonic acid. The chloride is dissolved in concentrated hydrochloric acid, and chlorine is passed in until the solution becomes greenish-yellow, and then hydrogen chloride is introduced. After purification by recrystallisation, the chloroantimonic acid is hydrolysed to antimonic acid, which is reduced to metal by fusion with potassium cyanide.

Tests for Impurities in Antimony.

Sulphur. The powdered metal evolves sulphuretted hydrogen gas (which blackens lead paper) on heating with strong hydrochloric acid.

Arsenic. If deflagrated with ¼ its weight of sodium nitrate, boiled with water and filtered, the arsenic enters into solution, leaving the antimony behind; the solution is saturated with sulphuretted hydrogen (if an orange precipitate, consisting of antimony sulphide, falls, this must be filtered quickly; it is due to the presence of a trace of antimony in the solution). The arsenic is deposited as the lemon-yellow sulphide on standing.

Lead and copper. The metal is powdered and treated with dilute nitric acid, evaporated nearly to dryness, taken up with water and filtered; the addition of sulphuric acid precipitates white lead sulphate, and the addition to the filtrate of potassium ferrocyanide gives a brown precipitate in presence of copper.

If sulphur as well as lead be present in the antimony, the lead is converted at once into sulphate by the action of nitric acid, the residue on evaporation is digested with yellow ammonium sulphide, which dissolves the antimonic oxide and leaves black lead sulphide.

Iron. The powdered metal is ignited with three parts nitre and washed with boiling water, the residue is boiled with hot dilute hydrochloric acid; on the addition of potassium ferrocyanide a blue precipitate is produced.

Detection of antimony. When fused on charcoal with potassium cyanide or sodium carbonate or a mixture of the two, antimonial compounds produce a brittle white bead of metallic antimony with white fumes and a white incrustation on the charcoal; the bead leaves a white residue on treatment with nitric acid, which is soluble in cream of tartar or tartaric acid. Sulphide of antimony melts readily in the candle flame.

A delicate confirmatory test, given by Crookes, is to add to the white incrustation on the charcoal one drop of ammonium sulphide, when the formation of the orange sulphide is conclusive evidence of the presence of antimony.

Estimation of antimony.—Wet assay.—(*a*) *Gravimetric.* In the case of ores and products, a weighed quantity is fused with sodium hydrate and a little potassium nitrate, the fused mass is extracted with water and a little hydrochloric acid if necessary. The solution obtained is filtered, and if much residue remains, it is re-fused. A few grammes of tartaric acid and excess of oxalic acid are added, and hydrogen sulphide is passed through the solution first cold and then after heating. The sulphide precipitate is filtered off and digested with sodium sulphide and filtered. To the solution, hydrochloric acid and potassium chlorate are added, and it is boiled until free from chlorine. The acidity of the solution is adjusted to 50 p.c., hydrochloric acid and hydrogen sulphide passed to precipitate arsenic, which, if present, is filtered off. The solution is diluted to three times its volume, and is ready for the precipitation of the antimony. In the case of alloys containing antimony, these are dissolved in hydrochloric acid with the aid of potassium chlorate to the solution, excess of tartaric acid is added, and it is poured into a solution containing soda in excess. The solution is digested, filtered, and the precipitate washed with sodium sulphide solution. The filtrate is acidified with hydrochloric acid, potassium chlorate is added, it is then boiled until free from chlorine, and excess of oxalic acid is added. In either case hydrogen sulphide is now passed into the cold solution for 20 minutes. Then, without stopping the current of gas, the solution is heated to boiling, and the gas allowed to pass for another 15 minutes. The resulting precipitate of sulphide may then be subjected to one of two methods of treatment. It may be collected on a Gooch crucible, washed with hot dilute acetic acid, saturated with hydrogen sulphide, and heated to constant weight at 230° in a current of carbon dioxide. Or the precipitate may be collected on a filter, washed successively with hot water, alcohol, equal parts alcohol and carbon disulphide, alcohol, and, finally, ether, and then dried. The greater part of the precipitate is transferred to a watch-glass, and that still adhering to the paper is dissolved in a little hot ammonium sulphide, and the solution allowed to run into a weighed porcelain crucible. This is then evaporated to dryness, the main portion of the precipitate added, and the whole treated with fuming nitric acid and warmed, the crucible being covered with a watch-glass. When the violent action has subsided, the contents of the crucible are evaporated to dryness, again treated with nitric acid, and finally evaporated to dryness and heated to redness till the weight is constant. The antimony is then weighed as tetroxide.

(*b*) *Volumetric*. The most important volumetric method is that of Möhr, in which antimony trioxide or any antimonious compound is dissolved in a solution of tartaric acid, neutralised with sodium carbonate, treated with a cold saturated solution of sodium bicarbonate in the proportion of 10 c.c. to each 0·1 gram Sb_2O_3, and quickly titrated with *N*/10-iodine solution, using starch as indicator.

(*c*) *Electrolytic*. Classen and others have shown that if antimony sulphide (*v.s.*) is dissolved in the minimum amount of concentrated solution of sodium sulphide, and treated with excess of sodium sulphite, or, better, potassium cyanide solution (to destroy polysulphides), the liquid can be successfully electrolysed in the cold with a current of 0·25–0·5 amp., using a platinum dish as cathode. The process takes about 12 hours, and gives a good coherent deposit of metal which can be washed with water, alcohol, and ether, and finally dried and weighed.

Properties of Antimony.

Antimony is a lustrous, bluish-white metal, which has a coarsely laminated or granular structure, according as it has been slowly or quickly cooled. By partial solidification it can be obtained in obtuse rhombohedra, approximating to cubes.

The sp.gr. of the metal is 6·72–6·86. It melts at 630·5° C. (Heycock and Neville, Chem. Soc. Trans. 1895, 186), and boils at about 1500° C. in a current of hydrogen. Antimony has a hardness of 3–3·5, and is so brittle that it can readily be powdered. It is a bad conductor of heat and electricity.

The most important physical property of antimony is that of expanding on solidification, a property possessed also by its alloys. At the ordinary temperature it is not acted on by the air, but oxidises quickly on melting, and burns at a red heat, producing white fumes of the trioxide. It is oxidised by nitric acid of various strengths, dilute acid producing principally the trioxide, and the concentrated acid producing the pentoxide (H. Rose, Analyt. Chem. 1, 258). Dilute sulphuric and hydrochloric acids are without action on it, but the strong acids produce the sulphate and chloride respectively. When fused with borax or other vitrifying material, it imparts to them a yellow colour.

Antimony combines directly with the halogens with evolution of light and heat, and also, at a higher temperature, with the elements of the sulphur group, and with phosphorus and arsenic. The element occurs in three modifications: (1) the crystalline or ordinary form described above; (2) an amorphous yellow modification, soluble in carbon disulphide, which is produced by the action of oxygen on liquid stibine at −90°; and (3) the amorphous explosive antimony, which is best prepared by the action of a weak constant electric current on a concentrated acid solution of antimony trichloride, the strength of current bearing a constant relation to the surface of deposition, not less than ½ grain being deposited per sq. inch per hour. Thus produced, it is bright and steel like in appearance, with an amorphous fracture and sp.gr. 5·78. When heated to 200°, or struck or scratched, it rapidly changes into the crystalline form, increasing in density, with the production of great heat. Antimony trichloride is always contained in the metal to the extent of 4·8–7·9 p.c., and is given off when the form changes. It is probable that this substance is a solid solution of an antimony halogen compound in an allotropic form of antimony, and that the explosion consists in the rapid transformation of the latter into the stable form. The change is accompanied by an evolution of heat amounting to 20 cals. per gram. Cohen and others (Zeit. physikal. Chem. 1904, 47, 1; 1905, 50, 291; 52, 129) have shown that this change goes on slowly when explosive antimony is preserved.

Antimony is precipitated as a fine powder by the action of zinc on an acid solution of an antimony salt. In this form it is sold as 'iron black' for producing an appearance of polished steel on papier maché, plaster of Paris, and zinc ornaments.

Brass can be covered with a fine lustrous coating of antimony by dipping in a hot mixture of 1 part tartar emetic, 1 part tartaric acid, 3 or 4 parts powdered antimony, 3 or 4 parts hydrochloric acid, and 3 parts water.

It may be deposited electrolytically on brass or copper by using a bath of the double chloride of antimony and ammonia acidulated with hydrochloric acid.

Alloys of Antimony.

Antimony alloys with most of the heavy metals and with the alkali metals. It dissolves in a solution of sodium in liquid ammonia. It generally increases the fusibility, brittleness, and hardness of the metals with which it is alloyed, and imparts the valuable property of expanding on solidification, thus producing very fine impressions. The sharpest impressions are produced when any of these alloys are cast at a low temperature (J. Soc. Chem. Ind. 1, 982). The castings are usually made in brass moulds coated with lampblack and turpentine.

With *lead*, antimony alloys readily in all proportions. An alloy of equal parts of lead and antimony is very brittle, and rings when struck. Nasmyth has recommended the addition of 5 p.c. antimony to lead for use instead of bronze in taking casts of works of art (Athenæum, No. 1176, 511).

Type metal is essentially an alloy of lead and antimony, frequently with addition of tin and containing less frequently copper. A few examples of common type-metals are.

	Lead	Antimony	Tin	Copper
Type metal .	55	30	15	—
„ . .	70	18	10	2
„ .	77·5	16	6·5	—
„ .	82	15	3	—
Stereotype plate .	85·7	14·3	—	—
„ „ .	82·5	13	4·5	—
Linotype metal .	84·5	13·5	2	—
„ „ .	83	12	5	—

The alloys, containing varying proportions of antimony, are also used, under the name of hard lead, in lead pipes, for making pumps and taps for raising acid in alkali works, in the manufacture of shrapnel and shot, and for the emery wheels and tools of the lapidary.

Tin forms numerous useful alloys with antimony, especially with the addition of other metals. *Common Britannia metal* contains tin 94, copper 1, antimony 5. Britannia metal for castings: tin 90·6, copper 0·2, antimony 9·2. The best Britannia metal contains tin 90, antimony 10, lead and bismuth being carefully excluded. Copper also is never added except for the production of colour. Increasing the proportion of antimony raises the m.p., increases the hardness, and decreases the malleability of the alloy. Good alloys take a brilliant polish, and show a fine-grained, jagged fracture. The presence of arsenic in the antimony diminishes the ductility of the product.

Metal argentum contains tin 85·5, antimony 14·5.

Ashbury metal: tin 77·8, zinc 2·8, antimony 19·4. Ships' nails, tin 50, lead 33, antimony 17.

Minofer is tin 68·5, antimony 18·2, copper 3·3, and zinc 10.

Bearing or *anti-friction metal* usually contains antimony, tin, lead and copper, but the composition is very variable. As the name indicates, it is used for machinery bearings, being especially suitable for light loads at high speeds. As examples of these alloys the following may be given:—

	Antimony	Tin	Copper	Lead
Babbit's metal . .	8·3	83·3	8·3	—
Railway bearings .	15	8	2	75
,, ,, .	13·5	11·5	3	72
,, ,, .	10	51	2	37
U.S. Rly. Babbit metal	7·4	88·9	3·7	—
German Rly. Babbit metal . . .	11·1	88·3	5·6	—

Copper. The presence of 0·15 p.c. of antimony renders copper both cold and hot short. With varying proportions of the two metals, shades from pure copper-red to rose-red, crimson, and violet may be obtained, the last when equal parts of each are present. Two definite compounds of copper and antimony appear to exist, viz. $SbCu_2$, a violet alloy known as 'Regulus of Venus,' and $SbCu_4$ (Kamensky, Phil. Mag. [5] 17, 270; *v.* also Ball, Chem. Soc. Trans. 1888, 167).

Antimony is sometimes added to brass to heighten its colour. These alloys are harder and finer in texture than copper or brass, and take a better polish, and are sometimes used for concave mirrors.

Zinc. Antimony forms alloys with zinc, which decompose water rapidly at the boiling temperature, and this action is promoted by the presence of traces of platinic chloride. Cooke has suggested the suitability of this reaction for the preparation of pure hydrogen.

Melted gold absorbs the vapour of antimony, but gives it up almost entirely on further heating. Gold loses its malleability when $\frac{1}{2000}$ of antimony is present. An alloy of 9 gold and 1 antimony is white and very brittle, with an amorphous porcelain-like fracture. Silver antimonide occurs as the mineral *discrasite*. C. O. B.

Compounds of Antimony.

The principal compounds of antimony are formed by combination with oxygen, sulphur, and chlorine; some compounds contain two of these negative elements, of which the oxychloride or *powder of Algaroth*, and the oxysulphide or *glass of antimony* are examples.

The most important of these are the trichloride, trisulphide, and trioxide.

Antimony trisulphide Sb_2S_3.

Crude antimony, antimony ore, sesquisulphide of antimony; Schwefelspiessglänz; Grau-Spiessglanzerz; Stibium sulphuratum nigrum; lupus metallorum.

This substance, as it occurs naturally, or after liquation, is usually too impure to be employed for other purposes than the preparation of the metal.

The ordinary sulphide may be prepared by the following methods:—

(1) Thirteen parts pure antimony are mixed with 5 parts flowers of sulphur, and projected in portions into a red-hot crucible; when completely fused, it is poured out and any free metal detached.

(2) Sulphuretted hydrogen precipitates it as an orange precipitate from a solution of an antimony salt.

(3) Digest for two hours in a closed vessel 1 part crude antimony sulphide, 1 part pearl ash, 1½ parts lime, and 15 parts water, and add sulphuric acid; the alkaline sulpho- salt first formed is decomposed by the acid with the precipitation of the pure sulphide. Antimony sulphide is soluble in alkaline sulphides and in acid potassium sulphate. When finely powdered and rubbed to a paste at 20° or 30° with strong sodium sulphide solution, a coppery metallic mass is produced, and the liquor, on addition of more sodium sulphide, yields Schlippe's salt.

The sulphide is used to some extent in refining gold from silver and copper, and in the preparation of safety matches and percussion pellets for cartridges, in pyrotechny and in veterinary surgery.

Kermes mineral. *Brown-red antimony sulphide. Pulvis Carthusianorum. Sulph. stibiatum rubrum.*

Kermes mineral usually consists of a mixture of the trisulphide and trioxide containing alkali. Berzelius and Rose state that some samples examined by them consisted of a true double sulphide of potash and antimony.

Preparation.—Fuchs asserts that if antimony sulphide is heated and *suddenly* cooled in water it yields an orange-red, less dense powder of kermes. A. Ditte (Compt. rend. 102, 212) does not confirm this statement.

(1) Four parts pure potassium carbonate and 11 parts pure antimony sulphide are heated to fusion in a covered crucible, cooled, boiled with water, and filtered. The solution on exposure to the air deposits kermes, the residue from the first boiling is heated with the mother liquor from some previously deposited kermes, and yields a further quantity; this operation is repeated until an insoluble residue of trisulphide and trioxide is left. Each successive deposit of the kermes contains a larger amount of the oxide.

(2) Fuse together 2 parts antimony, 1 sulphur, and 3 sodium carbonate; or, 1 antimony sulphide and 3 or 4 tartaric acid, until fumes cease to be evolved; and treat the product as in (1).

(3) The slags from the reduction of antimony ore with cream of tartar slowly precipitate

kermes when treated with water; this is sold to veterinary surgeons as ‘kermes by the dry way.’ When antimony sulphide is boiled with potash and precipitated with an acid, the kermes produced contains no oxide (Liebig). The kermes produced by the action of *dilute* alkaline carbonate on antimony sulphide also contains no oxide (Rose). The oxide may be removed from ordinary kermes by digestion with tartaric acid. A solution containing so much alkali as to give no precipitate on cooling gives, when treated with carbonic acid gas, a highly sulphurated kermes containing antimony pentasulphide.

Kermes is a brown-red, loosely coherent powder, with a brown streak, containing water, which is given off below 100°. It is lighter than the ordinary sulphide. The kermes containing antimony oxide, when fused and solidified, is destitute of crystalline structure, while that free from oxide produces a highly crystalline solid.

Antimony pentasulphide Sb_2S_5. *Golden sulphide of antimony; sulphur antimonii auratum.*

Prepared by boiling the trisulphide with potash and ground sulphur, filtering and precipitating with acid. Redwood recommends 4 parts black antimony sulphide, 8 lime, and 80 water, digested, filtered, and precipitated with hydrochloric acid; or, 2 sulphide, 4 potassium carbonate, and 1 sulphur, to be fused, treated with 20 parts water, filtered, and the solution precipitated with a large excess of sulphuric acid.

On treating the mother liquor from kermes mineral with an acid, the pentasulphide is precipitated with evolution of sulphuretted hydrogen. The mother liquor from Schlippe's salt also yields this substance on the addition of an acid (R. Bartley, Chem. Soc. Trans. 1876, 1, 748). It generally contains free sulphur.

Antimony pentasulphide is of some importance commercially, as it is used in the process of vulcanising rubber.

Antimony pentasulphide combines with alkaline sulphides, forming sulphantimonates, which as well as the sulphantimonites (which contain less sulphur) are known as ‘livers of antimony.’ Of these the sodium sulphantimonate, or *Schlippe's salt*, is the most important.

A mixture of 11 parts finely powdered antimony trisulphide, 13 crystallised sodium carbonate, 1 flowers of sulphur, 5 recently slaked lime, and 20 water, is digested at the ordinary temperature for 24 hours with frequent stirring, in a vessel which can be closed. It is then strained and washed several times with water, the solution and washings are evaporated in a porcelain or clean iron dish until a sample yields crystals on cooling; the solution is then cooled, and the resultant crystals washed with cold water and dried in the open air or in a desiccator at the ordinary temperature. The salt is more rapidly formed when the mixture is heated (Liebig, Handwörter. d. Chem. 2te Aufl. 2, 139; also Gm. 4, 384).

Oxysulphides of antimony are formed by the combination of the sulphides and oxides or by the partial oxidation of the sulphides.

Antimony crocus or saffron. Fuse together 3 parts of antimony trioxide and 1 part trisulphide, or fuse the oxide with the calculated quantity of sulphur.

The scoria from the fusion of the sulphide with carbon and alkaline carbonate in the preparation of the metal is known as crocus of antimony.

Crocus of antimony is a brownish-yellow body.

Glass of antimony. Vitrum antimonii. When antimony sulphide is fused until the necessary amount of sulphide has been converted into oxide, the whole forms a glassy mass of this compound. The best method of preparation is to roast the sulphide completely into oxide and fuse the product with $\frac{1}{20}$ part of sulphur. Its colour varies with the proportion of sulphur present from yellowish-red to hyacinth red. The best quality is of a fine red colour, and contains 8 antimonious oxide and 1 antimonious sulphide

Antimony cinnabar is an oxysulphide of a fine vermilion colour, soft and velvety, and unaltered by air or light; it is used in the preparation of oil and water colours, and in calico-printing. It is prepared by dissolving antimony oxide in hydrochloric acid, and placing the solution in a large wooden tub which is $\frac{7}{8}$ filled with calcium hyposulphite. The mixture is stirred and heated with steam to 70°, the precipitate soon subsides as a yellowish sediment which changes to a bright orange-red, and is thoroughly washed, and dried below 50°. N. Teck (Chem. Zentr. 26, 1880) prepared it from 4 parts tartar emetic, 3 tartaric acid, 18 water mixed at 60° with hyposulphite of soda and heated to 90° (Wagner), or 4 volumes antimonious chloride of sp.gr. 1·19 mixed with 10 vols. water and 10 vols. hyposulphite of 1·19 sp.gr., and heated gradually to 55° (Mattieu Blessy).

Antimony yellow (*Mérimée's yellow*). According to the method of Mérimée, a mixture of 3 parts bismuth, 24 parts antimony sulphide, and 64 parts nitre, is thrown little by little into a heated crucible, fused, powdered, washed, and dried. In this way bismuth antimonate is produced. Of this 1 part is mixed with 8 parts ammonium chloride and 128 parts litharge, and fused as before. The time occupied and the temperature used cause considerable variations in the colour. Mérimée's yellow is a fine permanent colour of good body. It is only used for the finest painting.

Naples yellow is essentially an antimonate of lead containing excess of lead oxide, but mixtures of carbonate and chromate of lead are also sold under the name. Many processes may be used for its preparation. According to Brunner, a mixture of 1 part tartar emetic, 2 parts lead nitrate, and 4 parts sodium chloride is heated, just to fusion, for 2 hours. The cooled mass is placed in water and soon falls to pieces. According to Guimet, it may be produced by heating a mixture of 1 part potassium antimonate and 2 parts red lead. It is a fine very permanent orange or yellow pigment, used in oil-painting, and, mixed usually with a lead glass, for glass and porcelain staining.

Antimony trichloride (*Butter of antimony*).

Prepared by dissolving the sulphide in strong hydrochloric acid with a small quantity of nitric acid and evaporating to dryness.

To prepare the pure chloride, the acid solution is evaporated until it just crystallises on standing in a cool place; it is then transferred to a retort and distilled until a drop of the distillate solidifies on a cold surface; the receiver is then changed, and the further distillate is pure.

It is a white, buttery, semivitreous, deliquescent solid. When pure, it is crystalline, and melts sharply at 73·2°, and boils at 223·5° (Beckmann, Zeitsch. anorg. Chem. 1906, 51, 96). It is used as a caustic in medicine, for the preparation of tartar emetic, and as a 'bronzing solution' for gun-barrels, &c. For this purpose a saturated solution is mixed with olive oil, rubbed over the warmed metal and exposed to the air until the proper colour is produced. When bronzed, the metal is polished with a burnisher or with wax, or coated with a varnish of 2 oz. shellac, 3 drachms dragon's blood, dissolved in 2 quarts of methylated spirit.

Antimony oxychloride. *Basic chloride, powder of Algaroth; pulvis Algarothi; S. Argelicus; mercurius vitæ, &c.*

Water is added to a solution of the trichloride until it is distinctly turbid, when it is filtered (the precipitate carries down any traces of sulphuretted hydrogen which may be present, and which if left would soon turn the substance yellow). Five to ten volumes of water are added, and the precipitate is washed with cold water and filtered. Its composition varies with the temperature at which it is produced and the amount of water used, varying between SbOCl and, where a very large amount of water has been used, Sb_2O_3. It is a white powder, and is principally used for the preparation of pure antimonious oxide and tartar emetic.

Antimonious oxide Sb_4O_6. *Trioxide of antimony.* If antimony is powdered and heated in a shallow dish, it eventually forms antimony tetroxide Sb_2O_4; this, together with the unchanged metal, is fused in a crucible, when the tetroxide and antimony react, forming antimonious oxide, the excess of antimony sinking to the bottom of the crucible.

For pharmaceutical purposes 20 parts of finely powdered antimony sulphide are gradually added to 100 parts hydrochloric acid containing 1 part nitric acid, and heated, gently at first, and then more strongly, until sulphuretted hydrogen ceases to be evolved. It is then boiled for an hour, enough water is added to produce a slight precipitate, which removes the last traces of sulphuretted hydrogen, and filtered into a vessel containing 1 gallon of water, precipitating the oxychloride, which is filtered and washed until it ceases to have an acid reaction; it has then become converted into the trioxide.

It is a white fusible solid, slightly soluble in water, volatile at a red heat. It becomes further oxidised to the tetroxide Sb_2O_4 on heating in air, and is then non-volatile.

In presence of alkalis it absorbs oxygen; for this reason it has been proposed to use it for reducing nitrobenzene to aniline, and in the preparation of aniline red.

It is used for the preparation of tartar emetic. When ground with linseed oil it is sometimes used as a substitute for white lead, being less injurious to the workmen and less acted upon by sulphur gases; it has, however, less 'body' and is more expensive.

Tartar emetic. *Potassium antimony tartrate. Tartarus stibiatus. Brechweinstein; spiessglanzweinstein.* $2C_4H_4K(SbO)O_6,H_2O$. Three parts antimonious oxide and 4 cream of tartar are made into a thin paste with water and digested for about half an hour, keeping the water at constant volume; 8 parts of water are then added, boiled, and filtered whilst hot. The oxychloride or oxysulphide may be substituted for the oxide, but not so satisfactorily.

Tartar emetic forms octahedral crystals, which give off a part of their water on exposure to the air. They dissolve in 14·5 parts cold and in 1·9 parts boiling water. They show an acid reaction with litmus, and have a nauseous metallic taste, 5–10 centigrams causing vomiting, and larger quantities being very poisonous.

It is used in medicine and in the preparation of pomades, &c., and also largely as a mordant in dyeing and calico-printing. Mixtures of tartar emetic for mordanting are sold containing as much as 33–59 p.c. zinc sulphate at a lower price, under the names *tartar emetic powder, tartar emetic substitute, antimony mordant*, &c. It is known that zinc acetate may partly replace the tartar emetic with advantage, but the sulphate appears to be a simple adulterant (H. Smid, Chem. Zeit. 1882, 949).

Several other compounds of antimony have been proposed for mordants instead of tartar emetic. E. Jacquet (Dingl. poly. J. 257, 168) advised the use of a mixture of basic antimony oxalate with twice its weight of ammonium oxalate. Nölting recommended the double oxalate of potash or of ammonia and antimony (Dingl. poly. J. [3] 255, 122). It is stated that the latter compounds have long been used under other names.

The use of the fluoride (which is not precipitated with excess of water) and the double fluorides of antimony and the alkalis has been patented by S. M'Lean. Watson, jun., patented a process for using trichloride with sufficient common salt to prevent the precipitation of the oxychloride (G. Watson, J. Soc. Chem. Ind. 1886, 5, 591; B. W. Gerland, J. Soc. Chem. Ind. 1884, 4, 643; and Kopp and Bruère, J. Soc. Chem. Ind. 1888, 566). A double salt of antimony fluoride and ammonium sulphate $SbF_3(NH_4)_2SO_4$, known as 'antimony salts,' is also used in dyeing, but as it attacks glass as well as metal, it should be stored and worked in wooden vessels. A good bath is 100 litres water, 400 grams antimony salts, 200 grams soda crystals, at a temperature of 50° (Frey, Bull. Soc. Md. Mulhouse, 1888, 301).

Tartar emetic as a mordant has, at the present time, been largely superseded by the double oxalate of potassium and antimony, as it is cheaper than the tartrate, and equally efficient, although it contains less antimony.

F. During has recommended the use of the double lactate of antimony and calcium, which can readily be obtained by mixing, in the dry state or in solution, alkali lactates with 'antimony salts,' or other antimonious compounds (Farber, Zeit. [20] 319). He states that at least 80 p.c. of the antimony in the solution will actually go into the cloth as mordant.

ANTIMONY SALTS. A compound of antimony fluoride with ammonium sulphate used as a mordant (*v.* ANTIMONY).

ANTINONIN. Trade name for a solution of potassium *o*-dinitrocresol used as a fungicide.

ANTIPERIOSTIN. Trade name for mercury iodocantharidate.

ANTIPYONINUM. Trade name for sodium tetraborate.

ANTIPYRIN. *Phenyldimethylpyrazolone* (*v.* PYRAZOLE).

ANTIRRHINIC ACID *v.* DIGITALIS.

ANTISEPTICS *v.* DISINFECTANTS.

ANTISEPTINE. Said to be a mixture of zinc iodide, zinc sulphate, boric acid, and thymol.

ANTISEPTOL. *Cinchonidine iodosulphate*, used as a substitute for iodoform.

ANTISPASMIN. Trade name for a combination of narceine and sodium salicylate. Used as a narcotic and sedative.

ANTITHERMIN. *Phenylhydrazone* of *lævulinic acid* $CH_3{\cdot}C(N_2H{\cdot}C_6H_5){\cdot}CH_2{\cdot}CH_2{\cdot}CO_2H$ is obtained by dissolving phenylhydrazine in dilute acetic acid, adding an aqueous solution of the equivalent quantity of lævulinic (acetopropionic) acid, and crystallising the resulting yellow precipitate from alcohol (Farbw. vorm. Meister, Lucius & Brüning in Höchst a. M., G. R. P. Pat. 37737).

It forms colourless, inodorous, and tasteless scales, melts at 98°–99°, is sparingly soluble in cold water, soluble in alcohol, ether, or dilute acids. It has been employed as an antipyretic (Nicot, Chem. Zentr. 1887, 415); but, according to Stark (Chem. and Drug, 32, 651), its use in medicine is now almost abandoned, as it is too toxic for use.

ANTIVENIN *v.* SNAKE VENOM.

ANTOZONE. A supposed third modification of oxygen, assumed to be present in the fogs produced when ozone acts on reducing agents such as sodium bisulphite or hydriodic acid. According to Rothmund (Z. Elektrochem. 1917, 23, 170), the phenomenon is due to the volatile character of the reducing agent and to be directly caused by the presence of these substances in the vapour phase.

ANTWERP BROWN *v.* PIGMENTS.

ANVULA *v.* AMLAKI.

AOOD-I-BALSAM. *Balsam of Mecca* (*v.* OLEORESINS).

APATITE. A crystallised mineral, consisting of calcium phosphate in combination with fluorine, chlorine, hydroxyl, or carbonic acid, the formula being $(CaF)Ca_4(PO_4)_3$ or $3Ca_3(PO_4)_2+CaF_2$, where F may be replaced by Cl, OH, or CO_3. There are thus several chemical varieties, namely, fluor-apatite, chlor-apatite, hydroxy-apatite, carb-apatite, and oxy-apatite; the last two being also called podolite (V. Chirvinsky, 1907), and voelckerite (A. F. Rogers, 1912) respectively. On the composition of these several members of the apatite group, *see* papers by A. F. Rogers (1914) and W. T. Schaller (1912). Similarly, by partial replacement of the calcium, there are the chemical varieties mangan-apatite, cupro-apatite, and talc-apatite. In addition to these, some other trivial names are applied to varieties of crystallised apatite; for example, asparagus-stone, from Murica in Spain; moroxite, from Arendal in Norway; and francolite, from Wheal Franco, near Tavistock in Devonshire. The distinction between fluor-apatite and chlor-apatite is, however, the only one of any importance. (For the varieties of massive apatite, *v.* PHOSPHORITE.)

Apatite is often found as well-developed crystals. These belong to the hexagonal system, and are usually bounded by a six-sided prism and pyramid with the basal plane, though sometimes numerous other brilliant facets are present. The colour is commonly greenish or brownish, but sometimes sky-blue, violet, or colourless. The crystals may be transparent or opaque, and they have a vitreous to sub-resinous lustre. Sp.gr. 3·2; hardness 5 (the mineral can be scratched with a knife). Owing to its variable appearance, apatite is frequently mistaken for other minerals, and it well deserves its name, from ἀπατάω, 'to deceive.'. In determining the mineral, it is always well to test for phosphoric acid.

As microscopic crystals, apatite is present as an accessory constituent of igneous rocks of all kinds. It also occurs in metamorphic rocks and in metalliferous veins. Fine specimens are found at many localities, but only in two regions—in Norway and Canada—is crystallised apatite mined for commercial purposes. In southern Norway, particularly in the neighbourhood of Kragerö and Oedegaarden, near Bamle, extensive deposits of chlor-apatite occur in connection with gabbro (a pyroxene-felspar rock of igneous origin). Large deposits of fluor-apatite are mined in Ottawa Co., Quebec, and in Renfrew Co., Ontario; here the mineral forms beds in Laurentian gneiss, usually in association with crystalline limestone. In the iron mines at Mineville, in Essex Co., New York, small grains of apatite occur disseminated in magnetite, sometimes to the extent of 5 p.c. of the mass. Here it is separated by a magnetic process, and used for the manufacture of fertilizers.

On the Norwegian deposits, *see* J. H. L. Vogt, Die Apatit-Ganggruppe, Zeits. prakt. Geol. 1895, iii, 367, 444, 465. On the Canadian deposits, the various publications of the Canadian Geological Survey. *See* also O. Stutzer, Die wichtigsten Lagerstatten der 'Nicht-Erze,' Berlin, 1911, i. L. J. S.

APERITOL. A mixture of equal parts of valerianyl and acetylphenolphthalein, used as a laxative.

APHTHITALITE. Native sulphate of potassium and sodium, $(K,Na)_2SO_4$, containing K : Na in ratios varying from 3 : 1 to 4 : 3. It occurs sparingly as crusts and delicate platy crystallisations on Vesuvian lava; these are colourless, or often tinged with blue or green. The crystals are rhombohedral and optically uniaxial, although often simulating orthorhombic forms; and are dimorphous with the usual orthorhombic modification of potassium sulphate obtained artificially. The same mineral has been found at Rocalmuto, Sicily, and in the potash-salt deposits at Douglashall, near Westeregeln, in Prussia. Synonyms are arcanite and glaserite. L. J. S.

APHTHITE. An alloy containing 800 parts of copper, 25 of platinum, 10 of tungsten, and 170 of gold (Zeits. f. d. C. Grossgew. 4, 313).

APIGENIN *v.* FLAVONE.

APIIN. A glucoside contained in parsley and celery, forming on hydrolysis *apigenin* and a disaccharide, made up of α-glucose and a pentose, *apiose* (Vongerichten, Annalen, 1901, 121), (*v.* FLAVONE and GLUCOSIDES).

APIOL *v.* OILS, ESSENTIAL.

APIOSE *v.* CARBOHYDRATES.

APIOS TUBEROSA (Moench.), *Glycine apios* (Linn.). A leguminous plant from North America, the roots of which have been proposed as a substitute for the potato, and the young seeds for peas. Payen (Compt. rend. 28, 189) gives the following analysis of the root: Nitrogenous matters, 4·5; fatty matters, 0·8; starch, sugar, &c., 33·55; cellulose, &c., 1·3; inorganic, 2·25; water, 57·8 (*cf.* Brighetti, Chem. Zentr. 1900, i. 914).

APIUM *v.* OILS, ESSENTIAL.

APIUM PETROSELINUM (*Carum petroselinum*) *v.* FLAVONE.

APOCYNUM *v.* DIGITALIS.

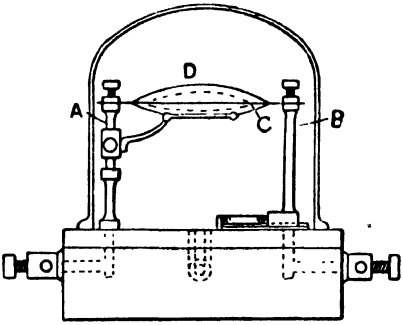
APOLLO RED *v* AZO- COLOURING MATTERS.

APOLYSIN. Trade name for monophenetidine citrate: antipyretic and analgesic.

APOMORPHINE *v.* OPIUM.

APONAL. Trade name for amy carbamate.

APOPHOROMETER, THE (Sublimation apparatus). The apophorometer consists essentially of a ribbon of thin platinum, about 6 cm. long and 4 or 5 mm. wide, stretched between two forceps, A, B, provided with binding screws so that an electric current can be sent through the platinum. One of the forceps is movable, and is acted upon by a light spring so as to keep the ribbon stretched. Beneath the ribbon is a watch-glass, C, held on a support which can be raised or lowered or turned to one side. From 5 to 30 mgrms. of the substance under examination are spread on the ribbon, the watch-glass is moved upwards into contact with the ribbon and then a second inverted watch-glass, D, is placed over the first one as a cover. A current is now passed through the ribbon and gradually increased until the sublimation temperature is attained. The temperature can be estimated with fair accuracy by means of an amperemeter. The whole apparatus may be placed under a bell-jar, if it be desired to work *in vacuô* or in an atmosphere of an inert gas. When necessary strips of thicker platinum or moulded strips of carbon may be used instead of the thin platinum ribbon. Sublimation experiments with this apparatus may with advantage be used instead of blowpipe tests for the identification of minerals, and details of experiments made with various minerals are given (Joly, Phil. Mag. 1913, 25. 301; J. Soc. Chem. Ind. 1913, 32, 509).



APOPHYLLITE *v.* CALCIUM.

APOREINE. A poisonous alkaloid found in the juice of *Papaver dubium*, m.p. 88°–89°. Forms crystalline salts, giving a bluish fluorescence in solution. The hydrochloride

$$C_{18}H_{16}NO_2,HCl,$$

forms silvery nacreous scales, subliming without decomposition in dry carbon dioxide between 220° and 240°. The neutral (normal) sulphate melts at 70°–75°, and when exposed to air and light, decomposes, forming a reddish-brown powder (Pavesi, Gazz. chim. ital. 1914, 44, 398).

APORETIN *v.* RHUBARB.

APOTHESINE. Trade name for the cinnamic ester of diethyl amino propyl alcohol. Used as a local anæsthetic. *V.* ANÆSTHETICS.

APOTURMERIC ACID *v.* TURMERIC.

APPALLAGIN. Trade name for a mercury compound of tetraiodophenolphthalien.

APPERTOL. Trade name for a preparation of sodium bisulphite. Used as a preservative and disinfectant.

APPLE. The fruit of *Pyrus Malus* (Linn.). Many varieties are known, differing greatly in size, shape, colour, and flavour.

The solid matter of apples consists largely of sugars—lævulose, sucrose and dextrose; their acidity is due to malic acid $C_2H_4O(COOH)_2$. In unripe apples starch is present—sometimes to the extent of 4 or 5 p.c., but the fully ripened fruit is devoid of starch. Cellulose forms about 1 p.c. of the weight of the ripe fruit, pentosans about 0·5 p.c., and pectose matters also about 0·5 p.c. (*cf.* Schneider, Analyst, 1912, 492). Mineral matter is usually between 0·2 and 0·3 p.c., and about half of this is potash. Apple peel contains small quantities of waxes, similar to bees-wax.

The following analyses of American Baldwin apples show the changes which occur during ripening:—

	Very green	Green	Ripe	Over-ripe
Water . .	81·33	79·81	80·36	80·30
Solids . .	18·67	20·19	19·64	19·70
Reducing sugars .	6·40	6·46	7·70	8·81
Cane sugar . .	1·63	4·05	6·81	5·26
Starch . .	4·14	3·67	0·17	none
Free malic acid .	1·14	—	0·65	0·48
Ash . . .	0·27	—	0·27	0·28

Hotter (Chem. Zentr. 1900, ii. 484) gives the following analysis of apple ash:—

K_2O	CaO	MgO	Fe_2O_3	SiO_2	SO_4	P_2O_5
51·58	4·22	3·71	1·18	1·08	2·49	10·42

Certain varieties of apples—particularly those used for cider-making—are rich in tannin, and, when the cells are broken, *e.g.* by cutting the apple or by a bruise, so as to admit air, a browning takes place—probably by the action of an oxydase upon the tannin.

Otto (Bied. Zentr. 1901, ii. 553; and 1902, 31, 107) found that the percentage of water increases during ripening on the tree, but diminishes on storing, that the starch diminishes and finally disappears, while the cellulose remains constant. The nitrogen increases during ripening on the tree, but afterwards diminishes.

The acidity diminishes during ripening, both before and after gathering.

The following figures relate to South-African apples (Ingle). The flesh and rind of the ripe fruit, the core and pips being rejected, contained :—

Variety	Koo	Reinette de Canada	Northern spy	Versfeld	Lord Wolseley
Water . .	85·08	—	82·64	87·65	84·41
Dry matter .	14·92	—	17·36	12·35	15·59
Ash . .	0·313	—	0·262	0·270	0·268
Acidity (as malic acid) .	0·47	0·65	0·48	0·71	0·47
Reducing sugars	7·44	6·87	10·26	9·43	10·85
Cane sugar .	4·63	3·68	4·77	1·36	1·58
Nitrogen .	0·046	0·094	0·058	0·057	0·043
Crude fibre .	1·33	1·24	1·26	—	0 88
Per cent. in ash:					
Potash .	54·48	—	48·52	53 30	51·58
Lime . .	2·63	—	1·95	1·82	2·70
Silica . .	1·51	—	1 58	1·25	0·90
Phosphorus pentoxide.	11·15	—	12·10	8·09	12·16
Sulphur trioxide .	2·46	—	2·67	3·13	3·10
Chlorine .	0·50	—	0·89	1·02	1·00

The proportions of lime found in these apples are apparently lower than those usually found in American apples, while the figures for phosphorus pentoxide and chlorine are higher.

Under normal conditions, the starch present in unripe apples is converted, during ripening, into sugar by the diastase present, but if the unripe apples be bruised, this change is incomplete in the bruised portion, and starch may be found in the browned tissues. According to Warcollier (Compt. rend. 1905, 141, 405), this is due to the paralysing effect upon the diastase of the tannin which escapes from the bruised cells (and which, by the action of an oxydase, gives rise to the browning), thus preventing the saccharification of the starch, upon which normal ripening depends.

According to Eoff (J. Ind. Eng. Chem. 1917, 9, 587), the preponderant sugar, in all the twenty varieties examined, was lævulose. This confirms the observations of Thompson and Whittier (Bull. 102, 1913, Delaware Coll. Agric. Expt. Stat.), and of Browne (A. 1902, ii. 371).

Apples are now dri d by artificial heat (with or without the use of sulphur dioxide, which improves the colour), and sold, either as whole fruit or as 'apple rings.' Fresh apples yield about one-seventh of their weight of the dried product. Zinc is frequently found in dried apples, probably from contact with zinc trays during the drying process. As much as 0·58 gram Zn per kilogram has been found in American dried apples. American analyses give as the average components of dried apples : 36 p.c. water, 1·4 p.c. protein, 3·0 p.c. ether extract, 57·6 p.c. carbohydrates, and 1·8 p.c. ash. The flavour, and particularly the odour, of apples can be imitated by *iso*-amyl-*iso*-valerate dissolved in spirits of wine. This constitutes the 'essence of apples' used in confectionery and perfumery.

H. I.

APPLES, ESSENCE OF, *v.* Apples.

APPLE-PULP (pomace) forms a by-product of cider manufacture, and has the following composition (8 samples) : Water (p.c.) 68·4–78·1 fat (ether extract), 0·82–1·43 ; protein, 1·03–1·82 ; crude fibre, 4·42–10·5 ; ash, 0·56–2·27 ; carbohydrates (sugar, &c.), 9·5–22·0. Most stock eat it readily, and it is a satisfactory feeding stuff if given as an adjunct to more concentrated foods. It must be given fresh, for it undergoes fermentation and putrefaction so rapidly as to be unfit for consumption in two or three days in warm weather. When dried it may be used in the manufacture of compound cakes and poultry feeds. If mixed with salt it may be preserved if tightly pressed in a silo. It usually contains from 0·2–0·6 p.c. of potash, 0·4 to 0·7 p.c. phosphoric acid, and 1·6 to 1·7 p.c. nitrogen, and makes an excellent manure, if mixed with half its weight of lime to neutralise acids (Barker and Gimingham, Journal of the Board of Agriculture, 1915, 22, 851). *See* Cider.

APPLE TREE. (*Pyrus malus*, L. ; *Pomme*, Fr. ; *Apfel*, Ger.) The wood is much used in turnery, and that of the crab tree is used by millwrights for the teeth of mortice wheels. The bark contains a tannin identical with that contained in horse-chestnut bark.

APRICOT. The fruit of *Prunus armeniaca* (Linn.).

The following analyses were made by Fresenius :—

		I. Medium size	II. Large wt. 60 grams
	Sugars . . .	1·14	1·53
Soluble	Free acid . .	0·90	0·77
	Nitrogenous matter.	0·83	0·39
	Pectins, gum, &c. .	5·93	9 28
	Ash . . .	0·82	0·75
Total soluble matter		9 62	12·72
Insoluble	Seeds (stone) .	4 30	3·22
	Skin and cellulose	0·97	0·94
	Pectose . .	0·15	1·00
	Ash . . .	(0·07)	(0·10)
Total insoluble matter, excluding ash . .		5·42	5·16
Water		84·96	82 12
		100·00	100·00

In Californian-grown apricots, Colby (Exp. Stat. Record, 1893, 4, 918) found in the whole fresh fruit, water, 85·16 ; dry matter, 14·84 ; containing nitrogen, 0·194 ; sugar, 11·10 ; ash, 0·49.

The ash was found to contain :

K_2O	Na_2O	CaO	MgO	MnO_2	P_2O_5	SO_3	SiO_2	Cl	Fe_2O_3
59·36	10·26	3·17	3·68	0·37	13·09	3 63	5·23	0·45	1·68

Californian apricots appear to contain more nitrogen than the European fruit. As many other analyses agree in giving about 11 p.c. of sugar, it is probable that some error has been made in Fresenius' figures, though they have been widely quoted.

The sugar is chiefly sucrose, with a little dextrose, and invert sugar, which becomes less when the fruit ripens (Desmoulière, Ann. Chim. anal. 1902, 7, 323). The colouring matter is probably related to carotin.

The acidity of apricots is chiefly due to malic and citric acids.

The kernels of apricot 'pits,' or stones, like those of the other members of the *Prunus* family, contain amygdalin and about 40 p.c. of a fatty oil resembling almond oil. This oil has a sp.gr. of 0·9204 at 15·5°, a pale-yellow colour, and a slight odour of almonds (Maben, Pharm. J. Trans. [3] 16, 797). More recent determinations give the following (Dieterich, Chem. Zentr. 1902, 2 [15], 943): sp.gr. at 15°C. 0·915–0·921, at 90°, 0·9010–0·9015; solidifying point, −14° to −20°; saponification value, 193·1–215·1; iodine value (Hübl), 100–108·7; refractometer value at 25°, 65·6–67·0; at 40°, 58·0; at 50°, 52·25. It can be distinguished from almond oil by Biber's reagent (fuming nitric acid, sulphuric acid and water), with which it gives a red colour, while almond oil only yields a faint yellow.

The flavour of apricots can be imitated by a mixture of *iso*amyl butyrate and *iso*amyl alcohol.

Dried apricots are prepared either by sun-drying or by artificial heat, sulphur dioxide being often employed in the latter case, in order to prevent darkening in colour. They are largely used in America and in some of the colonies. American analyses show them to contain about 32 p.c. of water, 63 p.c. of carbohydrates, 2·9 p.c. of nitrogenous matter, and 1·4 p.c. of ash.

H. I.

APRICOT, ESSENCE OF. A mixture of *iso*amyl butyrate and *iso*amyl alcohol.

APRICOT KERNEL OIL *v.* Apricot.

APYRON. Trade name for lithium acetylsalicylate.

AQUA FORTIS *v.* Nitric acid.

AQUA REGIA. *Nitromuriatic acid*; *Königswasser.* A name given by the alchemists to a mixture of nitric and hydrochloric acids, originally prepared by dissolving sal ammoniac in strong nitric acid, and used by them as a solvent for gold, sulphur, &c. Usually made by mixing 1 vol. of nitric acid with 4 vols. of hydrochloric acid. The mixture is at first colourless, but gradually—especially on heating—acquires a deep orange-yellow colour, due to the formation of nitrosyl chloride and free chlorine: $HNO_3+3HCl=NOCl+Cl_2+2H_2O$. The solvent action of aqua regia appears to be mainly due to the free chlorine.

AQUA VITAE. An alchemistic name used to denote common alcohol as obtained by distilling a liquid which has undergone vinous fermentation.

ARABIC GUM *v.* Gums.

ARABINOSE *v.* Carbohydrates.

ARACHIDIC ACID $CH_3(CH_2)_{18}COOH$ is found partly free and partly as a glyceride in earth-nut oil (from *Arachis hypogæa* (Linn.)); in butter, and in the fruit of *Nephelium lappaceum* (Heintz. Pogg. 90, 146; Grössmann, Annalen, 89, 1; Oudemans, Zeits. f. Chem. 1867, 256). It has been prepared by treating behenolic acid $C_{22}H_{40}O_2$ with fuming nitric acid (Grössmann, Ber. 1893, 644), and synthetically from aceto-acetic ester and octodecyl iodide (Schweizer. Arch. Pharm. 1884, 753): m.p. 77° (Baczewski, Monatsh. 17, 530). Solubility in 90 p.c. alcohol, 0·022 p.c. at 15°, and 0·045 p.c. at 20°.

The methyl ester melts at 54·5°, and the ethyl ester at 50°, and boils at 284°–286° under 100 m.m. pressure.

ARACHINE $C_5H_{14}ON_2$, an alkaloid occurring with choline and betaine in earth-nut (ground-nut, monkey-nut) meal (*Arachis hypogea* (Linn.)). Syrup; the aurichloride and platinichloride are crystalline. Produces somnolence in frogs and rabbits (Mooser, Landw. Versuch-Stat. 1904, 60, 321).

ARACHIS OIL is obtained from the seeds of *Arachis hypogæa* (Linn.), which are known in commerce as earth nuts, pea nuts, or monkey nuts. The cultivation of the arachis plant dates back so far in history that its origin is unknown. It is frequently assumed that the home of the arachis nut is Brazil. The plant is chiefly cultivated in the East Indies, Indo-China, Java, Japan, the West Coast of Africa, Mozambique, Madagascar, Egypt, Spain, Sicily, the United States of America, the Argentine, and in the West Indian Islands. The East Indian and West African nuts represent two distinct varieties. In commerce a distinction is made between decorticated and non-decorticated nuts. The Indian and Mozambique nuts are usually decorticated before they are shipped to Europe; as they undergo some detrimental changes on the voyage, they cannot be used for the production of best edible oil, and are mostly worked up for soap oil. The nuts coming from West Africa mostly arrive non-decorticated, and are therefore suitable for the preparation of best edible oil, the lower qualities only, derived from a second and third expression (*see* below) being used for technical purposes. The approximate composition of arachis nut, taking the average of nuts from various places of origin, is as follows: oil, 38–50 p.c.; water, 4·6–12·8 p.c.; albuminoids, 26–31 p.c.; carbohydrates, 5–19 p.c.; fibre, 1·1–4·1 p.c.; ash, 1·6–3 0 p.c.

The undecorticated nuts are shelled by special machinery and the inner red skin which surrounds the kernel is removed as completely as possible by a blast of air. The separated and cleaned kernels are then ground in the usual manner and subjected to hydraulic pressure. As the kernels contain so high a proportion of oil, the expression of the oil is carried out in two stages; frequently the meal is even expressed three times. The first expression takes place at the ordinary temperature, and yields the 'cold-drawn' oil; the second expression is carried out at a temperature of 30°–32°; and the third expression at 50°–55°.

The 'cold-drawn' oil is nearly colourless, and has a pleasant taste, recalling that of kidney beans; it is used as salad oil, and sold under the name 'huile surfine.' The oil obtained by the next expression also serves for edible purposes, in the sardine and margarine industries, or for burning; the lowest quality, which has been expressed at the highest temperature, is chiefly used for soap-making.

The arachis cakes serve as an excellent cattle food, for they contain the highest amount of proteins of all known oil cakes; moreover, these proteins are more easily digested than those of other cakes.

Their average composition is: water, 11·5;

fat, 8·8; cellulose, &c., 31·1; ash. 7·25; proteins, 41·35: nitrogen, 6·8 p.c. (Schädler).

On standing a few degrees above freezing-point, 'stearine' deposits from arachis oil. This stearine contains *arachin*, which does not settle out as a crystalline mass, so that it cannot be removed in the usual manner by expression. Hence it is necessary, in order to 'demargarinate' arachis oil, to allow it to stand for a prolonged time in the cold, when 'margarine d'arachide' settles out, so that the supernatant clear oil can be drawn off.

Amongst the solid fatty acids of arachis oil, arachidic acid and lignoceric acid have been identified. These two acids are characteristic of arachis oil, and as their proportion can be determined quantitatively, the separation and determination of 'crude arachidic acid' (*i.e.* a mixture of arachidic and lignoceric acids) furnishes an excellent means of identifying arachis oil, and estimating its proportion in mixtures with other oils. Amongst the liquid fatty acids of arachis oil, oleic acid undoubtedly predominates; in addition to it linolic acid has been identified, but the presence of hypogæic acid is doubtful, the only oxidation compound obtained from the liquid, fatty acids being a sativic acid (Klimont and Mayer, Monatsh. Chem. 1913, 34, 1195). Stearic acid does not appear to be present; the fatty acid, m p. 68°, separated by Hehner and Mitchell (Analyst, 1898, 21, 238), consisting of a mixture of lignoceric and arachidic acids (Klimont and Mayer, *l.c.*).

The sp.gr. of arachis oil is usually about 0·917–0·919 at 15°, but Sadtler (Amer. J. Pharm. 1897, 69, 490) obtained as low a value as 0·911 with oil from African nuts, whilst the oils from Indian nuts have given values of 0·9223 to 0·9256 (Crossley and Le Sueur, J. Soc. Chem. Ind., 1898, 17, 989). The usual limits for the iodine value lie between 87 and 100, but extremes of 84·4 (Schnell) and 105 (Oliveri) are on record. For its detection and estimation, *see* Evers, Analyst, 1912, 37, 487. As the iodine value of arachis oil lies so near that of olive oil, adulteration of olive oil with arachis oil takes place on the largest scale; indeed, very frequently arachis oil is entirely substituted for olive oil (as in the preparation of tinned sardines).

It is also a common adulterant of castor oil when used as a lubricant for aeroplane motors. Its presence may be detected by the turbidity temperature of an alcoholic solution of the oil, pure castor oil solutions remaining clear below −20°, whilst 1 p.c. of arachis oil causes the liquid to become turbid at a much higher temperature. Arachis oil itself is liable to be adulterated with sesame oil, which is added partly with the object of preventing solidification when the oil is exposed to a moderately low temperature. The addition may be detected by the Baudouin test (*see* Sesame Oil).

Arachis oil is chiefly expressed in the South of Europe (Marseilles and Trieste); therefore the lower qualities of this oil enter largely into the composition of the soaps of South Europe. Thus, one of the most characteristic component of the Marseilles white soap is arachis oil. The quantity of arachis nuts imported into France during the year 1907 was: arachis nuts in shells, 163,241 tons; decorticated arachis nuts, 117,404 tons. The total quantity of arachis nuts produced in the world may be taken to amount to about 350,000 tons. In 1910, 6,686,679 tons of oil seeds were imported into Marseilles, of which 34,800 tons were arachis nuts. Next to France, arachis nuts are largely imported into Trieste, Delft, and in smaller quantities to Germany (about 25,000 tons), and to the United States of America. The latter country produces about 50,000 tons per annum. The imports of arachis oil into Italy increased from 470 tons in 1908 to 5080 tons in 1910 (Molinari). J. L.

ARAGONITE. The orthorhombic form of calcium carbonate ($CaCO_3$), differing from the more common dimorphous form calcite (*q.v.*) in its greater density (sp.gr. 2·93), greater hardness (H. 3½), and in the absence of cleavage. It crystallises, together with calcite, from aqueous solutions containing carbon dioxide at temperatures above 18°, and the presence of various salts in the solution favours its growth. In nature it is deposited by thermal springs, for instance, those of Carlsbad in Bohemia, in the form of pea-like concretions, this variety of the mineral being known as *pisolite*. Another variety, called *flos-ferri* (flower of iron), is found as snow-white coralloidal forms in the iron mines of Styria. Crystals were first found embedded in red clay and gypsum in Aragon, Spain; and divergent groups of spear-like crystals have been found in an iron (hæmatite) mine in west Cumberland. Fine groups of twinned prismatic crystals are met with in the sulphur mines near Girgenti in Sicily, and in the copper mines at Herrengrund in Hungary. A variety containing about 5 p.c. of lead carbonate is called tarnowitzite from its occurrence at Tarnowitz in Silesia. L. J. S.

ARALIA BARK or *False Prickly Ash Bark*, the bark of *Aralia spinosa* (Linn.), contains a volatile oil, an amorphous bitter substance, (tannin), a grey acrid resin, and a glucoside to which the name *aralein* has been given (Lilly, Pharm. J. [3] 13, 305). By boiling aralein with dilute hydrochloric acid, *aralíretin* is obtained (Holden, Pharm. J. [3] 11, 210; Chem. Soc. Trans. 40, 105).

ARAROBA POWDER *v.* Chrysarobin.

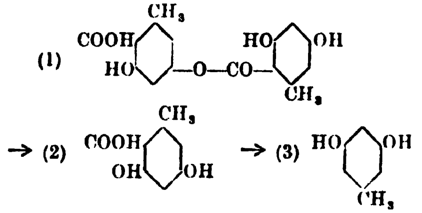
ARASINA GURGI. An impure gamboge from Camara, obtained probably from a species of Garcinia (Dymock, Pharm. J. [3] 7, 451).

ARBOL-A-BREA RESIN is obtained from *Canarium luzonicum* (Miq.), a tree belonging to the Burseraceæ, growing in the Philippines. The resin is greyish-yellow, soft, glutinous, and has a strong agreeable odour. It contains 61·29 parts of resin very soluble in alcohol; 25·00 parts of resin sparingly soluble in alcohol; 6·25 essential oil; 0·52 free acid; 0·52 bitter extractive matter; 6·42 woody and earthy impurities (Bonastre, Jour. Pharm. 10, 129). Baup has isolated four crystalline substances, *Amyrin*, *Breidin*, *Brein*, and *Bryoïdine* (Ann. Chim. Phys. [3] 31, 108).

ARBUTIN *v.* Glucosides.

ARCHIBROMIN. Trade name for monobromo*iso*valeryl glycolylurea.

ARCHIL or **ORCHIL** (*Orseille*, Fr.; *Orseille*, Ger.; *Oricello*, It.) appears in commerce in three forms: (1) as a pasty matter called *archil*; (2) as a mass of a drier character, named *persis*; and (3) as a reddish powder called *cudbear*. It is obtained from various lichens of the genus Roccella, growing on the rocky coasts of the Azores, the Canaries and Cape de Verd Isles, also of the Cape of Good Hope, Madeira, Corsica, Sardinia, &c., and from *Ochrolechia tartarea*, growing in Sweden and Norway. None of these lichens contains the colouring matters ready formed, but there are present certain colourless acids of the type of *lecanoric acid*, derivatives of orcin, into which they can be readily converted. Thus, lecanoric acid (1) gives first orsellinic acid (2) and subsequently orcin (3) according to the following scheme:—



Orcin itself, when acted upon by air and ammonia, changes into a purple substance called *orcein*, which is the name applied to the colouring matters of archil (Robiquet, Ann. Chim. Phys., [2] 47, 238).

Finely powdered orcin is placed in a thin layer under a bell jar, together with a beaker containing strong ammonia solution. As soon as the substance has become brown coloured, it is removed and exposed to air for some time. It is then dissolved in very dilute ammonia solution, reprecipitated with acetic acid, and dried. According to Gerhardt and Laurent, orcein has the composition $C_{14}H_7NO_6$ (Ann. Chim. Phys., [3] 24, 315), but more recent researches indicate that it is a mixture of substances. Liebermann, for instance (Ber. 7, 247; 8, 1649), considers that by this reaction three colouring matters are produced, having respectively the formulæ (*a*) $C_{14}H_{13}NO_4$; (*b*) $C_{14}H_{12}N_2O_3$; and (*c*) $C_{14}H_{12}N_2O_3$.

Zulkowski and Peters (Monatsh. 11, 227) allowed orcin to remain in contact with ammonia for two months, and from the product isolated three substances:—

(*a*) *Red orcein* $C_{28}H_{24}N_2O_7$, the main product, which appears to be formed according to the following equation:—

$$4C_7H_8O_2+2NH_3+6O=C_{28}H_{24}N_2O_7+7H_2O$$

It is a brown crystalline powder, soluble in alcohol with a red colour, and in alkaline solutions with a blue-violet tint.

(*b*) A crystalline yellow compound,

$$C_{21}H_{19}NO_5,$$

which is accounted for as follows:—

$$3C_7H_8O_2+NH_3+3O=C_{21}H_{19}NO_5+4H_2O$$

(*c*) An amorphous product similar to litmus.

These substances can be prepared much more rapidly by the addition of hydrogen peroxide to an ammoniacal solution of orcin.

There can be no doubt that this reaction proceeds in several stages, and that the character of the product varies according to the duration of the process. This is well known to manufacturers, who can prepare at will a blue or a red orchil. The constitution of these colouring matters has not yet been determined, but in view of the circumstances by which they are produced, it is most probable that they are members either of the *oxazine* or *oxazone* groups.

Orchil was originally prepared from the lichens by means of stale urine, which supplied the necessary ammonia, but ammonia solution is now exclusively employed. The older methods have, however, been greatly improved, and in the place of barrels the operation is carried out in large horizontal or vertical cylinders fitted with stirrers, and suitable openings for the admission of air.

In such an apparatus the weed is digested with about three times its weight of ammonia solution at 60° for from three days to one week, the admission of air being regulated according to the judgment of the manufacturer. The first product of the reaction has a blue colour, and if the process be stopped at this point, there is formed the dyeware known as *blue orchil*. On the other hand, if the action of the air and ammonia is allowed to proceed further, *red orchil* is obtained. These orchil pastes when dried and finely ground constitute the product known as *cudbear*.

Bedford (D. R. P. 57612, 1889) blows air or oxygen through the ammoniacal mixture, which, especially in the latter case, materially shortens the process. The apparatus employed is erected vertically, and by an ingenious arrangement of projecting shelves, the edges of which are turned down, a considerable quantity of the air or oxygen is entrapped, and exerts therefore a more powerful oxidising effect.

Orchil liquor is prepared by extracting the lichens with boiling water, concentrating the extract to from 8° to 10° Tw., and submitting this to the action of air and ammonia; whereas *orchil extract* is produced by the extraction of orchil paste itself.

In former times archil and cudbear were frequently adulterated with magenta, certain azo colours, extracts of logwood, brazilwood, &c.; but as the importance of these dyestuffs has now very greatly diminished, such a contamination is at the present time of rare occurrence.

Archil and its preparations are substantive colouring matters, which dye well in a neutral bath, but have the useful property of behaving nearly as well under slightly acid or slightly alkaline conditions. Even colours of considerable intensity are produced from it without difficulty, but unfortunately these are not fast to light. Wool is dyed in a neutral bath, or with addition of a trace of sulphuric acid, and silk is dyed in the presence of soap solution, acetic acid being sometimes added. Archil is not applied to cotton.

Archil was at one time employed to a large extent for 'bottoming' indigo, that is to say, the fabric was first dyed with archil and subsequently with indigo. The reverse process, known as 'topping,' has again been considerably in vogue. Cudbear and archil are also used to a limited extent in conjunction with other dyestuffs for the production of compound shades. White wines are sometimes coloured with archil, but its presence can be detected by precipitating with lead acetate and extracting with amyl alcohol, when a red colour indicates the presence of archil or magenta. The addition of a little hydrochloric acid changes the colour to yellow if magenta be present, but does not alter it if archil is the adulterant (Haas, Zeitsch. anal. Chem. 20, 869; J. Soc. Chem. Ind. 1, 119).

A. G. P.

ARCHIL REDS *v.* AZO- COLOURING MATTERS.

ARCHIL SUBSTITUTES *v.* AZO- COLOURING MATTERS.

ARCHIODIN. Trade name for monoiodo-*iso*valerylglycolylurea.

ARDENNITE. A mineral consisting of vanadio-silicate of aluminium and manganese, $H_{10}Mn_8Al_8V_2Si_9O_{46}$ or $H_{10}Mn_{10}Al_{10}V_2Si_{10}O_{55}$, containing 0·53-9·20 p.c. V_2O_5. The vanadium is partly replaced by arsenic (up to 9·33 p.c. As_2O_5), and in these varieties the colour is paler. It has as yet been found only at Salm-Châteaux, near Ottrez, in the Belgian Ardennes, where it occurs embedded in quartz veins in phyllites or slaty schists. It forms yellow to brown aggregates of bladed or columnar crystals; these are orthorhombic with a perfect cleavage parallel to the brachypinacoid, and good cleavages parallel to the unit prism. Sp.gr. 3·58-3·66; hardness, 6-7. It is readily fusible with intumescence before the blowpipe to a black glass; and is not attacked by hydrochloric and nitric acids, though slightly by sulphuric acid.

L. J. S.

ARECA NUT, *Betel nut,* is the seed of the areca palm, *Areca Catechu*, Linn., a native of the Sunda Islands, cultivated in tropical India and the Philippines. It is often chewed in the Far East together with lime and the leaves of betel pepper, and is also used as a vermifuge. In America and Europe it is used in veterinary practice, against tape worm. Arecoline hydrobromide, m.p. 170°, is employed for this purpose, and is official in the German Pharmacopœia. The nuts contain six alkaloids, all more or less closely related: *Arecoline*, $C_8H_{13}O_2N$, the principal alkaloid (0·1 p.c.) is a strongly alkaline liquid, b.p. 220°, and highly toxic (Meier, Biochem. Zeit. 1907, 2, 415). It is the methyl ester of *Arecaidine* $C_7H_{11}O_2N,H_2O$, m.p. 222°–223°, which is non-toxic and identical with Δ^3-tetrahydronicotinic acid

$$CH_2{<}\begin{matrix}CH_2\text{—}CH\\N{\cdot}Me\text{—}CH_2\end{matrix}{>}C{\cdot}COOH$$

synthesised by Wohl and Johnson (Ber. 1907, 40, 4721). *Guvacine* $C_6H_9O_2N$, m.p. 271–272°, is a lower homologue in which the N-methyl is replaced by hydrogen, is a tetrahydro*iso*nicotinic acid (probably Δ^3)

$$NH{<}\begin{matrix}CH_2{\cdot}CH\\CH_2{\cdot}CH_2\end{matrix}{>}C{\cdot}COOH$$

arecaine, m.p. 231°, is N-methyl guvacine, and hence the last two are both crystalline solids of neutral reaction. *Guvacoline* is guvacine methyl ether, b.p. 114°/13 mm., and an alkaline liquid which crystallises. For the constitution of these alkaloids, mostly discovered by Jahns (Ber. 1888, 21, 3404), for the properties of their salts and for earlier references, see Freudenberg (Ber. 1918, 51, 1668), who thinks that perhaps only arecoline and guvacoline occur as such in the nuts, and shows that arecaine of Jahns is identical with arecaidine. *Arecolidine*, $C_8H_{13}O_2N$, m.p. 110°, isomeric with arecoline, occurs in minute quantity in the mother liquors of technical arecoline hydrobromide, and is probably 3:4-dimethoxy 1-methyl, 1:2-dihydropyridine (Emde, Apoth. Zeit. 1915, 30 240).

G. B.

ARECAIINE, ARECADINE, ARECOLIDINE, ARECOLINE *v.* ARECA NUT.

AREOMETER *v.* HYDROMETER.

ARGAL *v.* ARGOL.

ARGALDIN. A combination of albumin-silver and hexamethylenetetramine.

ARGAN OIL. An oil obtained from the kernels of *Argania Sideroxylon* (Roem. et Schult) (ord. *Sapotaceæ*), growing in Morocco. The kernels are first roasted, ground to powder and mixed with water, when the oil separates (Pharm. J. [3] 10, 127).

ARGENTAMIN. Trade name for ethylene-diamine silver nitrate.

ARGENTAN *v.* ALUMINIUM and NICKEL.

ARGENTINE. A name given by R. Kirwan in 1794 to a variety of calcite ($CaCO_3$) occurring as small scales with a pearly white or silvery lustre.

ARGENTINE. Finely divided spongy tin, made by reducing a weak solution of tin salt (120 grams in 60 litres of water) by zinc. The tin is collected in a sieve, washed with water, and dried at a gentle heat. Used for tin-plating and also for printing upon fabrics and paper (Deut. Ind. Zeit. 23, 255; J. Soc. Chem. Ind. 7, 504).

ARGENTITE. A mineral consisting of silver sulphide Ag_2S, and occurring as cubic crystals or as compact masses. It is blackish lead-grey in colour, and perfectly sectile; surfaces cut with a knife are bright and shining. Sp.gr. 7·3. Containing 87·1 p.c. of silver, it is a valuable ore of the metal when met with in quantity, as in the Comstock lode in Nevada and in Mexico.

L. J. S.

ARGENTOL. A synthetic antiseptic, consisting of a compound of silver with quinosol, of the formula $C_9H_5N(OH)SO_3{\cdot}Ag$. Forms a yellowish powder, of a faint smell, sparingly soluble in water and alcohol (Pharm. Zeit. 1897, 42, 243).

ARGENTORAT. Trade name for a flash-powder consisting of a mixture of potassium perchlorate and aluminium, used in photography: gives very little smoke (*v.* FLASH-POWDERS).

ARGINASE. An enzyme occurring in the liver, also present in the kidney, the intestinal mucous membrane, thymus, and other organs (Kossel and Dakin, Zeitsch. physiol. Chem.

1904, 41, 321). Clementi (Atti. R. Accad. Lincei, 1914, [v.] 23, ii. 612, and *ibid.* 1916, 25, 1, 366) finds it in the kidney of mammals and in the liver of mammals, amphibia and fishes, but not in that of birds or reptiles; *see* also Edlbacher (Zeitsch. physiol. Chem. 1915, 95, 81–87; *ibid.* 1917, 100, 111); Shiga found it (Zeitsch. physiol. Chem. 1904, 42, 502) among the enzymes obtained from yeast. It is also found in various plants (Kizel, Bull. Acad. Sci. Petrograd, 1915, 1337–64). It can be extracted from the liver by water or dilute acetic acid, and is precipitated from solution by alcohol, ether, or ammonium sulphate. Arginase is a specific enzyme for the exclusive hydrolysis of *d*-arginine or of substances containing the *d*-arginine grouping, which it converts almost quantitatively into carbamide and *d*-ornithine. For the detection of arginase, *v.* Clementi (Atti R. Accad. Lincei, 1917, [v.] 26, i. 261). Creatine and other guanidine derivatives structurally similar to arginine, or guanidine itself, are incapable of hydrolysis by this enzyme (Dakin, J. Biol. Chem. 1907, 3, 435; and Clementi (Atti R. Accad. Lincei, 1915, [v.] 24, i. 483–489).

The action of arginase on arginine may be followed by titration of the arginine solution (in presence of formaldehyde) with N/5 sodium hydroxide solution, Clementi (Atti R. Accad. Lincei, 1914, [v.] 23, ii. 517–523); *see* also Sörensen (Biochem. Zeitsch. 1907, 7, 45–101).

M. A. W.

ARGININE $C_6H_{14}O_2N_4$, *a-amino-δ-guanino-n-valeric acid* $NH:C(NH_2)\cdot NH\cdot(CH_2)_3\cdot CH(NH_2)\cdot CO_2H$, first isolated by Schulze and Steiger (Ber. 1886, 19, 1177) from the etiolated germinated cotyledons of *Lupinus*, is the most widely distributed dissociation product of proteid matter, and can be obtained by hydrolysis of the proteid matter of seeds of *Lupinus luteus*, *Cucurbita pepo*, *Picea excelsa*, to the extent of 10 p.c., *Abies pectinata*, *Pinus sylvestris*, and other conifers (Schulze, Ber. 1891, 24, 276; Zeitsch. physiol. Chem. 1896, 22, 411, 435; 1897, 24, 276). According to Suzuki (Chem. Zeit. 1899, 23, 658) the arginine obtained from the seeds of conifers exists already formed, but in loose combination with the proteid material, and is also produced synthetically in the plant from ammonium salts and nitrates, either in full or diffused daylight (Bull. Coll. Agr. Tokyo Imp. Univ. 1900, 4, 25). It is found in a number of plants, generally in company with asparigine, less often with glutamine, and also when neither is present (Stieger, Zeitsch. physiol. Chem. 1913, 86, 268; Schulze, *l.c.* 81, 53). It is found in soil (Schreiner and Shorey, J. Biol. Chem. 1910, 8, 381; Schreiner, Lathrop, J. Amer. Chem. Soc. 34, 1242), and in the blood under normal conditions (Abderhalden, Zeitsch. physiol. Chem. 1913, 88, 478). For presence of arginine in hops, *see* Chapman (Chem. Soc. Trans. 1914, 105, 1899). According to Skinner (Bied. Zentr. 1913, 42, 213, from Proc. 8th Internat. Congress Applied Chem. 1912) it is produced in soil as a primary cleavage product of proteids and can take the place of nitrate in the soil. Arginine is also one of the constituents of the product of hydrolysis of proteids of animal origin, thus, horn yields 2·25 p.c.; glue, 2·60 p.c.; conglutin, 2·75 p.c.; albumen from yolk of egg, 2·3 p.c.; from white of egg, 0·8 p.c.; blood serum, 0·7 p.c.; and casein, 0·25 p.c. (Hedin, Zeitsch. physiol. Chem. 1894, 20, 186), whilst the protamines *Salmine*, *Sturine*, *Clupeine*, *Scombrine*, *Cyclopterine*, and *Crenilabrine* yield arginine as the chief product of hydrolysis (Kossel, Zeitsch. physiol. Chem. 1896, 22, 176; 1898, 25, 165; 1899, 26, 588; 1904, 40, 565; 1910, 69, 138). In cases of phosphorus-poisoning arginine is found in the urine (Wohlgemuth, Zeitsch. physiol. Chem. 1905, 44, 74), whilst the amount obtained from the liver is diminished (Wakeman, Zeitsch. physiol. Chem. 1908, 44, 335).

The cleavage of arginine in plants and animals due to enzyme action is identical with that which occurs in putrefactive processes: ornithine and carbamide are produced (Kossel and Dakin, Zeitsch. physiol. Chem. 1904, 41, 321; 1904, 42, 181; Ackermann, *ibid.* 1908, 56, 305; Kiesel, *ibid.* 1912, 75, 170, 196.)

When arginine is heated with barium hydroxide it is decomposed into ammonia, carbamide, and ornithine (*q.v.*) (*aδ-diaminovaleric acid*); cyanamide reacts with ornithine at the ordinary temperature to form arginine (Schulze and Winterstein, Zeitsch. physiol. Chem. 1898, 26, 1; Ber. 1899, 32, 3191), or with *a*-benzoylornithine to form the benzoyl derivative of arginine, and this is readily hydrolysed to arginine, which is thus proved to be *a-amino-δ-guanino-n-valeric acid* (Sörensen, Ber. 1910, 43, 643; *see* also Zeitsch. physiol. Chem. 1911–12, 76, 94).

Arginine yields a copper compound

$$Cu(C_6H_{14}O_2N_4)_2$$

Kober and Sugiura (J. Biol. Chem. 1912–13, 13, 5).

Arginine crystallises in brilliant monoclinic plates (Haushofer, Zeitsch. physiol. Chem. 1887, 11, 53); m.p. 207°–207·5° (Gulewitz, Zeitsch. physiol. Chem. 1899, 27, 178); it also crystallises with $1H_2O$ in rhombohedra (Hedin, Zeitsch. physiol. Chem. 1895, 21, 160); it dissolves readily in water, and is sparingly soluble in alcohol. Arginine contains an asymmetric carbon atom, and the dextrorotatory form is the natural product, the hydrochloride has $[a]_D + 12·5°$ in aqueous or $+25·5°$ in hydrochloric acid solution. Arginine is strongly alkaline, and its solution absorbs carbon dioxide from the air; it forms well-defined crystalline salts with acids, and compounds with certain metallic salts (Gulewitz, *l.c.*). The *nitrate* $C_6H_{14}O_2N_4,HNO_3,\frac{1}{2}H_2O$ has m.p. 126°; the *dinitrate* $C_6H_{14}O_2N_4,2HNO_3$ has m.p. 151°; the *hydrochloride* $C_6H_{14}O_2N_4,HCl,H_2O$ melts and decomposes at 209° when anhydrous; the *dl*-aurichloride $C_6H_{14}O_2N_4,2HCl,AuCl_3,\frac{1}{2}H_2O$ has m.p. 105°–115°; the *d*-arginine aurichloride $C_6H_{14}O_2N_4,2HAuCl_4,1\frac{1}{2}H_2O$ softens at 140° and melts at 160° (Weiss, Zeitsch. physiol. Chem. 1911, 72, 490); the *silver nitrate compounds* $C_6H_{14}O_2N_4,AgNO_3,\frac{1}{2}H_2O$ decomposes at 164°, and $C_6H_{14}O_2N_4,AgNO_3,HNO_3$ melts and decomposes at 180°; the *cupric nitrate compound* $2C_6H_{14}O_2N_4,Cu(NO_3)_2,3H_2O$ melts at 112°–114° or decomposes at 232°–234° when anhydrous; the *copper sulphate compound* melts at 110° or decomposes when anhydrous at 235°–238°; the *picrate* $C_6H_{14}O_2N_4$, $C_6H_3O_7N_3,2H_2O$, m.p. 205°, dissolves in 204·1 parts of water at 16°; the *picrolonate* $C_6H_{14}O_2N_4$, $C_{10}H_8O_5N_4,H_2O$, m.p. 231°, dissolves in 1124 parts of water, or 2885 parts of alcohol at the ordinary temperature (Schulze and Steiger, Ber. 1886, 19, 1177; Hedin, Zeitsch. physiol. Chem. 1894, 20, 186; Gulewitz, *ibid.* 1899, 27, 178; Steudel, *ibid.* 1903, 37, 219; Reisser, *ibid.* 1906, 49, 210). The aurichloride of a tetramethyl arginine

$$C_{10}H_{24}O_2N_4Au_2Cl_8$$

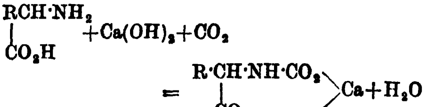
prepared by Engeland and Kutscher (Zeitsch. Biol. 1912, 59, 415) crystallises in short needles which melt 173°–175° to a clear fluid. Three methyl groups are in the side chain and one in the guanidine complex.

Certain acyl derivatives and esters of arginine have also been prepared, the *dibenzoyl derivative* $C_6H_{12}O_2N_4Bz_2$ crystallises in rhombic needles or prisms, m.p. 217·5°–218° (Gulewitz, *l.c.*), the *β-naphthalenesulphonic derivative* $C_6H_{13}O_2N_4\cdot SO_2\cdot C_{10}H_7$ is a colourless powder, m.p. 88°–89° (Reisser, *l.c.*); *diarginylarginine* is isolated as the *dipicrate* $C_{14}H_{38}O_4N_{12}(C_6H_3O_7N_3)_2,2H_2O$, m.p. 207°, from the product obtained by hydrolysing pepsin extract with hydrogen fluoride; *arginylarginine picrate* $C_{12}H_{26}O_3N_8,C_6H_3O_7N_3,2H_2O$, m.p. 213°, is similarly obtained from gelatin (Hugouenq and Morel, Compt. rend. 1909, 148, 236); *arginine methyl ester hydrochloride* has m.p. 195° (corr.) with decomposition, the *picrate* forms lemon-yellow crystals, which melt and decompose at 218° (corr.); and the *nitrate* melts at 189° (corr.) (Fischer and Suzuki, Sitzungber. K. Akad. Wiss. Berlin, 1904, 1333).

The presence of arginine assists the tryptic digestion of proteid matter and aids the emulsification of fats: this appears to be connected with its alkalinity, as sodium carbonate acts similarly (Lawroff, Zeitsch. physiol. Chem. 1899, 28, 303) When arginine (hydrochloride or carbonate) is administered as a food, it suffers complete decomposition, and 37–77 p.c. of the nitrogen so given reappears as urea (Thompson, Zeitsch. physiol. Chem. 1905, 33, 106), and the amount of arginine in the various organs shows no increase (Orglmeister, Beitr. Chem. Physiol. Path. 1905, 7, 27). Intravenous injection of arginine increases the creatine content of muscle (Thompson, Proc. Physiol. Soc. ii.–iii.; J. Physiol. 1917, 51; Jansen, Arch. Néerland. Physiol. 1, 618). Ackroyd and Hopkins (Bio-Chem. J. 1916, 10, 551–576) suggest that arginine plays a special part in purine metabolism in the animal body. Ringer, Frankel, Jonas (Bio-Chem. J. 1913, 14, 525–538), suggest that succinic acid is an intermediate compound in the katabolism of arginine.

Arginine gives the diacetyl reaction for proteids (Harden and Norris, J. Physiol. 1911, 42, 333).

Arginine is readily oxidised by hot calcium or barium permanganate yielding guanidine, γ-guaninobutyric acid and succinic acid (Bénech, Kutscher, Zeitsch. physiol. Chem. 1901, 32, 278, 413, and the estimation of the number of arginine groups in proteids is based on this reaction (Orglmeister, *l.c.*; Kutscher and Zickgraf, Sitzungsber. K. Akad. Wiss. Berlin, 1903, 28, 624), the guanidine thus obtained being isolated in the form of its sparingly soluble picrate, and either weighed as such, or the nitrogen estimated in the usual way. Another method of isolating and estimating arginine is based on Siegfried's carbamino-reaction of amino- acids (Zeitsch. physiol. Chem. 1905, 44, 85; 46, 402; 1907, 50, 171; Ber. 1906, 39, 397), whereby the barium, strontium, or calcium salt of the corresponding carbamic acid is formed when carbon dioxide is passed into a solution of the amino- acid containing excess of alkali earth hydroxide until the solution is neutral to phenolphthaleïn—



$$\begin{array}{l}\mathrm{RCH\cdot NH_2}\\ \ |\qquad\qquad +\mathrm{Ca(OH)_2}+\mathrm{CO_2}\\ \mathrm{CO_2H}\end{array} = \begin{array}{l}\mathrm{R\cdot CH\cdot NH\cdot CO_2}\\ \quad\ |\\ \quad\mathrm{CO_2}\end{array}\!\!>\mathrm{Ca}+\mathrm{H_2O}$$

The barium and strontium salts of these complex carbamic acids are much less readily soluble than the corresponding amino-acid, and afford a means of isolating the compounds (D. R. P. 188005, 1906). In order to estimate the amino- acid, the filtrate containing the calcium salt of the carbamic acid is decomposed by heating with boiled-out water into calcium carbonate, and the amino acid; the ratio $CO_2:N$ is determined by weighing the calcium carbonate thus precipitated, and estimating the nitrogen in the filtrate by Kjeldahl's method (Zeitsch. physiol. Chem. 1908, 54, 423).

Van Slyke (J. Biol. Chem. 1911, 10, 25) precipitates the arginine with phosphotungstic acid, decomposes the precipitate with barium chloride, and boils the filtrate gently with 50 p.c. potassium hydroxide for six hours; basing his estimation of arginine on the fact that it loses half of its nitrogen, in the form of ammonia, when boiled with dilute alkali.

Plimmer (Bio-Chem. J. 1916, 10, 115–119) decomposes the arginine with 20 p.c. alkali.

Wechsler (Zeitsch, physiol. Chem. 1911, 73, 138–43) dissolves the dried phosphotungstate precipitate in a mixture of acetone and water, and then decomposes it with barium hydroxide.

For the quantitative estimation of arginine, in proteins, Jansen (Chem. Weekblad, 1917, 14, 125) uses arginase to decompose the arginine and the urea thus produced is converted into ammonium carbonate by urease.

dl-Arginine is readily produced by the tryptic fermentation of fibrin, or by heating *d*-arginine nitrate at 210°–220° for 15–20 minutes (Kutscher, Zeitsch. physiol. Chem. 1901, 32, 476) or by heating *d*-arginine in 50 p.c. sulphuric acid in sealed tubes at 160°–180° for 33 hours (Reisser, Zeitsch. physiol. Chem. 1906, 49, 210); it decomposes at 210° (Cathcart, Proc. Physiol. Soc. 1905, 39); the *nitrate* $C_6H_{14}O_2N_4,HNO_3$, has m.p. 216°; the *dinitrate* $C_6H_{14}O_2N_4,2HNO_3$, m.p. 151°; the *cupric nitrate derivative* $2C_6H_{14}O_2N_4,Cu(NO_3)_2,3H_2O$, m.p. 228°–229°; the *silver nitrate derivative* $(C_6H_{14}O_2N_4,HNO_3)_2,AgNO_3$, m.p. 170°–172°; the *picrate* $C_6H_{14}O_2N_4,C_6H_3O_7N_3$, m.p. 200°–201°, is sparingly soluble

100 parts of water at 16° dissolve 0·22 part; the *picrolonate* $C_6H_{14}O_2N_4,C_{10}H_8O_5N_4$, m.p. 248°, 100 c.c. of water at 16° dissolve 0·03 grams of salt; the *β-naphthalene sulphonate* $C_6H_{12}O_2N_4\cdot SO_3\cdot C_{10}H_7,\frac{1}{2}H_2O$ has m.p. 85°–90° (Reisser, *l.c.*).

l-Arginine is formed by treating *dl*-arginine carbonate with the expressed juice of calf's liver, the ferment *arginase* present in the extract destroys the *d*-arginine, and does not attack the lævo- isomeride. With the exception of the difference in optical activity, the salts of *l*-arginine are identical with those of the dextro-isomeride, *l-arginine hydrochloride* has $[\alpha]_D^{20^\circ}$ −20·51° (Reisser, *l.c.*). M. A. W.

ARGININE. This name has also been given to an alkaloid discovered by Quiroga (J. Pharm. Chim. 1896, 16, 293) in a species of laurel (known by the natives as *viraro-mi*), growing in the east of the Argentine and west of Brazil. It forms prismatic crystals, soluble in chloroform or benzene, slightly soluble in ether, petroleum spirit, or water. Its aqueous solutions, acidified with hydrochloric acid, give a white ppt. with bromine water and a white ppt. with alkali soluble in excess. The bark and cambium contain 1·5–1·6 p.c., the wood 0·04–0·05 p.c. of the alkaloid. H. I.

ARGOFERMENT. A trade name for a form of colloidal silver.

ARGOL or ARGAL. (*Tartre brut*, Fr.; *Weinstein*, Ger.) Crude potassium bitartrate, known as red argol (*Cremore di Vinaccia*), or white argol (*Cremore di St. Artimo*), according to whether it is deposited from the red or the white grape (*v.* TARTARIC ACID).

ARGON. Sym. A or Ar. At. wt. and molec. wt. 39·88. As long ago as 1785, Cavendish (Phil. Trans. 75, 372) made experiments in order to determine whether the inert residue left after withdrawing oxygen, water, and carbon dioxide from air was homogeneous. He sparked a mixture of air and oxygen in presence of potash for the absorption of the acid produced, and removed the excess of oxygen by a solution of liver of sulphur. Only a small bubble of gas remained unabsorbed, and this did not diminish in volume on further sparking with oxygen. Cavendish concluded 'that if there is any part of the' nitrogen 'of our atmosphere which differs from the rest, and cannot be reduced to nitrous acid, we may safely conclude that it is not more than $\frac{1}{120}$ part of the whole.'

Cavendish's work was overlooked for more than a century, and attention was only directed to it after the discovery, in 1894, by Lord Rayleigh (Roy. Soc. Proc. 55, 340), that the density of 'atmospheric nitrogen' was one-half per cent. higher than that of nitrogen prepared by chemical means. This result gave fresh indication of the existence of some hitherto undiscovered gas in the atmosphere, and further investigations, carried out jointly by Rayleigh and Ramsay (Phil. Trans. 186, 187), led to the isolation of a new gaseous element. The gas, which has a density of approximately 20, and which constitutes nearly 1 p.c. by volume of the atmosphere, was called *argon*, owing to its remarkable chemical inertness, in virtue of which it can be readily separated from the accom-

Argon occurs in the atmosphere to the extent of 1·3 p.c. by weight (Leduc, Compt. rend. 123, 805) and 0·933 p.c. by volume (Schloesing, Compt. rend. 121, 604; Moissan, Compt. rend. 137, 600). It also occurs in a large number of mineral waters and thermal springs (Bouchard, Compt. rend. 121, 392; Troost and Ouvrard, *ibid.* 121, 798; Moissan, *ibid.* 135, 1278; Moureu, *ibid.* 135, 1335; 142, 1155), and in the volcanic gases of Mt. Pelée (Moissan, Compt. rend. 135, 1085); it is found, moreover, in fire damp and in coal (Schloesing, Compt. rend. 123, 233). Argon has also been observed, together with helium, in the gas evolved on heating numerous minerals.

Preparation.—(i.) *By sparking air with oxygen*, the method originally employed by Cavendish (*v. supra*). The gas is preferably confined over mercury, and a small quantity of potash introduced through a curved pipette. The sparks are passed between the ends of stout platinum wires, fused through the ends of U-shaped glass tubes. These tubes are filled with mercury, and serve to establish electrical connection with the secondary terminals of a Ruhmkorff coil capable of giving a 6-inch spark through air when worked by four lead accumulators. The sparking is usually continued for several hours after contraction has ceased; the excess of oxygen is then absorbed by phosphorus (Rayleigh and Ramsay, *l.c.*; Rayleigh, Chem. Soc. Proc. 13, 181; Becker, Z. Elek. 9, 600). To save time, it is customary to prepare by method (ii.) a gas consisting mainly of argon, and to employ the method of sparking only to remove the last traces of active gases.

(ii.) *From 'atmospheric nitrogen,' the nitrogen being absorbed by a metal.* In their original investigation, Rayleigh and Ramsay separated argon from nitrogen by continuously circulating the mixture over red-hot magnesium shavings, whereby the nitrogen was absorbed, forming magnesium nitride (*cf.* Ramsay and Travers, Roy. Soc. Proc. 64, 183). This method is no longer used; a dry mixture of pure lime (5 parts) and magnesium dust (3 parts), introduced by Maquenne, is employed instead, which, when heated to redness, produces metallic calcium and absorbs nitrogen with great rapidity. By passing atmospheric nitrogen over this red-hot mixture, and leading the residual gas over metallic calcium heated to dull redness, complete absorption of the nitrogen is readily effected (Moissan and Rigaut, Compt. rend. 137, 773). Metallic lithium has also been employed for the same purpose (Guntz, Compt. rend. 120, 777; 123, 995).

(iii.) The readiest means of preparing argon in quantity consists in leading air slowly over a mixture of calcium carbide (90 p.c.) and calcium chloride (10 p.c.) heated to 800°, the mixture having previously been heated under diminished pressure to drive off any volatile matter. Both oxygen and nitrogen are absorbed by the mixture. The issuing gas is led over hot copper oxide to burn any hydrogen, hydrocarbons, and carbon monoxide present, and the water vapour and carbon dioxide removed. Using 7 kilos. of carbide, 11 litres of argon may

Ber. 41, 2017). The cyanamide process is used in America as a means of producing argon in quantity. Nitrogen obtained from the air by the copper process is repeatedly passed through the cyanamide furnaces until concentrated argon remains. It is employed in the electric lamp industry, *cf.* Bodenstein and Wachenheim, (Ber. 1918, 51, 265).

The gas prepared by the above methods contains traces of the other inert gases *neon*, *krypton*, and *xenon*, from which it is separated by fractional condensation and evaporation (Ramsay and Travers, Roy. Soc. Proc. 67, 329; Liveing and Dewar, Roy. Soc. Proc. 68, 389). The total quantity of these gases present is, however, only 0·25 p.c., and 85 p.c. of this impurity is neon.

The commercial oxygen made from liquid air contains about 3 p.c. of argon (Claude; Morey). The liquid mixture is then distilled; the oxygen condenses and the argon passes on. There is obtained a gaseous mixture containing 75–80 p.c. of argon and 1–2 p.c. of nitrogen; the remainder being oxygen, which may be removed by combustion with hydrogen.

Argon may be obtained by passing cooled compressed air downwards through a rectifying column and bath of boiling oxygen at the base. The liquid air flows over to the higher part of the column, the interior of which consists of an inner chamber with draw-off cocks at different levels. In this the mixture is separated into purer oxygen, and a rich argon mixture, which can be used for electric lamps (Eng. Pat. 101860, 1916). Fonda and General Electric Co. (U.S. Pat 1211125, 1917) produce a liquid with 94 p.c. oxygen and 4 p.c. argon, and fractionate it on the counter-current principle in such a manner that argon is removed at the top and oxygen at the bottom of the apparatus (Reports of the Progress of Appl. Chem. 1917, 11, 201).

Argon is a colourless gas, condensing to a colourless liquid, boiling at 86·9° abs. (–186 1°–186·9°/760 mm.) (F. Fischer and Froboese, Ber. 1911, 44, 92), at which temperature its density is 1·4046 (Baly. and Donnan, Chem. Soc. Trans. 81, 914). A normal litre weighs 1·78376 at 0°, and 760 mm. (Schultze, Ann. Physik. 1915 [iv.], 48, 269), coefficient of dilatation $\beta=3669\cdot10^{6}$ (8°–32°). Its m.p. is 83·4° abs. (–189·6°), its critical temperature is 155·6° abs. (–117·4°–122·44°) (Crommelin), and its critical pressure is 52·9 atmos. (Ramsay and Travers, Roy. Soc. Proc. 67, 329).

The vapour pressures of liquid argon are represented by the formula $\log p=4\cdot85033-634\cdot391T+30769\cdot09T^{2}-1076464T^{3}$. For solid argon the observations are best expressed by the formula $\log p=A/T+BT+D\log T+C$ in which $A=+9034\cdot32$, $B=-1\cdot42112$, $C=-1014\cdot0278$, and $D=+533\cdot0275$. The molecular latent heat increases from 12·92 at –125·49° to 24 01° at –140·80°, and 35·00 (cal.) at –183·06° (Crommelin, Proc. K. Akad. Wetensch. Amsterdam, 1913, 16, 477; 1914, 17, 275).

Argon is more soluble in water than nitrogen, the absorption coefficient being 0·02561, at 1°, and falling regularly to 0·02567 at 50° (Estreicher, Zeitsch. phys. Chem. 31, 176); these figures may, however, be in error by 5 p.c. (*v.* Fox, Chem. News, 99, 250). The refractive index of the gas for sodium light at N.T.P. is 1·0002837 (Burton, Roy. Soc. Proc. 1908, 80, 390); its thermal conductivity is 0·00003894 (Schwaize, Pogg. Ann. 11, (iv.) 303); and its molecular specific heat at constant volume is 2·977 cals. (Pier, Z. Elek. 15, 536; Heuse Ann. de Physik, 1919, 59, 86). Its coefficient of expansion is 0·003668 (Kuenen and Randall, Roy, Soc. Proc. 59, 60). Argon passes through rubber more quickly than nitrogen (Rayleigh, Phil. Mag. 49, (v.) 220) or carbon dioxide (Kistiakowski, J. Russ. Chem. Soc. 30, 576), and does not pass through heated platinum or palladium; it is diamagnetic (Tanzler, Pogg. Ann. 24, (iv.) 931). (For its rate of effusion, *v.* Donnan (Phil. Mag. 49, (v.) 423).)

The density of argon has been determined by several observers, with the following results: (O=16); 19·940 (Rayleigh, Roy. Soc. Proc. 59, 201), 19·941 (Ramsay, Phil Trans. 186, 238); 19·945 (Fischer and Hahnel, Ber. 43, 1435). Argon is a member of the group of inert gases, and up to the present all attempts to combine it with other elements have failed (Rayleigh and Ramsay, *l.c.*; but *cf.* Cooke, Zeitsch. physikal. Chem. 55, 537).

Atomic and molecular weight. The molecular weight, 39·88, follows from the density determinations just cited; but the atomic weight cannot be determined in the usual manner, since argon forms no compounds with other elements. The ratio of the specific heat at constant pressure to the specific heat at constant volume is 1·644 (Rayleigh and Ramsay, *l.c.*), and this result, from analogy with the case of mercury vapour and by comparison with the ratio 1·666 theoretically required for a monatomic gas according to the kinetic theory, is regarded as proof that argon is monatomic. Its atomic weight is therefore 39·88, 39·91±0 01 (Leduc, Ann. Phys. 1918, [ix.] 9, 5), coefficient of departure from Boyle's Law 10·2, 10^{-6} between 1 and 5 atmos. mol. vol. 0·999 at 0° and 760 mm.

Spectrum. This is extremely characteristic, and has been carefully examined by Crookes (Phil. Trans. 186, 243), Kayser (Chem. News, 72, 99), Eder and Valenta (Monatsh. 16, 893; 17, 50), and by Trowbridge and Richards (Phil, Mag. 43, (5) 77; Stahl (Zeitsch. wiss. Photochem. 1911, 9, 302); Stead (Proc. Camb. Phil. Soc. 1912, 16, 607). The most prominent lines are two in the red, having wave lengths of 6965·6 and 7056 4, a yellow line (6038·4), two green lines (5610 and 4702), and a violet line (4200).

ARGONIN. Silver casein.

ARGULAN. Trade name for the mercury compound of dimethylphenylpyrazolene sulphamine.

ARGYRODITE. A sulpho-germaniate of silver, being the mineral in which the element *germanium* was discovered in 1886. It had, however, been mentioned by A. Breithaupt in 1823, under the name *Plusinglanz.* These occurrences in the Himmelsfürst silver-mine at Freiberg, Saxony, show only botryoidal crusts with a minutely crystallised surface. Later, the mineral was found as distinct, though small, cubic crystals in Bolivia, analysis of which proved the formula to be Ag_8GeS_6 (S. L. Penfield, 1893 and 1894). More recently, cubic crystals of larger size (3–5 cm. across; sp.gr. 6·235) from Colquechaca, Bolivia, have been described and analysed (V. M. Goldschmidt, 1908). At this locality the mineral appears to be not uncommon, and no doubt large quantities of it have been smelted for silver. In external appearance it is not unlike argentite, but is less sectile than this.

In the Bolivian mineral the germanium may be replaced isomorphously by tin, giving the species *canfieldite* Ag_8SnS_6 (Penfield, 1894). Intermediate members of this series, or stanniferous argyrodite, also occur (Prior and Spencer, 1898). L. J. S.

ARGYROL. Syn. for silver-vitellin.

ARHEOL. Trade name for santabol.

ARHOIN. Trade name for an addition product of diphenylamine and ethylthymylbenzoate.

ARIBINE $C_{23}H_{20}N_4,8H_2O$, m.p. 229° (anhydr.) is a crystalline diacid ditertiary alkaloid from the bark of *Arariba rubra*, a Brazilian tree. The bark is used for dying wool red (Reith and Wohler, Annalen, 1861, 120, 274). Aribine is one of the very few solid alkaloids free from oxygen, and sublimes on careful heating.

ARISTINIC ACID $C_{18}H_{13}O_7N$, greenish-yellow needles, m.p. 275° (decomp.). Occurs with *aristidinic acid* $C_{18}H_{13}O_7N$, and *aristolic acid* $C_{15}H_{11}O_7N$, in *Aristolochia argentina* (Griseb.) (Hesse, Arch. Pharm. 1895, 233, 684).

ARISTOCHIN or **ARISTOQUINININE.** Trade name for di-quinine carbonate $CO(O\,C_{20}H_{23}N_2O)$.

ARISTOL. Dithymol di-iodide used as an iodoform substitute. *V.* IODOFORM.

ARISTOLOCHINE $C_{17}H_{11}O_7N$ (or $C_{32}H_{22}O_{13}N_2$?), orange-yellow needles, decomposing at 215°. Occurs in *Aristolochia Clematitis* (Linn.) and *A. rotunda* (Linn.). It is a weakly acid base (Pohl, Arch. expt. Path. Pharm. 1891, 29, 282). According to Hesse (Arch. Pharm. 1895, 233, 684) aristolochine is a homologue of aristolic acid (*see* under *Aristinic acid*). The alkaloid is highly toxic. G. B.

ARJUN WAX *v.* WAXES.

ARMENIAN BOLE *v.* PIGMENTS.

ARNATTO *v.* ANNATTO.

ARNICA *v.* RESINS.

ARNICA YELLOW *v.* AZO- COLOURING MATTERS.

ARNOTTO *v.* ANNATTO.

AROMATIC VINEGAR *v.* ACETIC ACID.

ARRACK. (*Arack* and *Rack*, Fr.; *Arrack: Reisbranntwein*, Ger.) The term 'araq' or 'arak' was applied by the Arabs to distilled spirits generally, but it is now usually restricted to the spirituous liquor obtained by distillation of the fermented juice of the coco-nut palm (toddy or palm wine), or from rice, or from a mixture of both. Arrack is also made from the succulent flowers of the Bassia genus of trees and from other vegetable products, and is manufactured not only in the East, but also in the West Indies.

Where rice is used, it is steeped in water in large vats and agitated cautiously (so as not to damage the grains, which would interfere with the subsequent fermentation) until about half the rice has begun to germinate. The water is then run off from below, and toddy or molasses or a mixture of these is added to the rice. The whole is allowed to ferment, and the mixture is then distilled.

This method, which is said to produce the best quality of arrack, obtains at Batavia and in Jamaica, but in India arrack is frequently made from toddy alone.

The best qualities of arrack are agreeable to the taste and wholesome, which cannot be said of the commoner kind made from rice alone, in some parts of India and China. This has a somewhat nauseous odour and taste, due to a volatile oil which distils from the rice, and is narcotic and very unwholesome. Its intoxicating effect is frequently increased by the addition of hemp leaves, poppy heads, stramonium juice, &c.

A large amount of revenue is obtained from the manufacture of arrack in Siam and Ceylon, and the latter exports a considerable quantity to the United Kingdom, where it is used as a valuable ingredient in making *punch*.

An imitation arrack is sometimes made by flavouring rum with flowers of benjamin or benzoic acid. J. C.

ARRHENAL. Disodium methylarsinate. *See* ARSENICALS, ORGANIC.

ARROPE. Sherry boiled to a syrup used for colouring other wines.

ARROWROOT. The starch obtained from the rhizomes of *Maranta arundinacea*, grown in the West Indies. The starch prepared from other roots is often known locally as arrowroot; *e.g.* in Queensland, where the tubers of *Canna edulis* supply such a product.

The composition of the roots of true arrowroot grown in Jamaica is:

Water	Starch	Dextrin and sugar	Crude fibre	Ether extract	Proteid	Ash
63·4	27·8	2·1	3·9	0·2	1·6	0·9

(Leuscher, Zeit. öffentl. Chem. 1902, 8, 23.)

Commercial arrowroot contains from 83·5 to 86·9 p.c. starch, 11·0 to 15 p.c. water, proteins from 0·4 to 1·4 p.c., with small quantities (*circa* 0·3 p.c.) of ash, cellulose, and fat.

(For a series of analyses of arrowroots from various sources, *see* Ballard, Jour. Pharm. 1903, 17, [10] 476.) H. I.

ARSACETIN. The sodium salt of acetyl-*p*-aminophenyl arsenic acid—

$$CH_3{\cdot}CO{\cdot}NH{\cdot}C_6H_4{=}{\cdot}As\begin{cases}-OH\\=O\\-ONa\end{cases}$$

(*v.* ARSENICALS, ORGANIC).

ARSACETIN-QUININE. A mixture of 43 p.c. arsacetin and 54 p.c. of quinine.

ARSALYT. Bismethylaminotetra-aminoarsenobenzene.

ARSAMIN. Trade name for sodium arsanilate. Used in the treatment of sleeping sickness and other diseases of protozoal origin.

ARSAN. Glidin preparation of silver.

ARSANILIC ACID. p-Aminophenylarsinic acid. *See* ARSENICALS, ORGANIC.

ARSENIC. (*Arsenic*, Fr.; *Arsenic, Arsen*, Ger.) *Schwerbenkobalt, Fliegengift, Näpfchenkobalt Arsenicum. Regulus Arsenici.* Symbol, As; at. wt. 74·96.

Occurrence.—Arsenic, in small quantities, is one of the most widely distributed elements; it is found in mineral and other waters, in seawater and in sea-weeds, in coal smoke, in most pyretic minerals, and in a large number of ores.

In England it occurs principally with *tin ore*, and on the Continent in *mispickel.* Arsenic occurs native (usually associated with iron, cobalt, nickel, antimony, and silver) in crystalline rocks and in the older schists, generally in reniform and stalactitic masses, often mammillated; it also occurs occasionally in rhombohedral crystals. At Zimeoff in Siberia, large masses are found; it occurs in the silver-mines of Freiberg, Annaberg, Marienberg, and Schneeberg in Saxony; at Joachimsthal in Bohemia, Andreasberg in the Hartz, Kapnik in Transylvania, Orawitza in the Banat, Kongsberg in Norway, St. Marie-aux-Mines in Alsace, in Borneo, and in the United States.

As *arsenide* it occurs combined with iron in two forms $FeAs_2$ and Fe_2As_4; with nickel as *Kupfernickel* NiAs and $NiAs_2$; with cobalt as *tin white cobalt*, $CoAs_2$. With antimony it occurs as *arsenical antimony*, at Przibram in Bohemia; with blende, antimony and spathic iron, at Allemont, at Schladming in Styria and Andreasberg in the Hartz.

Arsenic is generally present in native sulphur. Combined with sulphur it occurs as *realgar* or *ruby sulphur* As_2S_2 in Hungary, Saxony, Switzerland, and China; and as *orpiment* As_2S_3 in Hungary and the Hartz.

With *sulphur* and *iron* it occurs as *mispickel, arsenical pyrites*, or *white mundic* FeS_2FeAs_2; with sulphur and cobalt in *cobalt glance* CoS_2CoAs_2; in *nickel glance* NiS_2NiAs_2, and in a number of other ores, being obtained as a secondary product in the roasting of *tin* and *copper ores, copper nickel, arsenical fahl ores, smaltine, cobalt* and *nickel glance*, &c.

With *oxygen*, arsenic occurs as *arsenolite* or *arsenite* As_4O_6, usually as a crust on other arsenical minerals, being formed by their decomposition. With *oxygen* and *cobalt*, it forms *cobalt bloom* or *arsenate of cobalt*; it also occurs as arsenates of iron, copper, and lead.

Preparation.—Metallic arsenic is used only to a small extent in commerce. It is usually prepared from native arsenic, arsenical iron, or mispickel, the latter being the only mineral used to any extent in England. The mineral used is heated in earthenware retorts or tubes laid horizontally in a long furnace. Great care is required in manufacturing the retorts; a mixture of 1 part fresh clay and 2 parts bricks or old retorts powdered, is made into the proper form, coated with a mixture of blood, loam, forge-scales and alum to produce the glaze, and burned. They are very strong and heat-resisting, and quite impervious to the vapour of arsenic. A piece of thin iron sheet is rolled and inserted into the mouth of the retort, and an earthen receiver luted on. On distilling, most of the arsenic condenses in the iron as a nearly white, coherent, internally crystalline mass, and is detached on cooling by unrolling the iron. If required, the arsenic is purified by redistillation.

At Altenberg in Silesia, arsenious oxide is heated with charcoal in an earthen crucible covered with an inverted crucible or conical iron cap. This method is more economical and productive than the one above described, but the metal is grey and pulverulent, and always contains arsenious acid.

It may also be prepared by heating the sulphides with charcoal and sodium carbonate or potassium cyanide.

Properties.—Arsenic is a very brittle steel-grey metalline mass of sp.gr. 5·62 to 5·96, of brilliant lustre, crystallising in rhombohedra, isomorphous with metallic antimony. It is a good conductor of electricity, and is odourless and tasteless.

It is volatile at temperatures above 100°, and is rapidly vaporised at a dull-red heat. At the ordinary pressure it volatilises without previous fusion, the vapour being yellow and of a garlic smell, but when heated under pressure it melts at 850°(±10°) (817°, Gouban, Compt. rend. 1914, 158, 121; 852° Heike, Intern. Zeitsch. Metallographie, 1914, 6, 49). Joubert states that above 200° its vapour is phosphorescent (Compt. rend. 78, 1853).

When the vapour is condensed at a temperature but little below the volatilising point, *i.e.* when condensed in an atmosphere of arsenic, a nearly white compact mass of strongly metallic lustre is produced which scarcely oxidises in the air even when heated to 80°. When it is deposited on a colder surface or in an atmosphere other than arsenic, it forms less dense, dark-grey crystals which readily oxidise in the air even in the cold, and especially on heating.

Ludwig (Arch. Pharm. [2] 97, 23) has obtained arsenic (?) with a perfectly bright surface resembling freshly granulated zinc, and of the low density 5·395, by distilling in a tube with a small quantity of iodine.

Bettendorf (Annalen, 144, 110) has obtained a specular, amorphous, vitreous arsenic of sp.gr. 4·69-4·716 by subliming arsenic in a stream of hydrogen and condensing it at 210°–220°. At 360° it is converted into the crystalline form with the evolution of considerable heat, and when heated suddenly it hisses and gives off vapour whilst transforming.

There is a yellow form of arsenic of sp.gr. 2·03 crystallising in the regular system. These various modifications are regarded as due to differences in molecular complexity, or as arising from the same quantity of matter distributed throughout a varying space (Kohlschütter, Frank and Ehlers, Annalen, 1913, 400, 268; Durrant, Chem. Soc. Trans. 1919, 134). Colloidal arsenic is known and would appear to be soluble in carbon disulphide.

When heated in air it absorbs oxygen, burning with a bluish flame and forming arsenious oxide. In pure water it is unaltered, but when exposed to air it forms a grey powder supposed by some to be a suboxide, but probably a mixture of metallic arsenic and arsenious oxide; this powder is sold as 'fly-powder.' When powdered and thrown into chlorine, it ignites, forming the trichloride; with the aid of heat it combines with bromine, iodine, and sulphur. Hydrochloric acid has but little action on arsenic, but it is rapidly dissolved by nitric acid, *aqua regia*, or by a mixture of hydrochloric acid and potassium chlorate.

When deflagrated with nitre it forms potassium arsenate.

Arsenic is a constituent of many alloys; it is used for bronzing brass and for the manufacture of opal glass.

(For the distribution of arsenic in commercial products, *v. Arsenious oxide.*)

Detection. — Arsenical compounds, when heated on charcoal, give off the characteristic garlic odour and white fumes of the oxide, with a white incrustation on the charcoal some distance from the assay. Metallic arsenic, and many arsenical minerals, such as mispickel, when heated in a tube closed at one end, form a blackish, shining metallic ring on the cooler portion of the tube; if heated in a tube open at both ends, the arsenic is oxidised, and condenses in a ring of white octahedral crystals, their shape being plainly visible under a lens. On cutting off the closed end of the tube containing the metallic mirror, and heating, it is also converted into the white ring higher up the tube. The white crystals dissolve in boiling water, and the solution shows the usual tests for arsenic. Antimony under like circumstances would produce a white ring, which, however, is not crystalline, and is not soluble in water. Oxides of arsenic require to be mixed with charcoal before they produce the black mirror. Sulphides require the addition of alkaline carbonate or potassium cyanide, or they may be heated with baryta alone (Brame).

White arsenic when heated with about 3 parts of sodium acetate, gives the offensive smell of kakodyl.

In solution the reactions of the two series of compounds, the arsenious and the arsenic, differ considerably; generally speaking, arsenic compounds may be converted into the arsenious form by heating with sulphurous acid or with a sulphite.

Reinsch's test. If a piece of clean metallic copper is immersed in a solution of arsenious acid or an arsenious compound acidulated with pure hydrochloric acid, it is coated with a grey film, which is probably an arsenide of copper. The action proceeds better at the boiling temperature. The acid must first be tested in the same manner to ensure the absence of arsenic, which is always present in the commercial acid. The metal is washed, dried gently and heated in a tube, when the arsenic becomes oxidised and forms a *crystalline ring* on the colder part of the tube. A film due to antimony, as mentioned before, would not produce a crystalline ring.

This method is used in testing for and removing arsenic from hydrochloric acid, and in toxicology; by it 1 part of arsenic can be detected in 250,000 parts of solution.

It is not so delicate as Marsh's or the electrolytic method.

When hydrogen is generated in a liquid containing an arsenious compound, the arsenic combines with it and passes off as the gaseous hydride; many very delicate tests are based on this reaction.

(1) *Fleitmann's test.* The solution is mixed with excess of caustic potash, a piece of *pure* zinc, or of magnesium, or aluminium foil inserted, and the solution heated. A piece of filter paper moistened with silver nitrate is held over the mouth of the tube. In presence of arsenic, arseniuretted hydrogen is produced and reduces the silver on the paper forming a greyish or purplish colour. Antimony is not evolved in this test. Fleitmann's test is therefore a ready means of finding arsenic in presence of antimony; it is not, however, so delicate as Reinsch's, Marsh's, or the electrolytic method. Or instead of silver nitrate the paper (preferably Michallet drawing paper), cut into strips, may be soaked in a 1 p.c. solution of mercuric chloride and, after drying, exposed to the gas, when the arseniuretted hydrogen produces a stain.

Gutzeit test. For a convenient form of apparatus for making this test, adapted to works practice, *see* Hollins, Jour. Soc. Chem. Ind. 1917, 36, 576.

(2) *Marsh's test.* This or Reinsch's test is usually used in toxicology. The solution is acidulated with pure hydrochloric acid and introduced into an apparatus in which hydrogen is generated by means of pure sulphuric acid and zinc. Arsenic hydride is formed and is passed through a narrow glass tube, which is heated at one spot by a lamp; the arseniuretted hydrogen as it passes over the heated portion is decomposed with the precipitation of arsenic as a black ring. In testing for very small quantities of arsenic, the action should be continued for about an hour. A blank experiment should always be performed in the same manner to ensure the purity of the zinc and acid. It is essential not only to obtain zinc and acid which are free from traces of arsenic, but also to see that the zinc used is 'sensitive,' and will permit all the arsenic in the solution to be evolved as arseniuretted hydrogen. The presence in the solution of certain metals—notably iron—is liable to retard, or entirely prevent, the evolution of arseniuretted hydrogen. (On the presence of arsenic in glass as a source of error in the detection of arsenic, *v.* W. Fresenius, Zeitsch. anal. Chem. 22, 397; Ber. 17, 2938.) Instead of heating the tube, the gas may be ignited at the mouth of the tube, and the flame caused to impinge on a cold surface of porcelain, or preferably of platinum foil. The arsenic film may be distinguished from that produced by antimony as follows:—

(1) The arsenic film is quickly evaporated, while that of antimony only slowly disappears. Helling (Das Microscop in der Toxicologie) recommends that small spots be heated and the vapour received on a slip of glass, when, under the microscope, the octahedral crystals due to arsenic are visible.

(2) The arsenic film quickly dissolves in a freshly prepared solution of sodium hypochlorite; the antimony film is very slowly soluble. Old hypochlorite solutions contain chlorite which dissolves the antimony mirror.

(3) The antimony film dissolves quickly in yellow ammonium sulphide, leaving an orange-yellow residue on evaporation; the arsenic film dissolves very slowly.

Magnesium may also be employed in place of zinc, and E. Davy and Al. Jandousch use an amalgam of 1 part sodium in 8 parts mercury, with or without acid.

The presence of nitrates or nitric acid interferes with this test, and the acids used should be dilute.

Bettendorf's test. A solution of stannous chloride in concentrated hydrochloric acid is mixed in a test-tube with a solution of the substance in hydrochloric acid, and heated to boiling, when a brown colouration indicates the presence of arsenic.

For the detection of small quantities of arsenic in toxicology, Billeter (Helv. Chim. Acta, 1918, 1, 475; Analyst, 1919, 51) recommends that the substance be treated with nitric and sulphuric acids to destroy organic matter, the sulphuric acid solution then distilled with the addition of sodium chloride and potassium bromide, the distillate evaporated with the addition of hypochlorous acid, and the residual solution tested in the Marsh apparatus. The distillation part of the process is essential to ensure removal of heavy metals, particularly mercury, traces of which completely mask the presence of relatively large quantities of arsenic in the Marsh apparatus. The addition of hypochlorous acid during concentration of the hydrochloric acid solution prevents loss of arsenic.

(For the detection and estimation of arsenic by electrolytical methods, *v. Arsenic* in art. ANALYSIS, ELECTRO-CHEMICAL.)

Estimation.—Arsenic is usually estimated as (1) magnesium pyro-arsenate; (2) as arsenic sulphide; (3) as metallic arsenic.

(1) For this method it is necessary that the substance should be present as an *arsenic* compound. The conversion from the arsenious to the arsenic condition may be effected by heating with nitric acid (*v.* Estimation as sulphide) or hydrochloric acid and potassium chlorate.

The acid solution, which should occupy only a small bulk, is mixed with 'magnesia mixture' and rendered *strongly* alkaline with ammonia. After standing for 24 hours, the solution is filtered, the last portions of the precipitate, which consists of ammonium magnesium arsenate, being washed entirely on to the filter paper with a little of the filtrate (the volume of this filtrate should be noted roughly). The precipitate is then washed with a mixture of 1 part strong ammonia and 3 parts water, until only a slight opalescence is produced on the addition of nitric acid and silver nitrate to a few drops of the washings. It is then dried, detached as much as possible from the filter paper, and transferred to a weighed porcelain crucible, moistened with nitric acid, dried, and ignited, at first gently, and finally to bright redness. The paper is moistened with nitric acid, dried, and ignited on the lid, and the crucible and its contents weighed. The ignited residue consists of magnesium pyro-arsenate $Mg_2As_2O_7$, and contains 48·27 p.c. of arsenic.

On account of the solubility of the ammonium magnesium arsenate, an addition should be made to the weight obtained of 0·001 gram for each 16 c.c. of filtrate obtained, not counting the washings.

(2) The arsenic for this method should be in the arsenious form. If *arsenic* compounds are present, they are preferably reduced by passing a current of sulphurous acid through the liquid, the excess of that gas being driven off by subsequent heating. Sulphuretted hydrogen is then passed through the liquid until thoroughly saturated, the liquid left to stand for some time, the excess of sulphuretted hydrogen driven off by heating, and the precipitated arsenious sulphide containing sulphur filtered off. The sulphide is dissolved in ammonia, filtered if necessary, and the arsenic estimated in the solution by one of the three following methods:—

(*a*) The solution is evaporated to dryness in a porcelain dish, then covered with an inverted funnel, and fuming nitric acid added. After the first violent action has ceased, the liquid is heated on a water-bath until the whole of the sulphur has disappeared, and only a small bulk of liquid remains; 'magnesia mixture' is then added, followed by excess of ammonia, and the process followed as already described.

(*b*) The ammoniacal solution is evaporated to dryness in a porcelain dish, and heated on a sand-bath to drive off the whole of the free sulphur and carbonise any organic matter (which is frequently present in toxicological analysis) without volatilising any of the arsenious sulphide. The residue is again dissolved in ammonia, filtered if necessary, evaporated to dryness, and gently heated in a weighed porcelain dish, and weighed as arsenious sulphide As_2S_3 (Mohr, Chem. Toxicologie, 56).

(*c*) The arsenic in the solution may be estimated by means of standard iodine solution (Champion and Pellet, Bull. Soc. chim. [2] 26, 541).

(3) For this method the arsenical mirror obtained by the Marsh-Berzelius method or the electrolytic method may be estimated by comparison with standard mirrors obtained under similar conditions to the estimation. Experience has shown that when in the preparation of standard mirrors, the quantities of arsenic used differ by amounts such as 0·002 milligram, a series of mirrors can be obtained showing differences in intensity which are sufficiently distinct and constant to be utilised for comparison.

Separation from other metals.—Certain heavy metals, if present, would be precipitated with the arsenious sulphide by means of sulphuretted hydrogen. From the sulphides of lead, bismuth, &c., the arsenious sulphide can be dissolved by digestion in ammonium sulphide. The solution would also contain antimony and tin, if present. The separation of arsenic from these two metals may be performed as follows:—

From antimony. The mixed sulphides are oxidised with *aqua regia*, as already described, and tartaric acid solution added, followed by excess of ammonium chloride and ammonia. The latter should produce no opalescence. If a precipitate is produced, a further quantity of tartaric acid or ammonium chloride must be added. The solution is then precipitated by 'magnesia mixture,' and the estimation made as before described.

From tin. A solution of oxalic acid is added to the solution in the proportion of 20 grams of oxalic acid for each gram of tin supposed to be present. The solution should be sufficiently strong for the acid to crystallise out on cooling. The liquid is heated to boiling and sulphuretted hydrogen passed through for 20 minutes. The liquid is allowed to stand for about 30 minutes, and the arsenious sulphide filtered off. It is quite free from tin.

Arsenious chloride in small quantities may be separated from other metals by distillation of the hydrochloric solution (Thorpe, Chem. Soc. Trans. 83, 971); in certain metals and alloys by distillation of the finely divided material with a suitable solution of ferric and calcium chlorides, acidified with hydrochloric acid (the materials used should be tested for arsenic). With a solution of zinc and cupric chlorides in hydrochloric acid boiling at 108° both arsenic and antimony may be separated from other metals; the arsenic is in the distillate from 108° to 115°, the antimony in the distillate from 115° to 160° (Gibb, J. Soc. Chem. Ind. xx. 3).

For the estimation of arsenic in ores, Parnell recommends the following method:—A weighed quantity of the *finely powdered* ore is heated to about 200° in a slow current of chlorine gas, the volatilised arsenious chloride being absorbed in a solution of chlorine water. After evaporation of the excess of chlorine, the arsenic may be estimated by any ordinary method. Antimony, if present in the ore, would also volatilise with the arsenic.

For technical purposes the following methods are largely used:—

A weighed portion is partially decomposed with a minimum quantity of strong nitric acid, dried and fused with sodium peroxide or a mixture of sodium carbonate and nitre. The fused mass is extracted with water and filtered. The solution of alkaline arsenate is acidified with nitric acid and boiled to effect decomposition of either peroxide or nitrite; it is next carefully neutralised and then acidified with acetic acid, and the arsenic determined by titration with a standard solution of uranium acetate. Pearce recommends separation as silver arsenate from the aqueous extract after fusion; the silver salt is dissolved in dilute nitric acid and estimated by Volhard's method. With very poor ores to the solution in nitric acid a sufficient quantity of tartaric acid is added, and the arsenic separated as magnesium ammonium arsenate. For the estimation of arsenic in organic salts ignite with sodium peroxide, reduce with hydriodic acid and titrate with iodine and starch in presence of disodium hydrogen phosphate (Morgan, Chem. Soc. Trans. 1909, 95, 1477).

Alloys of arsenic.

Arsenic combines with most metals, in many cases in atomic proportions, the alloys being then known as arsenides. Many natural arsenides occur as minerals.

The alloys may be prepared (1) by fusing the metals under a layer of borax, or in an atmosphere of some inert gas; (2) by reducing the arsenite or arsenate of the metal with potassium cyanide; and (3) in some cases—as with gold, silver, and copper—by placing arsenic in a solution of a metallic salt. W. Spring (Ber. 16, 324) has obtained crystalline alloys of arsenic with other metals by repeatedly compressing a mixture of the constituents at 6500 atmospheres.

When heated out of contact with air, arsenical alloys usually lose a portion of their arsenic; heated in air the arsenic is oxidised, a portion volatilising, and the remainder forming an arsenite or arsenate of the metal. When heated with nitre, arsenates are produced. (For a list of alloys of arsenic in atomic proportions, probably existing as arsenides, *v.* A. Descamps, Compt. rend. 86, 1022 and 1065.) Some ancient copper spear-heads from Cyprus contained 1·348 p.c. arsenic, and a bronze figure of the Ptolemaic period from Egypt contained 1·479 p.c.

The presence of arsenic generally renders an alloy more brittle, more fusible, and brighter. In Pattinson's process it tends to render the crystals smaller, and thus lengthens the time required for draining. Its alloys with iron, zinc, and tin are brittle; with gold and silver, brittle, and grey; and with lead and antimony, hard, brittle, and fusible. The addition of from 3 to 6 parts arsenic to 1000 lead (with occasionally little copper) causes the small shot in fallin down the tower to form spheres, instead c elongating, as they have otherwise a tendenc to do. The arsenic is frequently added in th proper proportions in the form of an alloy c lead and arsenic known as 'temper'; this i prepared by fusing together arsenious oxide an lead. By heating a mixture of lead and arseni to whiteness, Berthier obtained an alloy c the formula Pb_4As, any excess of arsenic beyon that corresponding to this formula being volatilised at that temperature. With copper it forms white, malleable, dense, and fusible alloys. White copper contains about 10 p.c. arsenic. Arsenic is also used in speculum metal, and is frequently present in common Britannia metal.

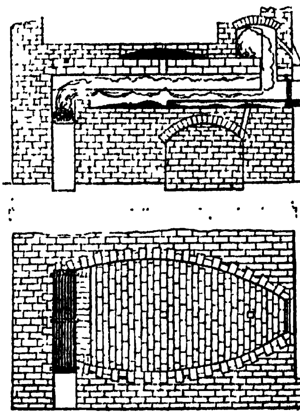


FIG. 1.

With potassium and sodium arsenic forms alloys which evolve arseniuretted hydrogen when placed in water. With platinum it forms a fusible alloy, and was formerly used to facilitate the working of that metal. It forms an amalgam As_2Hg_3 (Dumesnil, Compt. rend. 1911, 152, 868).

Arsenic trihydride. *Arsenetted or arseniuretted hydrogen. Arsine.* AsH_3. This gas is formed whenever hydrogen is liberated in a solution containing arsenious acid or an arsenite, as when zinc is introduced into an acid solution of the substance. It is a colourless, neutral, disagreeably smelling gas, slightly soluble in water, and highly poisonous, even when much diluted. At a red heat it decomposes into arsenic and hydrogen.

It can be condensed to a liquid, and forms a hydrate $AsH_3,6H_2O$ (De Forcrand).

It is evolved in the bronzing of brass with arsenic, in tinning sheet iron and frequently in the desilverisation of lead with zinc and subsequent heating of the argentiferous zinc with acid. It is a very powerful reducing agent, precipitating silver, gold, and other metals from their solutions. Methods for the quantitative estimation of arsenic are based on this property.

A solid hydride of arsenic H_2As_2 is formed by the action of an electric discharge on the trihydride in an ozoniser, or by the decomposition of sodium arsenide; or, mixed with arsenic, by the action of the trihydride on solid alkali hydroxide followed by the addition of water:

(1) $AsH_3+3KOH=K_3As+3H_2O$
(2) $2K_3As+6H_2O=As_2H_2+6KOH+2H_2$

(Reckleben and Scheiber, Zeitsch. anorg. Chem. 1911, 70, 255).

Arsenious oxide. *Arsenious acid. White arsenic. Flowers of arsenic; commonly known as 'arsenic.'* As_4O_6.

Preparation.—In Cornwall, Devon, and at Swansea, arsenious oxide is principally prepared by roasting mispickel, which occurs mixed with iron and copper pyrites, tin ore, wolfram, blende, galena, &c. These ores, if present in sufficient quantity, are separated as far as possible before roasting; tinstone by washing the finely powdered ore, and the other minerals by hand. Arsenious oxide is also largely prepared by roasting arsenical silver at Andreasberg, and from arsenical ores of nickel and cobalt.

In ores from which arsenic is produced as a principal product, the arsenical pyrites generally occur to the amount of about 12 p.c.

The ores are usually roasted in a reverberatory furnace. In a common form, the furnace bed is flat, 12–15 feet long and 7–9 feet wide in the middle; the arch is about 2 feet above the bed, and sinks gradually towards the flue, at which end there is an iron door, through which the ore is raked (Fig. 1).

From 8–15 cwt. of the stamped dried ore is introduced through a hopper over the centre of the fire-bridge and spread over the furnace bed. The heat is raised to dull redness and the ore is frequently stirred to ensure thorough oxidation of the arsenic and sulphur. In about 10 hours these have been expelled as oxides, and the arsenious oxide together with some of the sulphur collects in the flues. The spent ore is removed through an aperture in the bed, which is closed with an iron door during calcination.

Two such furnaces are sometimes built side by side, separated by a wall, and with their flues uniting. The furnace beds slope gently towards a narrow fireplace. In the first instance the ore is introduced through a number of doors on each side of the furnace. As the ore is worked downwards its place is constantly supplied by fresh ore through an opening in the roof.

Brunton's Calciner is much used in Cornwall. It is practically a reverberatory furnace with a revolving bed. The bed is of firebrick resting on a cast-iron table, and is higher at the centre than at the periphery. It is usually 8 or 10 feet in diameter; it revolves three or four times in an hour by steam or water power, about half-horse power being required. There are two furnaces on opposite sides of the bed.

The dried and finely stamped ore is introduced through a hopper over the centre of the bed. Above the bed are fixed radially three cast-iron frames in which are fastened a number of equidistant iron scrapers shaped like the coulter of a plough and placed obliquely, so that, as the bed revolves, they turn the ore over and outwards towards the periphery of the bed. It is thus thoroughly roasted, and, on reaching the edge, falls into the chamber beneath.

Oxland and Hocking's Patent Calciner (English Pat. 1868, 2950) is largely used, especially for 'rank' ores (Figs. 2 and 3). It consists of a wrought-iron cylinder, which, if 32 feet in length, is lined with sufficient firebrick to leave 4 feet clear internal diameter. Four longitudinal ribs of firebrick occur within the furnace, leaving sufficient space at the upper end for the continuous supply of the ore. The cylinder is generally mounted in an inclined position, the slope being usually ½ to 1 inch per foot, and is turned by means of a turbine or water-wheel once in 8 or 10 minutes upon friction-wheels.

The dried, finely powdered ore is introduced through an archimedean screw, or from a hopper at the upper end, and in the revolution of the tube becomes lifted to a certain height by the ribs of firebrick, and falls in a fine stream through the hot blast. In a few revolutions the ore is completely oxidised, the arsenic burning off first, and finally reaches the lower end of the tube, where it falls through a chamber beneath. A calciner of the above size will roast 6 to 7 tons of ore in 24 hours. In this furnace the amount of air required is minimised, thus rendering the condensation less difficult. The amount of fuel used is also small (*v.* further, Henderson, Proc. Roy. Inst. Mech. Engineers, 1873).

A modification of this furnace was patented by R. & C. Oxland (Eng. Pat. 7285, 1885). It is so arranged that the products pass into the condensing chambers unmixed with other gases. At the lower end of the rotating tube is a cast-iron prolongation, heated externally by a grate and a system of flues surrounding it. At the end of the prolongation is a door for removing

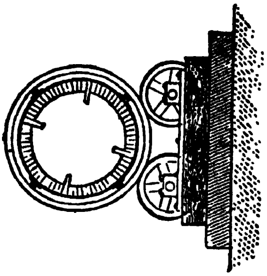

FIG. 3.

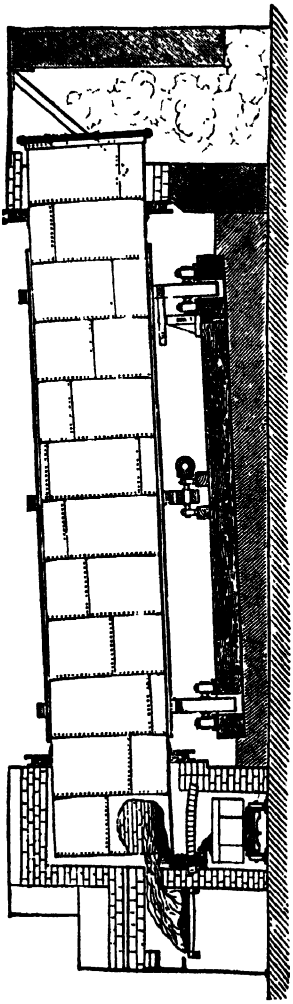

FIG. 2.

the calcined products and a regulator for admitting the required amount of air.

The practice in the West of England is to use these types of furnace for specific purposes, the Oxland type for calcination of selected mispickel ore, usually the size of gravel; the Brunton and reverberatory type for the calcination of concentrate produced in the washing of the tin ores. The small works favour the reverberatory furnace, and the large works the Brunton. More recently the Merton furnace has been installed by a few mines. It is an improved form of reverberatory furnace with several hearths in tiers and mechanical rakes for transferring the material progressively from one hearth to another.

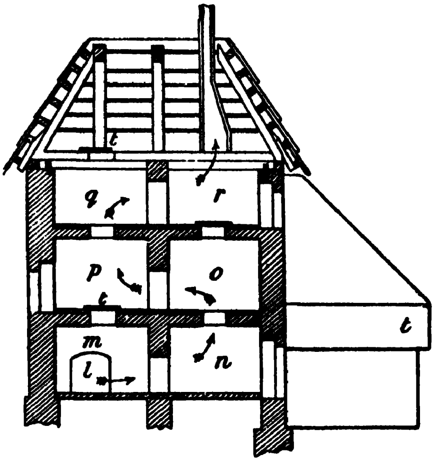

FIG. 4.—VERTICAL SECTION OF 'POISON TOWER.'

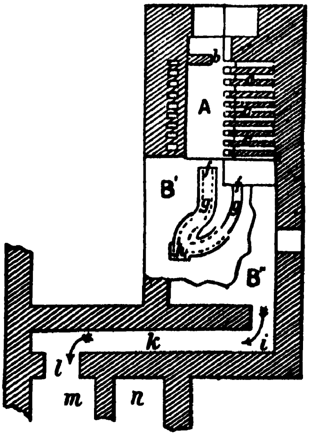

FIG. 5.—GROUND PLAN OF FURNACE.

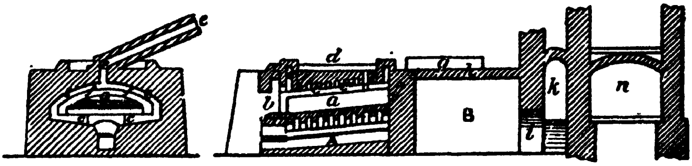
Roasting in muffle furnaces.—This process is used at Altenberg (Figs. 4, 5, and 6) and at Reichenstein in Silesia (Figs. 7 and 8), where wood is cheap.

The ore, reduced to a moderate size and

known as *schleich*, is introduced through an opening in the top in charges of about 10 cwt. and spread 2 or 3 inches thick on the floor of the muffle. It is first heated to redness, and then more gently, with the muffle door open, to oxidise the mass thoroughly before sublimation. The operation is completed in 11 or 12 hours.



Transverse Section. Longitudinal Section.

FIG. 6.—SUBLIMING FURNACE.

Condensation of the oxide. — The vapours passing off in the roasting are carried through chambers so arranged that the gases come in contact with a very large condensing surface passing through a series of chambers before escaping into the air. At the Devon Great Consols and other large works, the chambers are made of thin brickwork covered with iron plates to assist the cooling of the gaseous oxide. The ores, before calcination, are dried over iron plates on the condensers.

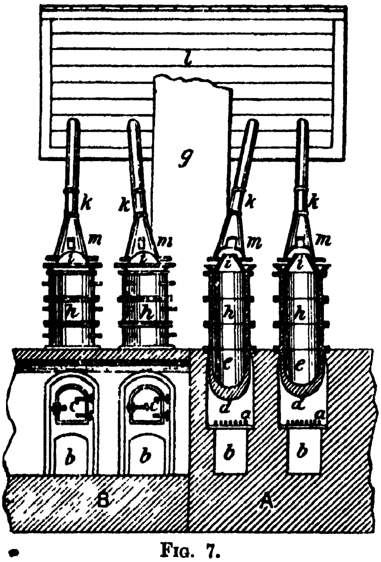


FIG. 7.

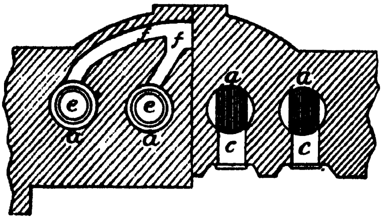

FIG. 8.—REICHENSTEIN FURNACES.

These chambers are cleared at intervals, some every fortnight, those at Silesia once in two months. Two sets of chambers are frequently used, so that one set may be working while the other is being cleared.

The oxide produced by all processes except that of the muffle is known as 'arsenical soot,' and is impure, containing carbon and sulphur compounds; when so mixed it is of a dark-grey colour and requires to be resublimed.

The condensing chambers connected with the muffles in Silesia are in a lofty building called the 'poison tower' (*Giftthürme*). The gases traverse, by a sinuous course, a series of chambers, depositing the finest product in the lower ones, that in the upper chambers containing sulphur. The chambers are cleared about every 2 months, and contain about 25 tons of white arsenic ('poison flour,' or *Giftmehl*). Being comparatively pure, it does not usually require refining, but may be at once converted into arsenical glass. The workmen engaged in clearing the chambers are clothed in leathern garments with glazed apertures for the eyes, and wear wet cloths over their mouths and noses to absorb the irritating fumes. It is stated at Salzburg that only 'arsenic-eaters' can perform this work continuously.

Refining or resublimation.—For this purpose a reverberatory furnace is used, which is usually much shorter than that in which the calcination is performed. The arsenical soot is charged from the top and paddled down through doors at the side, more being added as it sublimes. The fuel used is smokeless, usually a mixture of anthracite and coke.

The sublimate is collected in chambers similar to those already described. It is white, glistening, and minutely crystalline. It is ground between millstones, and is thence fed into kegs from a hopper through a leathern hose which fastens to the top of the cask and prevents any escape of the powder.

Arsenic glass, or vitreous white arsenic, is prepared by volatilisation of the powder under slight pressure. For this purpose, at Swansea, a cast-iron pan is used 2 feet in diameter and surmounted by a bell 2 feet 6 inches high. The pan is heated to a cherry red, and about ¼ cwt. of refined white arsenic introduced through an opening in the top of the bell, which is then closed with a plug. In about 2 hours the whole has evaporated and condensed on the bell as a transparent glass; more white arsenic is then introduced and condensed, until after 24 hours the glass has reached a thickness of about 1 inch. The later charges, owing to the condensing surface being hotter, require about twice as long to condense as the first.

At Silesia the subliming pots are deeper and of greater capacity; they are surmounted by iron drums and conical caps, which condense the 'glass' and open into condensing chambers. The temperature is carefully regulated. The arsenic glass produced amounts to about 92 p.c. of the 'flowers' used.

Analyses of Arsenic Powder and Arsenic Glass.

(1) Powder from Altenberg, from the condenser of a tin roasting furnace, near the furnace end (Lampadius).

(2) Do. from further end of condenser (Lampadius).

Properties and uses of arsenious oxide.—White arsenic occurs in the amorphous or glassy form, and in two crystalline modifications: (1) the octahedral or common form, of sp.gr. 3·874 at 0°, and (2) in trimetric prisms, occasionally found in sublimates; this form is converted into the octahedral variety when heated or boiled in water.

The amorphous form is transparent when first prepared, but becomes opaque when exposed to the air, especially when damp, diminishing slightly in specific gravity and forming the crystalline oxide. The action commences at the outside, so that even after a considerable time a piece is frequently found with a transparent nucleus. The vitreous form may be kept in a scaled glass tube unchanged for years.

The vitreous form, according to Buchner, is soluble in 108 parts of cold water, whilst the opaque form requires 355 parts; the solubility of an ordinary piece is therefore doubtful, depending on the amount of change it has undergone. It is very soluble in glycerol, and is stated by Jackson to form *glyceryl arsenite* (Chem. News, 49, 258).

On making a strong solution of the *vitreous* form in dilute hydrochloric acid by dissolving 3 parts in a mixture of 12 hydrochloric acid and 4 water, and slowly cooling, it is deposited in the octahedral form, each crystal as it falls producing a flash of light (H. Rose). If these crystals be redissolved or if the opaque form be used, no light is produced on crystallising, that phenomenon appearing to depend on the change of the amorphous into the crystalline form at the moment of crystallisation.

At about 193° arsenious oxide softens and sublimes without fusion; it fuses under pressure; its vapour is colourless and odourless. It is acid to test papers, but does not appear to form true arsenious acid on solution in water.

Arsenious oxide is a powerful febrifuge, being sometimes efficacious when quinine has failed. It is highly poisonous, 2 or 3 grains being a very dangerous dose. When used habitually, however, comparatively large quantities may be taken with impunity. The inhabitants of Styria eat it under the name of 'hydrach,' to increase their endurance. Many authentic cases are recorded of 6 grains and upwards being taken without ill effect. Arsenic-eaters are stated to be fresh complexioned, with a tendency to stoutness, to be long-lived, but to die suddenly. The workmen engaged in the manufacture of dyes where arsenic acid is used have been observed to have this tendency to stoutness (*v.* Roscoe, Mem. of Lit. Phil. Soc. Manchester, 1860). In cases of death from poisoning, the greater part of the arsenic appears to be contained in the liver and intestines; of the bones, those of the pelvis and neighbouring vertebræ appear to contain most.

Arsenious oxide is adsorbed by ferric hydroxide under conditions which have been studied by Lockemann and Lucius (Zeitsch. physikal. Chem. 1913, 83, 735). The total adsorption follows the formula $E = \beta A^p$, in which E represents the mg. of iron hydroxide, A the number of mg. arsenic per 100 c.c., and β and p are constants, which differ for different temperatures. The total adsorption is not materially influenced by the presence of sodium or ammonium salts. The precipitation of arsenic by iron hydroxide is a usable process for the purification of concentrated salt solutions, and for the detection of small traces of arsenic in solutions or nitre fusions

In manufactures, arsenious oxide is used; in glass-making, to remove the colour produced by the lower oxides of iron; in enamelling; in calico-printing; as a constituent of white fire in pyrotechny; for the prevention of boiler incrustations (40 parts white arsenic to 9 sodium carbonate); in the manufacture of arsenic acid; and of fly and rat poisons; and in the manufacture of a large number of pigments, arsenic being found in green, blue, pink, white, brown, and other colours. As a preservative it is thrown into the holds of ships, to prevent vegetable decomposition; as a wash for walls in India, to prevent insect ravages; to prevent smut in wheat; and with sodium carbonate as a wash for sheep; and in arsenical soap, for preserving skins.

Arsenious oxide is employed in the fixation of aniline colours, especially of aniline blue. It is used principally for preparing steam colours, either as a solution in glycerol containing 4 lbs. of the oxide to 1 gallon of glycerol, under the name 'arsenic and glycerine standard'; or as sodium arsenite, dissolved in sodium carbonate or borate.

In medicine it is used as Fowler's solution, which contains 4 grains of the oxide (in the form of sodium arsenite) in each ounce of fluid. In India it has been used as a cure for hydrophobia and serpent poisoning. In veterinary surgery it is largely used as a tonic, to eradicate worms, and for improving the coats of horses.

It occurs, either as an impurity or as an adulterant, in a large number of commercial products. Besides the ordinary commercial compounds in which arsenic is expected to be present, it has been found in caustic soda, potassium chlorate, commercial glucose (Clouët and Ritter), and in wine free from artificial colouring matter (traced to sulphuric acid used in purifying the casks). Dr. Tidy found about 38 p.c. of arsenious oxide in some 'violet powder' which had caused the death of at least two children (Lancet, Aug. 21, 1878).

In the year 1900 occurred a serious epidemic of arsenic-poisoning due to contamination of beer through the use of brewing sugars, glucose, or 'invert' sugar containing arsenic. The arsenic was introduced by the use of highly arsenical sulphuric acid in the production of the sugars. The total number of persons who suffered in consequence of the epidemic was certainly 6000, and probably considerably greater. At least 70 deaths were attributed to the epidemic.

Coal or coke used for malt drying always contains arsenic; with an ordinary malt kiln part of the arsenic volatilises and may deposit on the malt. Various methods have been tried and adopted in which it has been found that access of arsenic to malt may be obviated or diminished (Royal Commission: Arsenical Poisoning, 1903).

(For a statement of the amount of arsenic in the varieties of pyrites, and of its distribution in the preparation of sulphuric acid and alkali, v. H. Smith, Phil. Mag. [4] 44, 370; Chem. News, 26, 176; and C. Hjelt, Dingl. poly. J. 226, 174–181.)

Fresenius finds that the arsenic in many chemical glasses is removed by alkaline, but not by acid liquids; the bearing of this on judicial investigations is important.

The commercial article is frequently adulterated with gypsum, chalk, &c., these may easily be detected by heating a little on a knife, when they will remain after the oxide has volatilised.

Sodium arsenite. *Acid sodium arsenite*

$$Na_2O{\cdot}2As_2O_3{\cdot}2H_2O$$

is prepared by dissolving arsenious oxide in a solution of caustic soda or sodium carbonate, and evaporating the solution. The neutral salt, $Na_2O{\cdot}As_2O_3$, is formed by boiling this compound for some time with sodium carbonate, and washing the residual salt with alcohol (Pasteur).

Potassium arsenite is prepared in a similar manner.

Sodium arsenite is used as a substitute for dung in dyeing, but is not so reliable as the arsenate. It enters into the composition of all preparations in which arsenious oxide is dissolved with sodium carbonate.

A solution undergoes slow oxidation on warming in contact with air.

An arsenite of chromium and iron is used as a green pigment in wall-papers.

Scheele's green. *Arsenite of copper. Hydrocupric arsenite.* $CuHAsO_3$.

According to Scheele's method, 11 oz. arsenious oxide are gradually added to a solution of 2 lbs. potassium carbonate in 10 lbs. boiling water; this is filtered and poured into a solution of 2 lbs. copper sulphate in 30 lbs. water, so long as a grass-green precipitate falls. The precipitate is thrown upon a filter cloth, washed with warm water, and dried gently with the production of about 1½ lbs. of the pigment.

Scheele's green is a pulverulent, fine light-green colour, formerly largely used in calico-printing and for wall-papers. It is, however, much less used at the present time. It dissolves entirely in excess of alkali or in acids.

Schweinfurth green. *Imperial green. Emerald green. Mitis green. Aceto-arsenite of copper* (when mixed with gyspum or heavy spar, known also as *Mountain* or *Neuwieder green*).

$$3CuOAs_2O_3{\cdot}Cu{\cdot}(C_2H_3O_2)_2$$

Five parts of verdigris (basic copper acetate) are made into a thin paste with water and added to a boiling solution of rather more than 4 parts arsenious oxide in 50 parts water; the solution is kept boiling during the mixture. If a yellow-green precipitate falls, a little acetic acid is added, and the solution boiled a few minutes longer; the precipitate becomes crystalline and soon acquires the characteristic green colour.

A very fine product is prepared by the following method:—Boiling, concentrated solutions of arsenious oxide and copper acetate are mixed in such proportions that equal weights of the two substances are present when a bulky olive-green precipitate falls; an equal bulk of cold water is then added and the mixture placed in a flask which it fills to the neck, thus preventing any pellicle which may form on the surface from falling through the liquid and causing a premature crystallisation. The colour under these circumstances takes two or three days to perfect, the beauty of the product being much increased by slow formation. The workmen engaged in the preparation of this pigment do not appear to be injured by it. In contact with organic matter it is, however, liable to change. By the action of damp and moulds, such as *Penicillium brevicaule, Aspergilli,* &c., on paper coloured with this pigment a peculiar odour is frequently produced, which appears to be due to the formation of diethylcacodyl oxide $[As(C_2H_5)_2]_2O$, unaccompanied, as formerly supposed, by arseniuretted hydrogen (Klason, Ber. 1914, 47, 2634).

Arsenic oxide. *Arsenic acid, Arsenic pentoxide, Acide arsénique, Arsensaure, Acidum arsenicum.* As_2O_5.

Produced when arsenious oxide is acted upon by an oxidising agent.

On the large scale 4 parts white arsenic are gradually added to 3 parts nitric acid of not less than 1·35 sp.gr. in a vat capable of holding from 65 to 70 kilos. of white arsenic. Great heat is produced and the evolved fumes are passed over coke moistened with water, whereby about two-thirds of the nitric acid is recovered. In 24 hours a syrupy liquid is formed, containing a small quantity of arsenious oxide, which may be oxidised with a little more nitric acid.

Kestner performs the oxidation in large glass flasks, the nitrous fumes being passed through lead pipes and condensed in leaden chambers.

Arsenic oxide has also been prepared by suspending arsenious oxide in water, passing a current of chlorine through the liquid, and evaporating the solution thus produced.

It is a deliquescent solid fusing at a dull-red heat, of acid metallic taste and acid reaction. It dissolves in 6 parts cold and in 2 parts hot water. The solution evaporated in an open vessel at 50°, or under increased pressure at 150°, deposits crystals of the composition $3As_2O_5{,}5H_2O$. Above 200° crystals of As_2O_5

separate. Concentrated solutions crystallising spontaneously or by freezing deposit the hydrate $H_3AsO_4\frac{1}{2}H_2O$, or mixtures of this with $3As_2O_5,5H_2O$ (Balareff, Zeitsch. anorg. Chem. 1911, 71, 73). A cold, strong solution blisters the skin. Arsenic oxide and its salts are less poisonous than the corresponding arsenious compounds.

Sodium arsenate. *Hydric disodic arsenate*; '*Dung salt.*' Na_2HAsO_4.

It is prepared by saturating arsenious oxide with crude soda ash, drying, and deflagrating with sodium nitrate in a reverberatory furnace.

Arsenate of soda is largely used in calico-printing as a substitute for dung, its feebly alkaline properties rendering it useful for that purpose.

Arsenate of iron is an amorphous green powder containing 33·6 p.c. arsenic.

Arsenic sulphides. Arsenic forms three well-defined sulphides, As_2S_2, As_2S_3, and As_2S_5, the two former occurring naturally. A large number of other sulphides of indefinite composition also exist.

Arsenic disulphide or **Realgar.** *Ruby sulphur. Rothes Rauschgelb. Rothes Schwefel. Sulphuré rouge. Orpin rouge. Risigallo. Sandaraca.* As_2S_2.

Prepared by fusing together arsenic and sulphur or orpiment in the proper proportions. On the large scale it is obtained by distilling a mixture of arsenical ores, such as arsenical and iron pyrites, with sulphur or with the sulphide of arsenic precipitated in the purification of sulphuric acid.

The mixture should contain about 15 p.c. arsenic and 26–28 p.c. sulphur; it is placed in flask-shaped earthenware retorts, holding about 60 lbs. when two-thirds full, which are connected with similar receivers. The retorts are gradually heated to redness and kept so for 8–12 hours. The crude realgar should be compact, dark, and rich in arsenic; if sulphur be in excess it is friable and light red. It is re-melted rapidly in cast-iron pans with the requisite amount of sulphur or arsenic, or with realgar of poorer quality. The mass is cleared of slag and heated until quite fluid, and until a small quantity shows the proper appearance on cooling. It is then poured into conical sheet-iron moulds.

Greater care is necessary in the preparation of realgar than of orpiment, and an assay is frequently made to ascertain the exact proportions required before the final melting.

It is hard and brittle, generally opaque, with vitreous conchoidal fracture, orange or hyacinth red in mass and orange-red in powder. Its sp.gr. is 3·4–3·6, and its usual composition is arsenic 75, sulphur 25. It volatilises easily before the blowpipe with a smell of garlic and burning sulphur, is insoluble in water or hydrochloric acid, but soluble in alkaline sulphides.

Realgar is a constituent of blue fire and of 'white Bengal fire,' which is used as a signal light, and consists of realgar 2, sulphur 7, potassium nitrate 24.

The finest variety, especially that which occurs native, is used as a pigment by artists.

Arsenic trisulphide or **Orpiment.** *Operment. Gelbes Rauschgelb. Risigallum. Auripigmentum* (of which its usual name is a corruption). *Yellow Sulphide of Arsenic.* As_2S_3.

This sulphide is formed as a yellow precipitate when sulphuretted hydrogen is passed through a solution of arsenious acid in hydrochloric acid.

Precipitated arsenious sulphide is appreciably decomposed by water, and even by alcohol, with formation of hydrogen sulphide. It is also attacked to a considerable extent by dilute hydrochloric acid, but the action of dilute acid or of water is checked by the addition of hydrogen sulphide. The precipitate is apt to contain arsenic hydrosulphide $As(SH)_3$, together with arsenious oxide (Schmidt. Arch. Pharm. 1917, 255, 45).

On the large scale it is prepared by subliming sulphur with arsenious oxide, 2 parts of arsenious oxide and 1 part sulphur being a common proportion; the colour of the product is lighter when less sulphur is used.

According to R. Wagner, a very fine colour may be produced as follows:—2 parts finely ground barium sulphate are calcined with 1 part powdered charcoal or other carbonaceous matter, and the product is pulverised, mixed with 1 part ground orpiment, boiled in water and filtered. The solution, containing a sulpharsenite of barium, is precipitated by the addition of sulphuric acid. By the addition of a suitable amount of barium chloride before precipitation, the pigment may be correspondingly lightened in colour.

Orpiment is insoluble in water but very soluble in alkaline sulphides. It was formerly much used as a pigment under the name of King's Yellow, but now is largely replaced by chrome yellow. The lighter varieties contain as much as 80 to 90 p.c. of arsenious oxide, and are consequently very poisonous. The darker varieties contain from 1 p.c. to 15 p.c. of the oxide and from 0·2 to 3 p.c. non-volatile matter. It is used in pyrotechny, and the finer kind, especially the mineral, is made into pigment for artists.

It was formerly used as a deoxidising agent in the reduction of indigo blue, and in ammoniacal solution in silk-dyeing. A mixture of 9 orpiment and 1 quicklime made into a paste with water is used under the name of 'Rusma' for removing hair from skins, but is now generally replaced by the solution of sulphide of lime prepared from the spent lime gasworks.

Schultze (J. pr. Chem. 25, 431) considers that another form of the trisulphide exists which is soluble in water (*v.* COLLOIDS). For a description of its properties, *see* Dumanski, Zeitsch. Chem. Ind. Kolloide, 1911, 9, 262.

Arsenic pentasulphide As_2S_5. Berzelius in 1826 stated that this compound was formed when sulphuretted hydrogen is passed through a moderately concentrated solution of arsenic acid, but the precipitate was generally considered to be a mixture of the trisulphide and sulphur. Bunsen in 1878 showed that it was produced on passing a rapid current of sulphuretted hydrogen through a hot hydrochloric acid solution of an alkaline arsenate, and his results were confirmed by McCay in 1887 (*cf.* Brauner and Tomíček, Chem. Soc. Trans. 1888, 147; Travers and Usher, Chem. Soc. Trans. 1905, 87, 1370; and Foster, J. Amer. Chem. Soc. 1916, 38, 52).

Arsenic pentasulphide is totally insoluble in water, alcohol, or disulphide of carbon. The dry substance, on rubbing in a mortar, becomes strongly electrical.

Arsenic chloride. *Butter of arsenic. Caustic oil of arsenic* $AsCl_3$ is produced by the action of chlorine on arsenic; by distilling arsenic with mercuric chloride; by heating dry arsenious oxide with sulphur monochloride at 100°–125°: $As_4O_6+6S_2Cl_2=4AsCl_3+3SO_2+9S$, and by distilling arsenious oxide with strong hydrochloric acid. It is a colourless, oily liquid, of sp.gr 2·205 0°/4° boiling at 130·2° (Thorpe). A solution of arsenious oxide in strong hydrochloric acid loses arsenic on evaporation, but unless concentrated the loss by volatilisation is small. A *N*/10 solution of arsenious chloride, *N*/1 as regards acidity, may be concentrated to half-bulk without loss of more than one-thousandth part of the arsenic present.

Arsenic tri-iodide forms garnet to scarlet red hexagonal crystals: obtained by mixing arsenious oxide with iodine, and, after standing, extracting with carbon disulphide.

The chloride and iodide are used to a slight extent in medicine. H. W. H.

ARSENICALS, ORGANIC. HISTORICAL. The study of organo-arsenical compounds dates from the discovery of 'Cadet's fuming arsenical liquid,' a compound with an intolerable stench, and the singular property of spontaneous inflammability in air at ordinary temperatures to which L. C. Cadet de Gassicourt refers in his memoir on the production of sympathetic inks published in 1760. This liquid formed the distillate when equal parts of arsenious oxide and potassium acetate were heated in a glass retort. Guyton de Morveau, Morel, and Durande, who worked in Dijon, confirmed this discovery about eighteen years later, and in 1804 Thénard published further researches on the liquid (Ann. Chim. Phys. 30 Vendémiaire An. xiii. 1804, 52, 54), coming to the conclusion that the product was a complex acetate containing arsenic. The next important contribution to the subject was made in 1837 (Pogg. Ann. 1837, 40, 219; 42, 145; *v.* Annalen, 1837, 24, 27; 1839, 31, 175) when Robert Wilhelm Bunsen commenced his classical researches, which were carried on for a period of six years. He showed that the distillation product of arsenious oxide and potassium acetate contained the oxide of an arseniuretted radical, a group containing arsenic, carbon, and hydrogen which remained unchanged in composition when the oxygen was replaced by the halogens, sulphur or cyanogen. At first Bunsen supposed that the product contained no oxygen, and was C_2H_6As, and as this formula represents alcohol in which oxygen is replaced by arsenic, he adopted the name *Alkarsin* for the supposed arsenical analogue of alcohol. Berzelius suggested the presence of oxygen in Bunsen's 'Alkarsin' (*i.e.* the original distillate), and gave the name *Kakodyl* (Gr. kákos-odyl) to the compound radical which functioned as a 'compound element' in the series of reactions of 'alkarsin.' It is now evident that the distillate dealt with by the early workers must have contained, according to experimental conditions, varying amounts of cacodyl oxide and cacodyl, and this would account for the lack of uniformity in the interpretation of the results and for some temporary confusion in nomenclature. Further systematic investigation by Bunsen (Annalen, 1841, 37, 1–57; 1842, 42, 14–46; 1843, 46, 1–48) showed that the main constituent of Cadet's liquid is cacodyl oxide, which he was able to prepare in a pure state ('paracacodyl') by the hydrolysis of cacodyl chloride with potassium hydroxide. He also oxidised cacodyl oxide further to cacodylic acid (alkargen), and finally he isolated the radical cacodyl itself. The inner structure of the cacodyl radical was not investigated by Bunsen, but Frankland, Kolbé, and others have since shown that the radical may be regarded as tervalent arsenic associated with two methyl radicals. The cacodyl radical is $As(CH_3)_2$, and in the free state this univalent complex doubles on itself to give cacodyl $As_2(CH_3)_4$. Cacodyl oxide and cacodyl chloride have the structures:

$$\begin{matrix}CH_3\\CH_3\end{matrix}\!>\!As{-}O{-}As\!<\!\begin{matrix}CH_3\\CH_3\end{matrix}\qquad\begin{matrix}CH_3\\CH_3\end{matrix}\!>\!As{-}Cl$$

Arsenical compounds containing aromatic radicals were first investigated by Béchamp (Compt. rend. 1860, 50, 872; 51, 356; 1863, 55, 1172), who, studying the oxidising action of arsenic acid on aniline (*cf.* MAGENTA), noted that a colourless condensation product could be obtained. This substance functioned as a monobasic acid, and Béchamp assumed that the compound was an anilide of ortho- arsenic acid $C_6H_5{\cdot}NH\ AsO(OH)_2$.

Ehrlich and Bertheim have since shown (Ber. 1907, 40, 3292) that the product is *p*-aminophenylarsinic acid $NH_2{\cdot}C_6H_4{\cdot}AsO(OH)_2$. The sodium salt

$$NH_2{\cdot}C_6H_4{\cdot}AsO(OH){\cdot}ONa,xH_2O$$

(x=2–6 in various preparations) is the *Atoxyl* of therapeutics.

Ehrlich, who observed that aromatic compounds containing tervalent arsenic as distinct from the quinquevalent Atoxyl series had a more pronounced action in protozoal diseases, now instituted very extensive researches which, after 605 trials, culminated in the preparation of *Salvarsan*, or '606,' in 1910. *Neosalvarsan*, or '914,' was discovered in 1911, and both these substances have been highly successful in the arsenical treatment of syphilis.

More recent work has trended in the direction of increasing in these substances the trypanocidal power and reducing toxicity to the patient. Co-ordination compounds of salvarsan with heavy and noble metals have been investigated. *Luargol*, which has met with great success in the French Army, is a complex of salvarsan, silver bromide, and antimony. The preparation of primary arsines by Palmer and Dehn (Ber. 1901, 34, 3594) has prompted further researches on organo-arsenic compounds of therapeutic value. The discovery that the diazo- reaction could be applied to the synthesis of aromatic arsenicals has given a further impetus to the study of these compounds (Bart, D. R. P. 250264; Eng. Pat. 568, 1911).

CACODYL AND ITS MORE IMPORTANT DERIVATIVES (Bunsen, Annalen, 1842, 42, 14).

Cacodyl $[As(CH_3)_2]_2$, ***Tetramethyldiarsine***, a colourless, highly refractive liquid with intolerable smell; b.p. 170°; solidifies at −6°, forming square plates; vapour density 7·1; sparingly soluble in water, is prepared by treating cacodyl chloride with metallic zinc in an atmosphere of carbon dioxide. It inflames spontaneously in air, giving carbon dioxide, water, and arsenious oxide. It behaves as a univalent or tervalent radical combining with sulphur and the halogens.

Ethylcacodyl (*Tetraethyldiarsine*) $[As(C_2H_5)_2]_2$ an oil, b.p. 185°–190°, is produced, together with *triethylarsine* $As(C_2H_5)_3$, b.p. 140°, by the interaction of ethyl iodide and sodium arsenide; it yields, on oxidation, diethylarsinic acid, a soluble crystalline product (Landolt, Annalen, 1854, 89, 316; 92, 365). *Dimethyldiisoamylcacodyl* $(CH_3)_2As{\cdot}As(C_5H_{11})_2$, obtained by the following general method (Dehn, Amer. Chem. J. 1908, 40, 123):

$$R_2AsH+ClAsR'_2=HCl+R_2As{\cdot}AsR'_2$$

from a secondary arsine and a secondary arsenious chloride.

Cacodyl oxide $[As(CH_3)_2]_2O$, the main constituent of Cadet's liquid, is a heavy oil; sp.gr. 1·462/15°; b.p. 120°; solidifies at −25°; vapour density 7·55; sparingly soluble in water. It is prepared by distilling cacodyl chloride with aqueous potassium hydroxide, drying and redistilling in atmosphere of carbon dioxide (Baeyer, Annalen, 1858, 107, 282).

Cacodyl chloride $As(CH_3)_2Cl$, colourless liquid, heavier than water; b.p. 100°; vapour density 4·56; is insoluble in water. It has a penetrating, stupefying odour, and has a marked irritating action on the mucous membrane of the nose.

Concentrated hydrochloric acid and mercuric chloride are added successively to Cadet's arsenical liquid, and the resulting crystalline magma is liquefied by the addition of more hydrochloric acid and distilled. The distillate containing cacodyl chloride is purified by treatment with calcium carbonate to remove the acid, and with anhydrous calcium chloride to remove water.

Cacodyl cyanide $As(CH_3)_2CN$, colourless prisms; m.p. 33°; b.p. 140°; sublimes readily at ordinary temperatures to an exceedingly poisonous vapour. Is soluble in alcohol and ether, sparingly soluble in water. It is prepared by interaction between cacodyl and mercuric cyanide:

$$[As(CH_3)_2]_2+Hg(CN)_2=Hg+2As(CH_3)_2CN$$

Cacodyl sulphide $[As(CH_3)_2]_2S$, colourless oil; b.p. well above 100°; insoluble in water; miscible with ether and alcohol.

Cacodyl disulphide $[As(CH_3)_2]_2S_2$, white rhombic plates; m.p. 50°. *Cacodyl cuprisulphide* $Kd_2S,3Cu_2S$, lustrous octahedra.

Cacodylic acid. Dimethylarsinic acid.

$$As(CH_3)_2O{\cdot}OH,$$

(Bunsen, Annalen, 1843, 46, 2), inodorous colourless prisms; m.p. 200°; very soluble in water and alcohol. Is prepared by the oxidation of cacodyl oxide with mercuric oxide under water. It is very stable, not decomposed by the strongest oxidising agents; it forms crystallisable salts, certain of which have been used in medicine, including sodium cacodylate $KdO_2Na,3H_2O$ (Ph. Helv.).

Cacodyl trichloride $(CH_3)_2AsCl_3$ (Baeyer, Annalen, 1858, 107, 263), which crystallises from ether in prisms or leaflets, is very unstable, fumes in air, and decomposes at 40°–50° into *methylarsenious chloride* $CH_3{\cdot}AsCl_2$ and methyl chloride.

SYNTHESES OF ALIPHATIC ARSENICALS.

I. Interaction of an Alkyl Halide with an Alloy of Arsenic (Cahours, Compt. rend. 1859, 49, 87).

Methyl iodide reacts at 180° with zinc or cadmium alloys of arsenic, yielding double salts of the formulæ:

$$2As(CH_3)_4I,ZnI_2 \text{ and } 2As(CH_3)_4I,CdI_2$$

From these, tetramethylarsonium iodide is obtained by treatment with caustic alkali.

II. Interaction of an Alkyl Halide with Elemental Arsenic.

A modification of the first method by which the alkyl halide and arsenic are heated together in a sealed tube at 160°–200° (Cahours, Annalen, 1862, 122, 200). If amorphous arsenic be used the reaction may be brought about at ordinary temperatures (Martindale, Congress of Applied Chemistry, 1909). In either case a double salt, *e.g.* $As(CH_3)_4I,AsI_3$ is formed, and this, when decomposed by caustic potash, gives potassium arsenite, potassium iodide, and tetramethylarsonium iodide

III. Interaction of a Metallic Alkyl with an Arsenic Halide.

Zinc dimethyl reacts with arsenious chloride giving *trimethylarsine* (Hofmann, Jahresber. 1855, 538; Annalen, 1857, 103, 357).

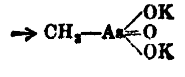
Mixed arsines may be prepared in this way: *e.g.* dimethylarsenious chloride reacts with zinc diethyl giving *dimethylethylarsine.*

The Grignard reaction—a special case of this method—affords an important means of preparation of organo-arsenic compounds (Hibbert, Ber. 1906, 39, 160). Arsenious bromide treated with excess of Grignard reagent (magnesium methyl iodide) yields *trimethylarsine.*

IV. Alkylation of Arsenical Oxy- Compounds.

In this process, due in the first place to G. Meyer (Ber. 1883, 16, 1440), but since generalised by Klinger and Kreutz (Annalen, 1888, 249, 147), and by Dehn and McGrath (Amer. Chem. J. 1905, 33, 138; 1906, 28, 351), sodium arsenite is treated with alkyl iodide in alkaline solution giving sodium alkylarsenate.

This synthesis, unlike the preceding methods, which require anhydrous solvents or an inert atmosphere, can be carried out in aqueous solutions under ordinary atmospheric conditions. Potassium methylarsinate is produced by mixing together potassium arsenite and methyl iodide in aqueous methyl alcoholic solution. After several days a white precipitate $2As_2O_3,KI$ is removed and potassium methylarsinate is obtained from the filtrate:



Dealkylation of Aliphatic Arsenicals.

This process, originally due to Baeyer (Annalen, 1858, 107, 282), who confirmed and extended Bunsen's work, is effected by converting cacodyl chloride into cacodyl trichloride by direct addition of chlorine and by distilling the trichloride, when methyl chloride is eliminated, and methylarsenious chloride CH_3AsCl_2 is produced. This monoalkylated arsenical is successively chlorinated and hydrolysed; the final product, methylarsinic acid, is a substance of therapeutic utility, having been employed in the form of its sodium salt $CH_3{\cdot}AsO(ONa)_2,H_2O$, arrhenal or new cacodyl (Auger, Compt. rend. 1903, 137, 925; Auger and Billy, *ibid.* 1904, 139, 599).

ALIPHATIC ARSENICALS.

Trimethylarsine $As(CH_3)_3$, liquid; b.p. 70°; synthesised by method III. (above). Is also prepared by distilling tetramethylarsonium iodide $As(CH_3)_4I$ with dry potassium hydroxide. Tetramethylarsonium iodide is a solid crystallising in colourless leaflets, which decompose at 170°-180°. It is synthesised by method II. (above).

Tetramethylarsonium hydroxide, obtained by the action of moist silver oxide on the iodide, is a strongly caustic soluble substance resembling sodium or potassium hydroxide.

Methylarsinic acid $CH_3{\cdot}AsO(OH)_2$, anhydrous colourless crystalline solid; m.p. 161°; soluble in water and alcohol; decomposes carbonates and forms an ammonium salt. The sodium salt, arrhenal or new cacodyl $CH_3{\cdot}AsO(ONa)_2H_2O$, has been used in medicine, as also have sodium dimethylarsinate (sodium cocodylate)

$$(CH_3)_2AsO_2Na,3H_2O$$

and corresponding salts of magnesium, iron, strychnine, guaiacol, and antipyrine.

Dimethylarsine $(CH_3)_2AsH$, colourless liquid with odour of cacodyl; b.p. 35·6°; spontaneously inflammable in air above 10° (Palmer, Ber. 1894, 27, 1378; Dehn and Wilcox, Amer. Chem. J. 1906, 35, 3).

Strong hydrochloric acid is dropped slowly on to a mixture containing crude cacodyl oxide, amalgamated zinc-dust and alcohol. The distillate is passed through a water wash-bottle and a soda lime tube to a condenser surrounded by a freezing mixture of ice and salt.

Methylarsine $CH_3{\cdot}AsH_2$ (Palmer and Dehn, Ber. 1901, 34, 3594), volatile, colourless, highly refractive liquid with odour of cacodyl; b.p. 2°; very poisonous, not spontaneously inflammable; practically insoluble in water; soluble in alcohol, ether, or carbon disulphide; is prepared by reducing methylarsinic acid with amalgamated zinc-dust and alcoholic hydrochloric acid with precautions similar to those taken in the preparation of dimethylarsine.

Arsenomethane $(CH_3{\cdot}As:As{\cdot}CH_3)_2$ (Auger, Compt. rend. 1904, 138, 1705), heavy yellow oil with garlic odour; b.p. 190°/13 mm. Is prepared by reducing sodium methylarsinate with sodium hypophosphite and sulphuric acid.

VOLATILE ARSENICAL COMPOUNDS FROM MOULDS.

It has been observed that wallpapers and carpets containing arsenical pigments have become a source of danger owing to the evolution of volatile arsenic compounds of a decidedly poisonous character. It is now known that the presence of certain moulds is a necessary condition for the production of such gases. These moulds, the most important of which is *Penicillium brevicaule*, evolve a volatile arsenic compound when cultivated in a medium containing sodium arsenite. Several observers have examined this phenomenon, and P. Biginelli has prepared fairly well-defined solid derivatives of the gas and thereby concludes that the gas itself is *diethylarsine* $(C_2H_5)_2AsH$ (Atti. R. Accad. Lincei, 1900 [v.] 9, ii. 210, 242), although his results have not yet been confirmed by the isolation of the secondary arsine itself.

SYNTHESES OF AROMATIC ARSENICALS.

Two general methods are due to Michaelis, who, in collaboration with many pupils, has given them a very wide application (Ber. 1876, 9, 1566; Annalen, 1880, 201, 184).

I. Interaction of the Arsenic Halide with a Diaryl Derivative of Mercury.

The mercury diaryl derivative is prepared by the action of sodium amalgam on the aryl bromide. The action of the mercury diaryl takes place in two stages. In the first, the *arylarsenic dihalide* is produced, *e.g.*

$$Hg(C_6H_5)_2+2AsCl_3=HgCl_2+2C_6H_5{\cdot}AsCl_2$$

If the action is carried further the diaryl arsenic halide is formed

$$Hg(C_6H_5)_2+2C_6H_5{\cdot}AsCl_2=2(C_6H_5)_2AsCl+HgCl_2$$

A modification of this method has been employed (Ber. 1914, 47, 2748), whereby the arylmercuric chloride is heated at 100° with arsenious chloride with the production of the arylarsenious chloride.

II. Interaction of Sodium with Chloroaryls and Arsenious Chloride (or the corresponding bromo- derivative).

This process is a modification of Fittig's synthesis of hydrocarbons, *e.g.*:

$$AsCl_3+3C_6H_5{\cdot}Cl+6Na=6NaCl+As(C_6H_5)_3$$

The tertiary arsine thus formed readily forms dihalides which on heating give secondary arsenic halides:

$$(C_6H_5)_3AsCl_2=C_6H_5{\cdot}Cl+(C_6H_5)_2AsCl$$

Primary derivatives can be formed by heating the tertiary arsine with arsenious chloride under pressure at 250°; the secondary compound is formed at the same time:

$$(C_6H_5)_3As+2AsCl_3=3C_6H_5AsCl_2$$
$$2(C_6H_5)_3As+AsCl_3=3(C_6H_5)_2AsCl \text{ (by-product)}$$

III. Grignard Reaction.

To the foregoing processes due to Michaelis this reaction adds a third method which has been applied with considerable success to the synthesis of triphenylarsine and its homologues.

IV. Diazo- Synthesis.

Aromatic primary amines are converted into the corresponding arylarsinic acids by treating the diazonium salt or alkali diazooxide with aqueous sodium arsenite with or without copper powder (Bart, D. R. PP. 250264; 254345).

AROMATIC ARSENICALS.

Phenylarsenious chloride $C_6H_5\cdot AsCl_2$ (La Coste and Michaelis, Ber. 1878, 11, 1883), colourless, highly refractive viscous liquid; b.p. 252°–254°; with pungent odour, more pronounced on warming; very irritating action on the skin.

Arsenobenzene $C_6H_5\cdot As:As\cdot C_6H_5$ (Michaelis and Schulte, Ber. 1881, 14, 912; 1882, 15, 1952), light yellow needles; m.p. 196°; insoluble in water or ether; sparingly soluble in alcohol; soluble in benzene, chloroform, or carbon disulphide. An alcoholic solution of phenylarsenious oxide is warmed with excess of crystallised phosphorous acid. The pasty product yields well-defined crystals from boiling xylene.

Phenylarsinic chloride $C_6H_5\cdot AsCl_4$ (Michaelis, Ber. 1877, 10, 622), flattened yellow needles, m.p. 45°; decomposes violently in water, dissociates on warming into the dichloride and free chlorine, the action being facilitated when conducted in a stream of dry carbon dioxide. At 150° it is decomposed completely into chlorobenzene and arsenious chloride.

Phenylarsinic acid $C_6H_5\cdot AsO(OH)_2$ (La Coste and Michaelis, Annalen, 1880, 201, 184; Michaelis, Ber. 1877, 10, 626), colourless prisms passing into the anhydride at 158°, soluble in absolute alcohol; very stable towards oxidising agents; on reduction gives phenylarsine (*q.v.*).

Diphenylarsenious chloride $(C_6H_5)_2AsCl$ (La Coste and Michaelis, Ber. 1878, 11, 1885; Annalen, 1880, 201, 215), well-defined colourless tabular crystals; m.p. 38°–41° (formerly described as a yellow oil). Slight odour, more pronounced on warming. Vapour very irritating to the skin. Alkalis hydrolyse it to *diphenylarsenious oxide*, crystalline aggregates; m.p. 91°–92°, and this product reduced with phosphorous acid furnishes *phenylcacodyl* $(C_6H_5)_2As\cdot As(C_6H_5)_2$ crystalline mass; m.p. 135°.

Diphenylarsinic acid $(C_6H_5)_2AsO\cdot OH$, colourless needles; m.p. 174°. Sparingly soluble in cold water, ether, or benzene, more soluble in hot water or alcohol.

Triphenylarsine $(C_6H_5)_3As$ (La Coste and Michaelis, *l.c.*), colourless plates from alcohol; m.p. 58°–60°; b.p. above 360° (without decomposition in carbon dioxide). Very soluble in ether or benzene, sparingly soluble in alcohol.

Triphenylmethylarsonium iodide

$$(C_6H_5)_3As(CH_3)\cdot I$$

pale yellow leaflets from alcohol; m.p. 176°. Soluble in alcohol or ether, sparingly soluble in water.

Tribenzylarsine $As(CH_2\cdot C_6H_5)_3$ (Michaelis and Paetow, Annalen, 1886, 233, 60; Paetow, Inaug. Dissert. Rostock, 1885), colourless monoclinic prisms from alcohol; m.p. 104°. Insoluble in water, sparingly soluble in alcohol; soluble in ether, benzene, and glacial acetic acid. Oxidised by hot dilute nitric acid to arsenic and benzoic acids. Obtained, together with its dichloride and dibenzylarsinetrichloride, by the action of sodium on arsenious chloride and benzyl chloride.

Dibenzylarsinic acid $(C_6H_5\cdot CH_2)_2AsO\cdot OH$ (*ibid.*), leaflets from alcohol; m.p. 210°, decomposing at higher temperatures; sparingly soluble in ether, acetone, or benzene; bitter salt taste and very irritating effect on the mucous membrane.

Benzylarsinic acid $C_6H_5\cdot CH_2\cdot AsO(OH)_2$ (*ibid.*); Dehn and McGrath, J. Amer. Chem. Soc. 1906, 28, 354), colourless needles; m.p. 167°.

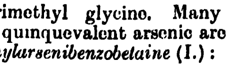
Benzylarsine $C_6H_5\cdot CH_2\cdot AsH_2$ (Dehn, Amer. Chem. J. 1908, 40, 113), light yellow liquid; b.p. 140°/260 mm.

p-*Benzarsinic acid* $CO_2H\cdot C_6H_4\cdot AsO(OH)_2$ (Michaelis, Annalen, 1902, 320, 303; Ber. 1915, 48, 870; Sieburg, Arch. Pharm. 1916, 254, 224; Bertheim, Ber. 1908, 41, 1854). This is a typical example of the carboxylated derivatives which can be obtained by oxidising arylarsinic acids containing methyl groups. This acid forms colourless plates, sparingly soluble in water, very sparingly so in alcohol and glacial acetic acid.

1. *p*-Tolylarsinic acid $(CH_3\cdot C_6H_4\cdot AsO(OH)_2)$ is treated with alkaline potassium permanganate in aqueous solution, the mixture being left for some days, when the filtrate is evaporated to dryness after acidifying with acetic acid; the residue, extracted with alcohol to remove potassium acetate, is then decomposed by concentrated hydrochloric acid when *p*-benzarsinic acid is deposited in well-defined crystals.
2. Oxidation of *p*-tolylarsinic acid by means of nitric acid in sealed tube at 170° for three hours gives a good yield of *p*-benzarsinic acid.
3. *p*-Arsanilic acid is diazotised in the presence of cuprous cyanide, the resulting *p*-cyanophenylarsinic acid, being hydrolysed by concentrated potassium hydroxide, furnishes *p*-benzarsinic acid. Its isomerides are similarly prepared.

BETAINES OF AROMATIC ARSENICALS (Michaelis, Annalen, 1902, 320, 297; *ibid.* 1902, 321, 174).

Ordinary naturally occurring betaine has the constitutional formula:



and is trimethyl glycine. Many analogues containing quinquevalent arsenic are known.

Trimethylarsenibenzobetaine (I.):

I.

II

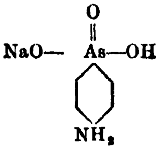
The hydrochloride of the triethyl compound corresponding with (I.), which was the first arsenical betaine to be prepared, is obtained by oxidising *p*-tolyltrimethylarsonium chloride with alkaline permanganate.

Triphenylarsenibetaine (II.). The betaine of the second type is produced by successively treating triphenylarsine with chloroacetic acid and alcoholic potash. Both these preparations have been generalised.

THE USE OF ORGANIC COMPOUNDS OF ARSENIC IN THERAPEUTICS.

Diseases of protozoal origin, such as 'sleeping sickness,' syphilis, &c., do not, in general, lend themselves to serum treatment, and certain antiseptics which are inimicable to the existence of the protozoal parasite are quite as injurious to the tissues of the more highly organised 'host.' Nevertheless, the protozoa are more sensitive to chemical treatment than are bacteria, which are much more highly resistant, and it has been shown that it is possible to treat certain protozoal diseases with antiseptics which react specifically with the protozoa, and are yet comparatively innocuous to the host. The treatment of malaria with quinine is a typical instance of this method. With a view to their use in this branch of therapeutics, organic derivatives of arsenic, as against inorganic preparations, have been extensively investigated, and the success which has attended their use seems to be due in part to their relatively low toxicity to the higher organism, their higher solubility, which probably increases their penetration, and their comparative stability, whereby only the small fractions needful for the destruction of the protozoa become decomposed in the body, the remainder passing through the body unchanged.

Atoxyl, Sodium-p-*arsanilate*, Syn. *Arsamin, Soamin, Natrium arsanilicum.*



This salt crystallises with 2–6 molecules of water, according to the solvent used in its preparation. The corresponding mercury salt, *Asyphil*, has been used for injections.

4-Aminophenyl-1-arsinic acid (p-*Arsanilic acid*)

A mixture of aniline (180 grams) and arsenic acid (140 grams) is heated gradually to 170°–200° in a vessel fitted with an efficient stirrer, the temperature being maintained at 190°–200° for one to two hours. The product rendered alkaline is distilled in steam to remove excess of aniline, filtered, and neutralised with hydrochloric acid when crude *p*-arsanilic acid separates on cooling. The product dissolved in aqueous caustic soda is decolourised with animal charcoal and filtered into alcohol when sodium *p*-arsanilate (atoxyl) crystallises. A by-product, *sodium 4 : 4′-diamino diphenylarsinate* remains dissolved in the alcohol (O. and K. Adler, Ber. 1908, 41, 932; Benda and Kahn, *ibid.* 1674, 2370; Pyman and Reynolds, Chem. Soc. Trans. 1908, 93, 1184).

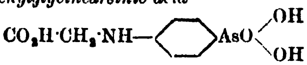
The foregoing condensation, due originally to Béchamp (*l.c.*), has more recently been generalised and extended to the case of the homologues of aniline containing a free para-position with respect to the amino- group (D. R. P. 219210; Eng. Pat. 14937, 1908; U.S. Pat. 913940, 1909; Welcome and Pyman, Eng. Pat. 855, 1908; Adler, Ber. 1908, 41, 931; Benda and Kahn, *ibid.* 1672). Aromatic primary amines substituted in the para-position are also amenable to the Béchamp reaction, but with the exception of *p*-nitroaniline the yields of orthoamino arsinic acids are small (Benda, Ber. 1909, 42, 3621; 1911, 44, 3294; D. R. P. 243693; Eng. Pat. 29196, 1911).

Phenol and its homologues containing free para- positions with respect to the hydroxyl group also undergo the Béchamp condensation with arsenic acid with the formation of *p*-hydroxyarsinic acids (D. R. P. 205616).

Ehrlich and Bertheim's demonstration that atoxyl was the sodium salt of *p*-amino-phenylarsinic acid rather than the anilide of arsenic acid, and that therefore atoxyl was a true organic arsenical, suggested numerous significant possibilities of syntheses, many of which have since been realised, the aim in general being directed to improvements in stability and specific action. For instance, the amino-group may be acetylated, benzoylated, or replaced by halogen or hydroxyl, or a substituted amine can be used in the initial stage of the synthesis instead of aniline. As an example of this procedure may be cited the acetylation of atoxyl, whereby a derivative is obtained which, while just as toxic to trypanosomes, is more stable and much less toxic to the host than atoxyl. This derivative:

is known as *arsacetin*, or acetylatoxyl (contains 3–4 H_2O). Large numbers of similar derivatives have been prepared, some of which have assumed commercial importance. *Benzenesulphonylatoxyl*, termed *Hectine*, has been employed in therapeutics.

Phenylglycinearsinic acid



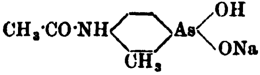
and its homologues are less toxic than atoxyl, the glycine group, which resists hydrolysis in the organism, being much more firmly attached than the acetyl group.

Atoxyl is digested with aqueous chloracetic acid in a reflux apparatus for 6–8 hours, the crystalline glycine derivative being freed from unchanged arsanilic acid by washing with dilute hydrochloric acid.

Other aromatic primary amines yield derivatives analogous to those obtained from aniline.

Sodium 2-aminotolyl-5-arsinate, '*Kharsin*,' obtained by extending the Béchamp reaction to *o*-toluidine, crystallises with 3½–5 H_2O.

Sodium acetyl-2-aminotolyl-5-arsinate '*Orsudan*' (Wellcome and Pyman, Eng. Pat. 855, 1908):



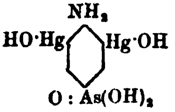
5 or 7 H_2O

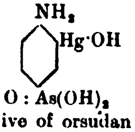
produced by acetylating the preceding compound, has also been used in protozoal diseases.

The fact that the treatment of certain protozoal diseases with azo- dyes has met with considerable success has led to the attempt to prepare dyes from the diazotisable *p*-arsanilic acid, and a number of monoazo- and polyazo-dyes have been prepared, which in the main are less toxic to the host than atoxyl and more so to protozoa.

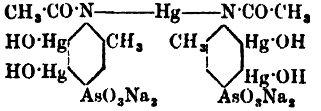
The promising results arising from the joint arsenical and mercurial treatment of syphilis suggested attempts to combine the beneficial effects in one drug, and several derivatives have been prepared which possess the anticipated properties to a more or less degree.

3 : 5-Dihydroxymercuri - 4 - aminophenylarsinic acid and 3-hydroxymercuri-4-aminophenyl arsinic acid are two well-defined examples

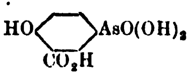




The hydroxymercuric derivative of orsudan known as '*Hydryl*,' has also given promising physiological tests :—



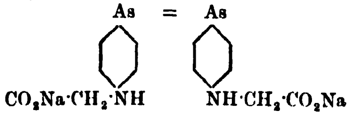
Enesol is the mercury derivative of salicyl-4-arsinic acid :



and has been employed successfully in the treatment of syphilis.

Tervalent arsenic derivatives are therapeutically of greater value than the corresponding quinquevalent derivatives, from which they are obtained by reduction.

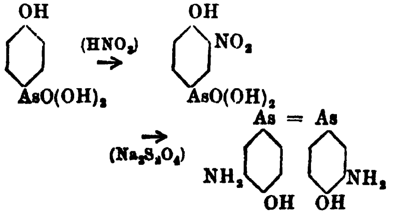
Phenylglycinearsinic acid (*q.v.*) yields *arsenophenylglycine* in reduction with sodium hydrosulphite. Its *sodium* salt, under the name *Spirarsyl* (No. 418 in Ehrlich's series) :



has been used, and is a decided improvement on atoxyl, having less toxicity for the host and greater trypanocidal power.

Similarly *p*-hydroxyphenylarsinic acid yields *p*-arsenophenol on reduction, and the fact that these substances had been used with good results in trypanosomiasis in mice led Ehrlich to prepare and examine many substances of similar constitution.

Salvarsan (Syn. *Kharsivan, Arsenobenzol, Arsenobillon, Ehrlich* 606). 3 : 3-′*Diamino*-4 : 4′ *dihydroxyarsenobenzene*, *p*-hydroxyphenylarsinic acid is successively nitrated and reduced with alkaline sodium hydrosulphite and magnesium chloride, two molecules of the compound uniting in the reduction, according to the following equation :



The foregoing *p*-hydroxyphenylarsinic acid is obtained either from *p*-arsanilic acid through the diazo- reaction, by boiling the diazo- compound with water, or directly from arsenic acid and phenol, by extending the Béchamp reaction to the latter compound.

Salvarsan can also be prepared by starting from dimethylaniline. This base, treated with arsenious chloride, yields p-*dimethylaminophenylarseniousdichloride*, oxidation of the chloride leads to p-*dimethylanilinearsinic acid*, which, on nitration, gives 3-*nitro*-4-*dimethylaminophenylarsinic acid*. The nitro- compound, on warming with 40 p.c. aqueous caustic soda, gives rise to 3-nitro-4-hydroxyphenylarsinic acid, which is reduced as above. This nitro-hydroxy compound is also obtainable by putting *p*-chloroaniline through the Bart process and successively nitrating and hydrolysing the resulting *p*-chlorophenylarsinic acid.

The crude moist preparation of salvarsan base is dissolved in methyl alcohol, and its dihydrochloride precipitated by the successive addition of methyl alcoholic hydrochloric acid and ether, and is dried in an inert atmosphere. The free base is insoluble in water or in physiological salt solution, and it does not form neutral salts, since it is an amphoteric substance, being feebly basic and having also phenolic properties.

These characteristics constitute a drawback to its utility for intravenous injections and in practice the hydrochloride has to be very carefully neutralised immediately before use by means of sodium hydroxide.

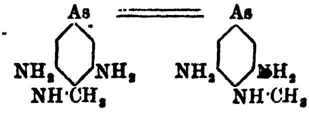
There are nine possible symmetrically constituted isomerides of salvarsan, and the following five have been obtained :—

4 : 4′	-diamino-	3 : 3′	dihydroxyarsenobenzene
2 : 2′	„	3 : 3′	„
2 : 2′	„	5 : 5′	„
4 : 4′	„	2 : 2′	„
5 : 5′	„	2 : 2′	„

In no case is the isomeride comparable in therapeutic value with salvarsan. The methylation of salvarsan increases the toxicity of the compound to the host and diminishes the trypanocidal value, *e.g.* the hexamethyl derivative is 3–5 times as toxic as the unmethylated compound, and is inactive with regard to the protozoa. Carboxylation leads to similar tendencies. Many other salvarsan derivatives have been prepared and examined.

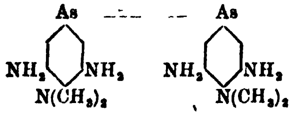
Certain polyaminoarsenobenzenes are already of considerable therapeutic importance, and significant developments in this direction seem likely. Among these salvarsan analogues the following are noteworthy :—

4 : 4′ *Dimethyl*-3 : 4 : 5 : 3′ : 4′ : 5′-*hexaminoarsenobenzene*



has low toxicity towards human beings and high trypanocidal powers.

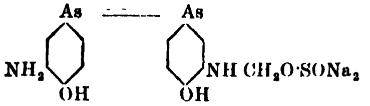
4 : 4′-*Tetramethyl*-3 : 4 : 5 : 3′ : 4′ : 5′-*hexaminoarsenobenzene*



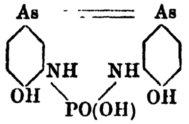
and the corresponding ethyl derivative have similar properties. These bases have the remarkable property of dissolving in soluble bicarbonates, giving rise to stable complex carbamates precipitated from aqueous solution by alcohol or acetone.

Certain limitations in the usefulness of salvarsan have already been mentioned. The drug (dihydrochloride) does not give rise to neutral solutions, and accordingly its application is lacking in simplicity. The replacement of an atom of hydrogen in one of the amino-groups of salvarsan by a methylenesulphinic group confers sufficient acidity on the molecule to enable soluble neutral and stable alkali salts to be prepared. The introduction of the methylenesulphinic group into the hydrochloride of salvarsan is brought about by the action of sodium formaldehydesulphoxylate followed successively by sodium carbonate solution and hydrochloric acid.

Sodium-3 : *3′-diamino*-4 : *4′-dihydroxyarsenobenzene*-N-*methylenesulphinate, Neo-salvarsan* is the sodium salt of the acid thus produced



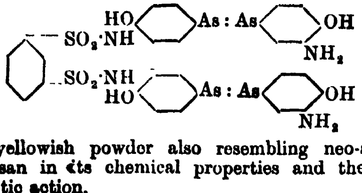
The product is a pale-yellow powder giving a neutral aqueous solution. Its curative effect closely resembles that of salvarsan. The *phosphamic* acid derivative of salvarsan, first prepared by Mouneyrat, is also an acidic substance yielding neutral solutions in aqueous sodium carbonate. It is known as *Galyl* (No. 1116 of Mouneyrat's series), and its constitution is as follows:—



(4 : *4′-Dihydroxyarsenobenzene*-3 : *3′-phosphamic acid*).

Ludyl (' 1151 ' of Mouneyrat's series).

Benzene-m-3′ : *3′-disulphamino-bis-3-amino*-4 : *4′-dihydroxyarsenobenzene*



a yellowish powder also resembling neo-salvarsan in its chemical properties and therapeutic action.

Co-ordination compounds of metals with arsenoaryl compounds were first discovered and investigated by Ehrlich, who made known his results at the International Congress of Medicine held in London in 1913. Danysz shortly afterwards made similar observations, and since the first communication was made a very large number of these complexes have been prepared and examined. The arsenoaryls giving the best results so far are arsenobenzene, salvarsan, and neosalvarsan, and of these the copper co-ordination compounds are isolated most readily, whilst the silver co-ordination compounds show the greater promise in therapeutics.

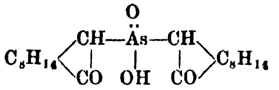
The most important of these compounds so far produced is that derived from salvarsan, silver bromide, and antimony. It is the silver bromide antimonyl sulphate co-ordination compound of salvarsan having the formula:

$$[C_{12}H_{12}O_2N_2As_2]_2AgBr,SbO(H_2SO_4)_2.$$

The name *Luargol* has been given to this substance, and it promises to be very efficacious in protozoal diseases, having much more marked trypanocidal properties than salvarsan, with no increase in toxicity. Luargol is insoluble in water, and is rendered soluble by caustic soda (0·4 gram of NaOH to 1·0 gram of drug). It is preferably injected intravenously, ill-effects are produced by subcutaneous application.

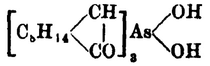
MISCELLANEOUS ORGANIC DERIVATIVES OF ARSENIC.

Dicamphorylarsinic acid



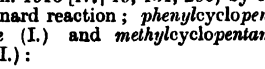
A condensation product of sodium, camphor and arsenic trichloride, consists of colourless transparent prisms; m p. 266° (with decomposition); $[\alpha]_D^{20}+186{\cdot}6°$; practically insoluble in water or petroleum, more soluble in benzene, freely soluble in chloroform or alcohol (Morgan and Micklethwait, Chem. Soc. Trans. 1908, 93, 2146; 1909, 95, 1476; Morgan and Moore, Chem. Soc. Trans. 1910, 97, 1699).

Tricamphorylarsinic acid



is obtained from the final mother liquors of the above preparation after systematic fractionation, the ultimate product being a brown amorphous solid very soluble in benzene, alcohol, or acetic acid, and recovered from these solvents as a viscid mass (Morgan and Micklethwait, *l.c.*).

Cyclic derivatives of arsenic have been obtained recently (Grüttner and Wiernik, Ber. 1915, 48, 1473; 1916, 49, 437; Lappe, Bull. Soc. chim. 1916 [iv,] 19, 151, 290) by employing the Grignard reaction; *phenyl*cyclo*pentamethylenearsine* (I.) and *methyl*cyclo*pentamethylenearsine* (II.):



$$CH_2<\begin{matrix}CH_2\cdot CH_2\\ CH_2\cdot CH_2\end{matrix}>As\cdot C_6H_5$$

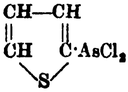
I.

$$CH_2<\begin{matrix}CH_2\cdot CH_2\\ CH_2\cdot CH_2\end{matrix}>As\cdot CH_3$$

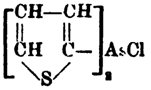
II.

Arsenical derivatives of thiophen may be synthesised by the use of organo-mercury compounds as employed by Michaelis in his earlier work (Michaelis, Annalen, 1880, 201, 196; 1902, 320, 272).

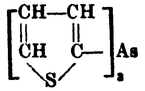
Thienylarsenious chloride (I.), *Dithienylarsenious chloride* (II.), and *Trithienylarsine* (III.):



I.



II.



III.

are obtained as successive fractions from the filtrate when arsenious chloride and mercuridithienyl are allowed to react under carefully regulated conditions (Steinkopf, with Banermeister, Annalen, 1917, 413, 331).

This reaction was first studied by Finze and Furlotti (Gazz. chim. ital. 1915 [ii.] 45, 280, 290 who oxidised the two chloro- compounds to the corresponding *thienylarsinic* and *dithienylarsinic acids*.

Strontium chloroarsinobehenolate

$$Sr(C_{22}H_{39}O_3AsCl)_2,$$

a colourless amorphous precipitate introduced into pharmacy under the name of *Elarson*, and giving good clinical results in anæmia, is prepared by heating together behenolic acid and arsenious chloride at 140°, the additive compound being then treated successively with aqueous caustic alkali and methyl-alcoholic strontium chloride containing ammonia. In this process arsenious chloride is added to the triple linking of behenolic acid (E Fischer, Annalen, 1914, 403, 109)

$$-C\equiv C- \rightarrow -\underset{\displaystyle Cl}{\underset{|}{C}}=\underset{\displaystyle AsCl_2}{\underset{|}{C}}- \rightarrow -\underset{\displaystyle Cl}{\underset{|}{C}}=\underset{\displaystyle AsO}{\underset{|}{C}}-$$

Protein combinations containing arsenic.—Insoluble combinations containing firmly attached arsenic which does not give the ordinary analytical reactions of the element are produced by dissolving albumin from white of egg in acetic anhydride, and by adding successively to the solution phosphoric anhydride and arsenious chloride. The protein precipitate is freed from phosphoric and arsenious acids by washing with water (Guezda, D. R. P. 201370).

Arsenical preparations insoluble in the gastric juices are produced by adding arsenious chloride to gliadin or glutenin suspended in alcohol. The final product is soluble in hot water and contains 4·3 p.c. of arsenic (D. R. P. 214717).

Soluble stable combinations of salvarsan base and proteins have been recommended for use in therapeutics (D. R. P. 261542); they are prepared by dissolving in alkali the additive compounds of salvarsan, and the alkali salts of lysalbic and protalbic acids or similar protein acids. The reacting alkali salts are precipitated by alcohol-ether or obtained by concentration *in vacuô*.

THE USE OF ORGANIC ARSENICALS IN CHEMICAL WARFARE.

The organic arsenicals chiefly employed in the chemical offensive of the Great War were aromatic arsenicals containing tervalent arsenic. These compounds had very disagreeable physiological properties and functioned as lachrymators, sternutators and respiratory irritants. *Diphenylarsenious chloride* (*diphenylchloroarsine*) possessed these irritating properties in a very marked degree. It was prepared for this purpose by heating triphenylarsine (2 mols.) and arsenious chloride (1 mol.) at 300° in autoclaves. The by-product of this reaction, *phenylarsenious chloride*, was also a respiratory irritant and had a vesicating action on the skin. It was separated by fractional distillation from diphenylarsenious chloride.

Alternatively phenylarsinic acid was prepared from sodium arsenite and benzenediazonium chloride in presence of copper sulphate (Bart's reaction). This acid, reduced with sulphurous acid in the presence of hydrochloric acid, gave rise to phenylarsenious chloride. The latter compound dissolved in aqueous sodium hydroxide and treated with benzenediazonium chloride furnished diphenylarsinic acid, which on reduction with sulphurous and hydrochloric acids yielded diphenylarsenious chloride. The overall yield by these processes varied between 24 and 36 per cent. The foregoing repetition of the Bart reaction was avoided by a combination of the Michaelis and Bart method leading to diphenyl-arsenious chloride when triphenylarsine is heated to 300° with phenylarsenious chloride.

Diphenylarsenious cyanide $(C_6H_5)_2As\cdot CN$, of which large quantities were employed in the later stages of the war, was manufactured by digesting diphenylarsenious chloride with a warm concentrated aqueous solution of sodium or potassium cyanide. It was obtained in colourless crystals melting at 31°.

The aromatic arsenicals containing quinquevalent arsenic, such as triphenylarsine dichloride, when vapourised by heat, behaved as sternutators and respiratory irritants; but this effect was probably due to the formation of compounds of tervalent arsenic akin to diphenylarsenious chloride. The corresponding organic antimonials, although irritant and lethal, offered no advantages over the aromatic arsenicals.

The aliphatic arsenicals of the cacodyl and alkyl arsenious chloride series were found to be respiratory irritants and lethal agents, methylarsenious chloride, ethylarsenious chloride and cacodyl cyanide being among the most toxic. Methylarsenious chloride was manufactured in America by methylating sodium arsenite with dimethyl sulphate, reducing the resulting sodium methylarsinate to methylarsenious oxide, and treating this oxide with hydrogen chloride. Ethylarsenious chloride, manufactured at Höchst and Ludwigshafen, was prepared by a similar series of processes, starting from sodium arsenite and ethyl chloride (Journ. Indust. Engin. Clem. 1919, 11, 105, 826). But on the whole these aliphatic derivatives were not more effective in producing casualties than the above-described aromatic arsenicals.

Bibliography.—Organic Compounds of Arsenic and Antimony, G. T. Morgan. London. 1918. Handbuch der Organischen Arsenverbindungen, A. Bertheim. Stuttgart. 1913. Die Aromatische Arsenverbindungen, H. Schmidt.

Berlin. 1912. Dir Arzneimittel Synthese, S. Fraenkel. Berlin. 1912, 603. Salvarsan or '606' (Dioxydiaminoarsenobenzol). Its Chemistry, Pharmacy, and Therapeutics. (W. H. Martindale. London. 1911.) Chimie et toxicologie de l'arsenic et de ses composes.' A Valeure. Paris. 1904. G. T. M.

ARGATOXYL. Silver-*p*-aminophenyl arsenate.

ARGOCHROM. Silver methylene blue.

ARSALYTE. Dimethyl amino tetramido arsenobenzene.

ARSAMINAL. Japanese name for salvarsan.

ARSENICAL PYRITES or *Arsenical mundic.* Names commonly used by miners for the mineral *mispickel* (*q.v.*) or *arsenopyrite* (FeAS), which is the principal ore of arsenic.

ARSENIC MOULD. *Penicillium brevicaule.* This organism, first obtained by Gosio, in presence of an arsenic compound, forms *diethylarsine* $AsH(C_2H_5)_2$, to which the poisonous gas developed by wall-papers containing arsenic is probably due. The formation of diethylarsine by the action of this mould has been used as a test for arsenic by Markmann (Chem. Zentr 1900, ii. 1187); Galli-Valerio and Strzyzowski (*ibid.* 1901, i. 63).

Penicillium brevicaule also gives garlic or mercaptan-like odours with compounds of selenium and tellurium (Maassen, Chem. Zentr. 1902, i. 1245).

ARSENOFERRATIN. Sodium arseno-ferri-albuminate.

ARSENOGENE. Trade name for an albuminous preparation of arsenic and iron obtained by heating peptonised casein with arsenic acid and ferric ammonium sulphate. Used in medicine (Salkowski, Apoth. Zeit. 1908, 23, 114).

ARSENOPYRITE *v.* Mispickel.

ARSENOTRIFERRIN. Iron arseno-*p*-nucleinate.

ARSEN-PHENOLAMINE. Syn. for salvarsan. *See* Arsenicals, Organic.

ARSINE. *Arsenic trihydride* (*v.* Arsenic).

ARSINOSOLVINE. Sodium salt of amino phenylarsenic acid.

ARSPHENAMINE. U.S. Pharm. title for salvarsan.

ARTARINE $C_{21}H_{23}O_4N$, m.p. 240°, is an amorphous alkaloid from Ar ar-root of *Xanthoxylon senegalense.* The hydrochloride $B,HCl,4H_2O$ forms yellow needles, very little soluble in water (Giacosa and Soave, Gazz. chim. ital. 1889, 19, 303).

ARTEMISIN. An alkaloid isolated by Merck from the mother liquors obtained in the preparation of santonin from the seeds of *Artemisia maritima.* Forms colourless crystals; m.p. 200°; sparingly soluble in water, more soluble in alcohol; $[\alpha]_D -84{\cdot}3°$. With hot soda solution gives a carmine-red solution, colourless on cooling. Gives an oxime with hydroxylamine, and a hydrazone with phenylhydrazine (Bertolo, Pharm. J. 1902, 489; Freund and Mai, Ber. 1901, 3717; *cf.* Wedekind and Koch, Ber. 1905, 1845)(*v.* Santonica).

ARTERENOL. Trade name for *o*-Dihydroxyphenylaminomethyl carbinol hydrochloride. *V.* Adrenaline.

ARTICHOKE. Three vegetables are known by this name: (1) the Globe artichoke—the flower head of *Cynara scolymus*; (2) the Jerusalem artichoke—the tuber of *Helianthus tuberosus*; (3) the Japanese or Chinese artichoke—called also Chorogi—the tuber of *Stachys tuberifera.*

The following are analyses of the tubers of the two latter:—

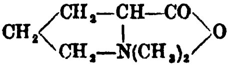
	Water	Protein	Fat	Carbohydrates	Ash
Jerusalem artichoke . .	79·5	2·6	0·2	16·7	1·0
Stachys tuberifera	78·05	4·32	0·16	14·63	1·21

(Strohmer and Stift, Bied. Zentr. 21, 820.)

The 'protein' of the Jerusalem artichoke includes much material other than true proteid; the carbohydrates consist largely of inulin and levulin.

According to Tanret (Compt. rend. 1893, 117, 50), two other carbohydrates—*helianthenin* m.p. 176°, $12C_6H_{10}O_5+3H_2O$, and *synanthrin*, m.p. 170°, $8C_6H_{10}O_5+H_2O$—are also present, and the levulin or synanthrose described by other observers as occurring in artichokes, is a mixture of saccharose and synanthrin.

The tubers of *Stachys tuberifera* contain many nitrogenous substances of an amide nature—*glutamine, tyrosine, arginine, choline, trigonelline,* and the characteristic body, *stachydrine*



The amount of the last-named is estimated at 0·18 p.c. of the dry substance (Schulze and Trier, Zeitsch. physiol. Chem. 1910, 67, 59). The characteristic carbohydrate is *stachyose* $C_{18}H_{32}O_{16},3H_2O$ (*q.v.*). H. I.

ARTOCARPUS BARK. The inner bark (bast) of the bread-fruit tree [*A. incisa* (Linn.)] is used by the South Sea Islanders for making ropes and clothing. According to Moeller (Dingl. poly. J. 231, 463), this fibre would probably be a very useful one. It can be obtained in large quantities.

ARTOCARPUS INTEGRIFOLIA (Linn. f.). (*Jack Tree*) *v.* Jackwood; Dyes, Natural.

ARUM MACULATUM (Linn.). The common arum, 'wake robin,' or 'lords and ladies,' 'cows and calves,' formerly known as 'abron' janus, 'ramp,' 'starch wort,' contains a starch which was made into a kind of arrowroot in the Isle of Portland, and was the active ingredient of 'Portland powder,' a so-called specific for gout. Occasionally sold in Paris as a cosmetic, under the name of *poudre de Cypre.*

Amorphophallus campanulatus (Blume) is used in India as a vegetable and also in medicine, as are other of the Arums. Many of the Aroideæ act as poisons, their toxic action being due apparently to the irritation induced by the raphides contained in the cells (Pedler and Warden, Jour. Asiatic Soc. of Bengal, 57, 2, 106; Stahl; Pflanzen und Schnecken, Zeitsch. Nat. u. Med. Jena, xxii. N. F. xv. 1888).

ASAFŒTIDA *v.* Gum resins.

ASAPROL *v.* Abrastol.

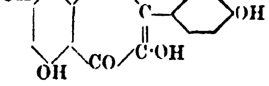
ASARUM CANADENSE (Linn.). A plant indigenous to North America, where it is known by the names of 'Wild Ginger,' or 'Canada Snake-root.' The rhizome yields on distillation an essential oil used in perfumery, containing a phenol $C_9H_{12}O_2$, *d-* and *l-* pinene, *d*-linalool, -borneol, *l*-terpineol, geraniol, eugenol methyl ether, a lactone $C_{14}H_{26}O_2$, a mixture of fatty acids, including palmitic and acetic, and a blue oil of undetermined composition, consisting of oxygenated substances of alcoholic nature (Power and Seed, Chem. Soc. Trans. 1902, 81, 59).

ASBARG. Asbarg consists of the dried flowers and flowering stems of the *Delphinium zalil*, which is found in great quantity in Afghanistan. The dyestuff is collected and taken to Multan and other Punjab towns, from which it is conveyed all over India. It is or was much used in silk-dyeing for the production of a sulphur-yellow colour known as 'gandkaki,' and, together with *Datisca cannabina*, to obtain a similar shade on alum-mordanted silk; it is also used in calico-printing. The flowers, which are bitter, are likewise employed medicinally as a febrifuge.

The colouring matters of asbarg are present entirely as glucosides, and are best isolated in the crude condition by digesting the boiling aqueous extract with a little sulphuric acid (Perkin and Pilgrim, Chem. Soc. Trans. 1898, 268). A brownish-yellow powder thus separates, which contains three substances: *isorhamnetin*, *quercetin*, and *kaempferol*.

Iso*rhamnetin* $C_{16}H_{12}O_7$, the sparingly soluble constituent, forms yellow needles, resembling rhamnetin in appearance. With lead acetate in alcoholic solution, an orange-red precipitate is formed, whilst ferric chloride gives a greenish-black colouration. Fused with alkali, *phloroglucinol* and *protocatechuic acid* are produced, and when air is aspirated through its alkaline solution, *phloroglucinol* and *vanillic acid* are obtained.

With acetic anhydride *iso*rhamnetin gives a *tetra-acetyl* derivative $C_{16}H_8O_7(C_2H_3O)_4$, colourless needles, m.p. 195°–196°; and with methyl iodide a *trimethyl ether*, which is identical with *quercetin tetramethyl ether*. As, moreover, by the action of hydriodic acid *iso*rhamnetin yields quercetin, its constitution can only be represented as follows:—



The dyeing properties of *iso*rhamnetin are similar in character to those given by kaempferol. *iso*Rhamnetin is also present in yellow wallflowers (*Cheiranthus cheiri*) (Perkin and Hummel), and in red clover flowers, *Trifolium pratense* (Power and Salway, Chem. Soc. Trans. 1910, 97, 245). A description of the more soluble colouring matters quercetin (*quercitron bark*) and kaempferol (*Delphinium consolida*) is given elsewhere.

In dyeing properties asbarg closely resembles quercitron bark, but yields with aluminium mordant a purer or less orange-yellow. It is, however, a much weaker dyestuff, having but 35 p.c. the dyeing power of quercitron bark. The colouring matter of the flowers, apart from the flowering stalks, is present to the extent of 3·47 p.c.

The stems and flowers of the *D. saniculæfolium* gives shades analogous to, though somewhat weaker than, those yielded by the *D. zalil*.

A. G. P.

ASBESTOS, from ἄσβεστος, 'unquenched.' Both in ancient and modern times various silicate minerals, closely resembling one another in their finely fibrous texture and flexibility, have been and are still confused under this name. The same is true also of the name 'amianthus' or 'aminatos' (ἀμίαντος, 'undefiled,' because not injured by fire). They are, therefore, collective names of no more definite signification than the adjective 'asbestiform.' Mineralogists are, however, agreed in limiting the name asbestos to the fibrous forms of hornblende, but this limitation is not generally observed. Any ambiguity may be avoided by using the terms amphibole-asbestos (or hornblende-asbestos), serpentine-asbestos, &c., for these asbestiform minerals. The finely fibrous texture is, of course, an accidental character of the mineral species, depending on the enormous elongation in one direction of the individual crystals which form the aggregate. Such a character might, indeed, be assumed by many kinds of minerals; but it is only the following that are of any importance in this connection:—

Tremolite, $CaMg_3(SiO_3)_4$.
Actinolite, $Ca(Mg,Fe)_3(SiO_3)_4$.
Crocidolite, $NaFe'''(SiO_3)_2 \cdot Fe''SiO_3$.
Anthophyllite, $(Mg,Fe)SiO_3$.
Serpentine, $H_4Mg_3Si_2O_9$.
Palygorskite group (pilolite, &c.), $\left\{ \begin{array}{l} nH_8Mg_2Si_3O_{12} \\ mH_2Al_2Si_4O_{12}, 5H_2O. \end{array} \right.$

The first two of these differ only in the relative proportions of the mutually replaceable magnesium and ferrous iron (and consequently also in their colours, which are white and green respectively), and they are merely varieties of the species amphibole or hornblende. Crocidolite is another species of the amphibole group of minerals, crystallising in the monoclinic system, and also with an angle of 56° between its prismatic cleavages. It is known in the trade as 'blue asbestos,' and it gives the name to the Asbestos Mountains in South Africa, where it is found. Whilst hornblende is more frequently found as stout crystals and compact masses, crocidolite, on the other hand, is as yet known only in the finely fibrous form. Anthophyllite also belongs to the amphibole group, but is orthorhombic in crystallisation. Some of the asbestos mined in the United States (Georgia and Idaho) is of this kind. Serpentine occurs in nature as large rock-masses, and the compact rock is frequently traversed by veins of fibrous material of the same composition; the latter is known to mineralogists as *chrysotile*, and in the trade as 'asbestos' or 'Canadian asbestos.' In the minerals of the palygorskite group (A. E. Fersman, Bull. Acad. Sci. St. Petersburg, 1908, ii, 255, 637) the fibres rarely show a parallel arrangement, but are more usually matted and interwoven, giving felted masses known as 'mountain-leather,' 'mountain-cork,' and 'mountain-wood.' It is, however, to be remembered that these trivial names may also be applied to similar aggregates of fibrous amphibole.

From a practical point of view, the most important of these are *tremolite-asbestos* and *serpentine-asbestos*, which in the trade are known as 'Italian asbestos' and 'Canadian asbestos' respectively. The former is met with as aggregates or bundles of white or greyish fibres, sometimes several feet in length, usually arranged parallel to the surfaces of crevices in the metamorphic and crystalline rocks of mountainous districts. It is mined in the Alps, Urals, and Appalachians. The supply is limited and uncertain, and the hardness of the enclosing rocks makes mining difficult. The principal mines are those in the north of Italy, in the Susa and Aosta valleys in Piedmont, and the Valtellina in Lombardy. These are, however, now of little importance, since the use of hornblende-asbestos has been largely replaced by serpentine-asbestos.

Serpentine-asbestos, or chrysotile, occurs in small veins forming an irregular network in serpentine-rock. It has in the closely compacted mass an oil-yellow or greenish colour with a pronounced silky lustre and a certain degree of translucency. When rubbed or crushed, it readily separates into white cottony fibres (pierre à coton of the French-Canadians). The fibres are arranged perpendicularly to the walls of the vein, and are usually only an inch or two in length, never exceeding 6 inches. The mineral usually contains 2-3 p.c. FeO isomorphously replacing magnesia. Chrysolite is found at all the localities where serpentine-rock occurs (*e.g.* the Lizard district in Cornwall), and it is extensively mined in Canada, Russia, South Africa, and the United States. Of these the most important are the Canadian deposits, which have been worked since 1878. The mining districts are near the villages of Thetford, Black Lake, East Broughton, and Danville in Quebec; and extend over the United States border into Vermont. The mineral is also mined in Arizona and California. In Russia, the principal deposits are in the Ural Mountains, in the neighbourhood of Ekaterinburg and Orenburg; and there are others in the Caucasus. Recently, rich deposits have been opened up in Rhodesia in the Victoria and the Gwelo districts, and in the Caroline district in the Transvaal. The asbestos quarried by the ancients at Karystos in Eubœa (Karystian stone), and in Cyprus, was also a serpentine-asbestos (J. W. Evans, Mineral. Mag. 1906, xiv, 143; Geol. Mag. 1909, vi, 286). He suggests the name *Karystiolite* as an alternative for chrysotile, owing to its confusion with chrysolite—a synonym of olivine). It was used for wicks in the perpetually burning lamps of the temples; and was woven into napkins, which could be cleansed by fire, and into cremation shrouds.

The blue asbestos or crocidolite (*q.v.*) of South Africa has during the last twenty years become of commercial importance and has been mined in increasingly large amounts. It occurs as layers interbedded in the brown jaspers and ironstones of the lower portion of the Pretoria series of sedimentary rocks, and is quarried or mined as slabs in which the fibres of the mineral run perpendicularly or somewhat obliquely to the surfaces. The belt of crocidolite-bearing rocks extends for a distance of about 300 miles, with a width of 4–20 miles, from the Orange River through the Asbestos Mountains in Griqualand West into Bechuana Land. Beautiful silky, loose fibrous material is known from Cochabamba in Bolivia.

These various kinds of asbestos differ somewhat in their resistance to acids and heat. Chrysotile is decomposed by hydrochloric and sulphuric acids; at a red heat (but not below) it loses water, and the fibres can be fused in the bunsen-flame. Tremolite-asbestos is not attacked by acids, and it is more difficultly fusible. On the other hand, the fibres of chrysotile are more flexible and more suitable for textile purposes. Crocidolite is readily fusible to a black magnetic glass, but it has the advantage that it is but slightly attacked by acids, chemical solutions, and sea-water. It possesses a greater tensile strength and is more elastic than chrysotile; and is further a good insulator for heat and electricity. Notwithstanding these differences, these varieties of asbestos are put to much the same uses, but serpentine-asbestos is employed in far larger quantities.

Spun asbestos is largely used for steam packings, fireproof curtains; and as cloth, twine, and rope it finds a variety of applications. As an insulating material, asbestos fibre is used for coating steam and hot-water pipes and cold-storage plants; and as a lining in safes, stoves, and furnaces. For use as a constructional fireproof material, it is made into bricks, boards, millboards, plasters, and paints, being often mixed with other materials. The so-called 'asbestic,' largely used for wall plaster, is prepared by grinding the poorer material and waste, which consists of narrow veins of asbestos still enclosed in the serpentine-rock. In the laboratory, asbestos is used for filtering (a pure white tremolite-asbestos being best for this purpose), for stoppings in combustion tubes, and in the form of card for supports. Asbestos paper or twine, soaked in sodium silicate and afterwards treated with calcium chloride solution, can be used for repairing glass apparatus.

L. J. S

ASDUANA *v.* BRIDELIA BARK.

ASEPTIN. Trade name for a mixture of hydrogen peroxide, boric acid, and salicylic acid; used as an antiseptic.

ASEPTOL. Trade name originally given to a solution of *o*-phenolsulphonic acid $C_6H_4(OH)SO_3H$. It is a thick reddish fluid, of 1·45 sp.gr., having a faint odour like phenol. Occasionally called *sozolic acid*. It is an antiseptic, but does not possess the poisonous action peculiar to phenol, and is therefore recommended for surgical and ophthalmic operations (Chem. Zentr. 1884, 720).

The aseptol of Merck is *p*-phenol sulphonic acid mixed with about 6 p.c. of the *o*-acid (Obermiller, Chem. Zentr. 1907, 1615).

The name is also given to a preparation containing from 0·25 to 10 parts potassium oxyquinoline sulphate, 0·5 to 10 parts soap, dissolved in 1000 parts of water, mixed with terpineol or other aromatic substances, and occasionally glycerol (Pharm. Zeit. 1897, 770).

Aseptol is also the name given to an ill-defined mixture of phenyl ethers and sulphonated phenols, obtained by the action of sulphuric acid on phenol in presence of alcohol (Trillat, J. Soc. Chem. Ind. 1892, 1028).

***ASFRAX** or *Tbayamanu*. An Indian drug, consisting of the flowers, flower-stalks, and immature fruit of a species of *Delphinium*. Used in Bombay as a medicine, and as a yellow dye for silk (Dymock, Pharm. J. [3] 8, 161).

ASH. This term is sometimes used to denote the inorganic or mineral matter contained in any substance, but more generally refers to the residue left on completely burning or incinerating it. The two meanings are not necessarily the same, since in any animal or vegetable substance the inorganic constituents are usually present in very different states of combination to those in which they occur in the residue left when the substance is completely oxidised.

To ascertain the exact amount and composition of the inorganic matter present in any organic substance is often a matter of considerable difficulty, and, in many cases, is impracticable.

The term 'ash' should be used, therefore, only in the second sense given above.

Most animal and vegetable substances leave, on combustion, a residue containing the following constituents in varying proportions :—

Acidic	Basic
Chlorine	Sodium
Carbon dioxide	Potassium
Sulphur trioxide	Calcium
Sulphur	Magnesium
Phosphorus pentoxide	Iron
Silica	Manganese

Other constituents, generally in small quantities, are also often present.

In the original substance the greater portions of the basic constituents in the above list are probably present in combination with organic acids, and, consequently, are left in the ash as carbonates (often largely the case with potash and soda) or as oxides (*e.g.* portions of the lime, magnesia, oxides of iron, and manganese) ; while the carbonates, sulphates, and phosphates are, in many cases, derived from organic combinations of carbon, sulphur, and phosphorus existing in the original substance. The determination of the amount and composition of the ash of animal and vegetable substances, though, perhaps, inadequate to ascertain the exact nature of the inorganic constituents of the organised bodies, affords valuable information as to their fitness as foodstuffs, and as to the needs of animals or plants.

In the process of incineration, there is great danger of loss of chlorides of potassium and sodium by volatilisation, also of reduction of phosphates and sulphates by the reducing action of the hot carbon. Berthelot proposed to overcome these difficulties by heating in a current of oxygen, the substance to be incinerated being previously mixed with a known weight of sodium carbonate (Compt. rend. 128, 23 ; *cf.* Roberts, Analyst, 1918, 254).

Shuttleworth (Chem. Zentr. 1899, ii. 114) has suggested the addition of calcium acetate in order to prevent the sintering which is so often an obstacle to complete incineration, and has devised a special platinum vessel in order to prevent loss of chlorides by volatilisation, and to hasten incineration. A modified form of this apparatus is described by Tucker (Ber. 32, 2583).

A convenient method of minimising the loss of chlorides by volatilisation is to char the substance thoroughly at a moderate temperature, then cool and extract the black residue with water, filter off the soluble matter, and complete the incineration of the residue after drying. When all black particles have disappeared, the residue is allowed to cool, the aqueous extract added, evaporated to dryness, and then moderately heated. Addition of ammonium nitrate to the black char hastens the combustion of the carbon.

Ash of animals. The proportion of ash constituents present in the whole body of an animal depends largely upon its condition, being greater in lean than in fat animals. According to the Rothamsted experiments, the following table gives the average proportions of ash and of its main constituents in the whole bodies of various farm animals in a fatted condition :—

—	Total ash	Phosphoric acid P_2O_5	Lime CaO	Magnesia MgO	Potash K_2O
Fat calf .	3·9	1·54	1·65	0·08	0·21
Half-fat ox .	5·1	1·84	2·11	0·09	0·21
Fat ox . .	4·2	1·55	1·79	0·06	0·18
Fat lamb .	3·2	1·13	1·28	0·05	0·17
Store sheep .	3·3	1·19	1·32	0·06	0·17
Fat sheep .	3·0	1·04	1·18	0·05	0·15
Store pig .	2·8	1·07	1·08	0·05	0·20
Fat pig .	1·7	0·65	0·64	0·03	0·14

The other constituents of the ash consist chiefly of sodium, chlorine, fluorine, iron, manganese, iodine, and silica.

The bones and teeth contain the greater part of the phosphoric acid, lime, magnesia, and fluorine; potash is present largely in muscle, blood, and many of the secretions; sodium, chlorine and iron are largely present in the blood and the secretions, while iodine is mainly accumulated in the thyroid gland.

(For the amount and composition of the ash

The following table, compiled chiefly from Wolff's analyses, gives the average proportions of ash and of its chief components in various fresh or air-dried agricultural products.

100 parts of the substance contain:—

Substance	Water	Ash	K_2O	Na_2O	MgO	CaO	P_2O_5	SO_3	SiO_2	Cl	S

of various portions of the animal body, and of certain animal products, v. Bones; Blood; Milk; &c.)

A characteristic of the ash of animal substances in general, is the usual preponderance of lime over phosphorus pentoxide and the relatively high ratio of sodium to potassium.

Ash of plants. The nature of the ash of the leaves, stems, &c., of plants is affected to a considerable extent by the composition of the soil in which the plants grow, but the amount and composition of the ash of the *seeds* are much less variable.

In nearly all seeds the largest constituents of the ash are phosphorus pentoxide and potash. In certain seeds generally used in their husk, *e.g.* oats, millet, spelt, and barley, silica is a large constituent.

But in the leaves and stems of plants, phosphorus pentoxide usually forms but a small constituent of the ash, whilst potash and lime become relatively more abundant. In cereals and grasses, silica often forms more than half of the total ash of the straw and chaff.

In addition to the constituents given in the above table, small quantities of oxides of iron and manganese are almost invariably present in vegetable ashes.

Titanium (Wait, J. Amer. Chem. Soc. 1896, 18, 402), aluminium fluorine, and boron (Crampton, Amer. Chem. J. 11, 227, Jay, Compt. rend. 121, 893; Baumert, Ber 21, 3290), are also frequently present in small quantities in the ash of certain plants

Lithium, rubidium, zinc, copper, barium, and arsenic have also been detected in the ash of certain plants grown in soils containing these constituents (Passerini, Chem. Soc. Abstr. 1893, ii. 225; Homberger, *ibid.* 1899, A, ii. 506; Macdougal, *ibid.* 1900, A, ii. 235)

Even chromium, molybdenum, and vanadium have been detected in the ash of fir, oak, vine, and poplar (Demarçay, *ibid.* 1900, 235).

Indeed, the composition of the soil has a great influence upon the amount and composition of the ash of the crop grown upon it, though this influence is much more marked upon the foliage, stem, &c., than upon the seed.

Certain plants, originating from plants of the seashore, *e.g.* asparagus, beet, and carrot, generally leave an ash containing unusually high amounts of chlorine and sodium, and application of common salt as manure to such crops is usually stated to be beneficial, although on no very sufficient evidence

Plants like salt-worts (*Salsola*) and samphire (*Salicornia*) growing on the coast, contain relatively enormous quantities of soda—in the former 6 times, in the latter 14 times, as much soda as of potash.

The ash of the club-moss (*Lycopodium*) contains from 20 to 50 p.c. of alumina.

Manganese is invariably present in tea-leaves, and, according to the writer's observations, is present in the soluble matter (*i.e.* in the infusion).

As already stated, some of the phosphates and sulphates found in the ash of plants result from the oxidation of phosphorus and sulphur organic compounds present in the original plant.

Posternak (Compt. rend. 137, 1903) detected the existence in peas, beans, potatoes, and the seeds of the red fir, pumpkin, white and yellow lupines of *anhydro-oxymethylene diphosphoric acid*—

$$O\begin{cases}CH_2—OPO(OH)_2\\ CH_2—OPO(OH)_2\end{cases}$$

or *inositol phosphoric acid* $C_6H_6(PO_4H_2)_6$. Patton and Hart (Bull. 250 (1904), N. York. Agric. Expt. Station) have shown that about 86 p.c. of the total phosphorus in bran, 81 p.c. in malt sprouts, and 50 p.c. in oats, is soluble in 0·2 p.c. sol. of hydrochloric acid; and that the greater portion of this is present in the bran as calcium, magnesium, and potassium salts of inositol phosphoric acid (*v.* BRAN).

Importance of the Ash Constituents of Foods.

The influence of the mineral matter in the food of animals upon their health and well-being is probably much greater than is generally recognised. Not only is it essential that all the inorganic constituents required for building up the tissues and producing the various digestive and other secretions be supplied in sufficient quantities, but it is important, at least with certain pairs of constituents, that they be supplied in appropriate ratios to each other.

A preponderance of phosphoric acid over lime and magnesia in the diet is probably the cause or a predisposing cause of certain diseases of the bones of horses, mules, and donkeys (Ingle, Jour. Comp. Pathology and Therapeutics, 1907; Jour Agric. Science, 1908, iii. 22; Jour. Roy. Inst. Public Health, 1909); while the ratio of potash to soda in the food has an important bearing upon health, and especially upon the susceptibility to certain diseases, *e.g.* scurvy.

The cereals contain a large excess of phosphoric acid over lime, and the use of an exclusively cereal diet may lead to imperfect bone nutrition (*l.c.*; also Illustrated Poultry Record, 1910).

The necessity of an adequate supply of chlorides in the diet is well recognised, and in many countries the ordinary food supplies of domestic animals have to be supplemented by common salt to ensure healthy existence.

Whenever the rations are restricted to one or two items, there is considerable probability that certain mineral constituents will be lacking or supplied in improper proportions.

It is too often the practice, in discussing the feeding of animals, to devote much consideration to the organic portions of their food, but beyond requiring that sufficient mineral matter or 'bone-forming' material be present, to pay little or no attention to its composition.

Thus bran is widely regarded as a food particularly rich in mineral matter, and therefore valuable for bone nutrition; but the ratio of phosphorus pentoxide to lime in this food is about 11 to 1, and the practice of feeding animals largely upon bran is known to produce a disease of the bones—'bran rachitis' in horses.

Kellner (Scientific Feeding of Animals, 1909) estimates that for oxen, 50 grams of phosphorus pentoxide and 100 grams of lime per 1000 kilos. body weight per day, are required in the food, while for full-grown sheep, 1 gram of the former and 11 grams of lime suffice.

In England, fortunately, hay—either meadow or clover—forms a large part of the rations of farm animals, and this contains a large excess of lime over phosphoric acid, and thus neutralises the opposite preponderance in the grain or cake used with it.

But in South Africa and perhaps some other countries, meadow or clover hay is but little used, and many horses are fed entirely upon oat hay or oat hay and maize. In either case there is a large preponderance of phosphoric acid over lime, and to this fact the prevalence of certain bone diseases is almost certainly due.

Similar considerations apply to other animals kept in confinement, especially to poultry when deprived of a grass run, and to pigs. H.I.

ASIPHYL. *See* ASYPHIL.

ASPARAGINE. *Aminosuccinamic acid* $C_2H_3{\cdot}NH_2(CO_2H)(CO{\cdot}NH_2)$ occurs in two optically active forms, differing in direction of rotatory power and in taste. *Lævo-asparagine*, discovered by Vauquelin and Robiquet (Ann. Chim. anal. 1805, 57, 88) in the young shoots of asparagus (*Asparagus officinalis*, Linn.), is widely distributed in the vegetable kingdom, occurring in most plants at the time of budding and during the flowering period, and, with glutamine, forms the chief non-proteid compounds present in the juice of ripening oranges (Scurti and de Plato, Chem. Zentr. 1908, ii. 16, 1370; Stieger, Zeitsch. physiol. Chem. 1913, 86, 245, 269; Smolenski, Zeitsch. Ver. deut. Zuckerind, 1911, 435; Tutin, Chem. Soc. Trans. 1913, 103, 1274; Chapman, *ibid.* 1914, 105, 1901; Tutin and Clewer, *ibid.* 1914, 570). It is also found in blood (Abderhalden, Zeitsch. physiol. Chem. 1913, 88, 478–483). Miyacha (Bull. Coll. Agric. Imp. Univ. Tokyo, 1897, 2, 458) has shown that in the case of *Pæonia albiflora* and *Thea chinensis*, even old leaves, showing incipient decay, can produce asparagine. It occurs to a larger extent in leguminous plants than in any other natural order, and is most abundant at the time of germination, the quantity being greater in etiolated than in normal plants (Borodin, Bied. Zentr. 1879, 357; *see* also Ritman, Izv. Moskow. Selsk. Khoz. Inst. 18, 212–220; from Abs. Amer. Chem. Soc. 1913, 3144; Nicolaieva, Bull. Agr. Intelligence, 1917, 8, 204). Sachsse (Landsw. Versuchs. Stat. 1874, 17, 88) found that the amount of asparagine in germinating peas increased from 0·67 to 6·94 p.c. during 24 days' growth; and Schulze and Umlauft (*ibid.* 1875, 18, 1) found 17·9 p.c. of asparagine in the dried shoots of *Lupinus luteus* seedlings germinated in the dark in distilled water (*cf.* also Mercadante, Gazz. ital. chim. 1875, 5, 187; Schulze, Landsw. Versuchs. Stat. 1895, 46, 383; Stoklasa, Landw. Jahrb. 1895, 24, 827; Bourquelot and Herissey, J. Pharm. 1898, (vi.) 8, 385; Bréal, Ann. Agron. 1900, 26, 5; Schulze and Barbieri, Landsw. Versuchs. Stat. 21, 63; Kinoshita, Bull. Coll. Agric. Imp. Univ. Tokyo, 1895, 2, 203); Schulze and Bosshard, Zeitsch. physiol. Chem. 1885, 9, 420; Bungener, Bied. Zentr. 1885, 861; Behrens, Bot. Zentr. 1894, 178). Asparagine is one of the decomposition products of proteid matter (Schulze, Bied. Zentr. 1901, 30, 106; Chem. Zentr. 1901, i. 1108; Ber. Deut. Bot. Ges. 1907, 25, 213), and its accumulation in the plant during the periods of germination and budding, particularly when the development occurs in the dark is attributed by Borodin (Bied. Zentr. 1879, 357) and Schulze and Barbieri (J. pr. Chem. 1882, [2] 25, 145), to the absence of carbohydrates which under conditions of normal assimilation effect the reincorporation of amides into proteid molecules; and this view is confirmed by Monteverde (Ann. Agron. 17, 376), who found that branches of lilac plunged in distilled water or 4 p.c. glycerol solution and kept in the dark, contained abundance of asparagine at the end of 15 days, but neither starch nor mannitol. When, however, branches of the same plant were kept in solutions of glucose, sucrose, or mannitol, they formed no asparagine in a month, but contained much mannitol and starch. Another source of asparagine in the plant is its synthetic formation from ammonium salts, urea, or nitrates supplied by the soil. This synthetic production is only possible in the presence of sugar, and under conditions that exclude the formation of proteids (Suzuki, Bull. Coll. Agric. Imp. Univ. Tokyo, 1895, 2, 196). The function of the asparagine in the plant economy is the production of proteid matter; hence the addition of leguminous seeds after steaming to the mash in brewing is recommended by Birner (J. Soc. Chem. Ind. 1882, 333), as the asparagine they yield forms excellent nutriment for the yeast cell; and Kinoshita (Bull. Coll. Agric. Imp. Univ. Tohyo, 1895, 2, 196) found that young shoots of soja bean that showed an increase in asparagine, from 21·5 to 28·7 p.c. after four weeks' natural growth, became poorer in asparagine (18·9–13·7 p.c.) if grown for the same period in methyl alcohol and glycerol solution, but contained reserve proteid matter. According to Ciamician and Ravenna (Atti R. Accad. dei Lincei [5] 20, 1, 614–624), there is an increase of alkaloid in the tobacco plant and date when supplied with asparagine. Morgen, Beger, and Westhausser (Landw. Versachs. Stat. 1911, 75, 265–320), experimenting with sheep, claim that, given a sufficiency of carbohydrate, a deficiency of protein may be made good with ammonium acetate and asparagine.

Asparagine can be extracted from the juice expressed from young vetch seedlings that have germinated in the dark, 10 kilos. of vetch yielding 150 grams of pure asparagine (Piria, Annalen, 1848, 68, 343). Sure and Tottingham found that asparagine is made use of in the nitrogen metabolism of etiolated pea plants (J. Biol. Chem. 1916, 26, 535).

Asparagine crystallises from aqueous solution in large rhombic lævo- hemihedral prisms, $a : b : c :: 0{\cdot}4752 : 1 : 0{\cdot}8294$ (Freundler, Compt. rend. 1897, 125, 657), containing $1H_2O$, which it loses at 100°, and then melts at 234°–235° (Michael, Ber. 1895, 28, 1620); it has a sp.gr. 1·5434 at 14·8°/4° (Piutti, Gazz. chim. ital. 1904, 34, 36); the molecular heat of combustion is 448·4 Cals., and the heat of formation 205·1 Cals. (Berthelot and Andre, Compt. rend. 1890, 120, 884; *see* also Emery and Benedict, Amer. J. Physiol. 28, 301–307); it is sparingly soluble in cold, readily so in hot water—1 part dissolves in 82 parts of water at 10°, in 47 parts at 20° (Becker, Ber. 1881, 14, 1028), in 58 parts at 13°, and 1·89 parts at 100° (Guareschi, Gazz. chim. ital. 1876, 6, 370; *cf.* Bresler, Zeitsch. physikal. Chem. 1904, 47, 611). The aqueous solution is weakly acid, has an insipid and disagreeable taste, and is lævo-rotatory $[a]_D -5° 4'$ (Piutti, Compt. rend. 1886, 103, 134); the rotatory power of the solution is increased by raising the temperature and by the addition of alkalis, inverted by mineral acids and by solutions of certain inorganic salts and destroyed by acetic acid (Champion and Pellet, Compt.

rend. 1876, 82, 819; Becker, Ber. 1881, 14, 1028; Smolenski, Zeitsch. Ver. deut. Zuckerind, 1910, 215; and 1912, 791; Pellet, Zeitsch. Ver. deut. Zuckerind, 1911, 435–443; Clough, Chem. Soc. Trans. 1915, 107, 1513; Andrlik and Stanek, Zeitsch. Zuckerind. Böhm. 31, 417). Advantage is taken of this last fact to eliminate the error due to the presence of asparagine in saccharimetric determinations of sugar liquors from beets and canes. Asparagine is partially hydrolysed by boiling with water, forming *aspartic acid* (*aminosuccinic acid*) $C_2H_3{\cdot}NH_2(CO_2H)_2$ and ammonia; the change is rapid and complete when excess of barium hydroxide or dilute hydrochloric or sulphuric acid is employed (Schulze, Landsw. Versuchs. Stat. 29, 233); by the action of potassium permanganate, asparagine is oxidised to carbamide and ammonia; and when used in 5 p.c. aqueous solution for the culture of *Bacillus pyrocyanicus*, it is converted into aspartic acid after 60 hours, and completely decomposed after 72 hours (Arnaud and Charrin, Compt. rend. 1891, 112, 755; Adeney, Proc. Roy. Irish Acad. 1905, 25, 6). An aqueous solution in presence of sunlight yields acetaldehyde, ammonia, and carbon dioxide (Ganassini, Giorn. Farm. Chim. 1912, 62, 439–444). Under the action of enzymes, asparagine yields a mixture of formic, propionic, and succinic acids (Neuberg and Cappezzuoli, Biochem. Zeitsch. 1909, 18, 424), and a similar change is effected by brewer's yeast (Effront, Mon. Sci. 1909, (iv.) 23, i. 145; and Kurono, J. Agric. Tokyo, 1911, 1, 295–330).

The presence of asparagine (1 : 19,000) may be detected by means of triketohydrindene hydrate (Abderhalden and Schmidt, Zeitsch. physiol. Chem. 85, 143–147).

The estimation of asparagine is based upon its quantitative conversion into aspartic acid and ammonia by the action of hydrochloric acid, the aspartic acid may be removed in the form of its sparingly soluble copper salt (Engel, Compt. rend. 1888, 106, 1734) and the ammonia determined by Sachsse's method (J. pr. Chem. 1872, [2] 6, 118) or by one of the modifications of Schloessing's method described by Meunier (Ann. Agron. 6, 275), by Schulze (J. pr. Chem. 1885, [2] 31, 233), or by Brown and Millar (J. Soc. Chem. Ind. 1904, 135). Palet (Anal. Soc. Quim. Argentina, 1917, 5, 95) points out that the results of the estimation by Schloessing's method are influenced by the employment of different alkalis.

Asparagine has feeble basic and acidic properties, and forms salts with acids and bases (Chautard and Dessaigne, Annalen, 1848, 68, 349; Dessaigne, Annalen, 1852, 82, 237; Smolka, Monatsh. 1887, 6, 915); it also forms double compounds with certain salts of the heavy metals, the sparing solubility of the compound with mercuric nitrate is made use of in isolating small quantities of asparagine from solutions containing carbohydrates (Schulze, Ber. 1882, 15, 2855); it forms stable complex internal salts with certain heavy metals; the chromium salt $Cr(C_4H_7O_3N_2)_3$ crystallises in microscopic rose-violet needles (Tschugaeff, Serbin, Compt. rend. 1910, 151, 1361–1363) and combines with copper hydroxide to yield a copper complex of the formula $Cu(C_4H_7O_3N_2)_2$ (Kober and Sugiura, J. Biol. Chem. 1912–1913, 13, 1–13); the *alum* $(C_4H_8O_3N_2)_2H_2SO_4,Al_2(SO_4)_3,24H_2O$ forms octahedral crystals. Asparagine is converted into *l*-chlorosuccinic acid and fumaric acid by the action of nitrosyl chloride in hydrochloric acid solution (Tilden and Forster, Chem. Soc. Trans. 1895, 67, 489); it yields the amide of uramidosuccinic anhydride

$$\begin{array}{l}CO{\cdot}NH_2{\cdot}CH_2{\cdot}CH{\cdot}NH{\cdot}CO{\cdot}NH\\ \qquad\qquad\qquad\quad\ \ |\qquad\qquad\quad\ \ |\\ \qquad\qquad\qquad\quad CO\text{———————}\!\rfloor\end{array}$$

when fused with carbamide (Guareschi, Gazz. chim. ital. 1876, 6, 370), and is converted into amidosuccinuric acid

$$CONH_2{\cdot}CH_2{\cdot}CH\begin{array}{l}\diagup NH{\cdot}CO{\cdot}NH_2\\ \diagdown COOH\end{array}$$

m.p. 137°–138°, by the action of potassium cyanate (Guareschi, Ber. 1877, 10, 1747). Certain condensation products of asparagine with other amino- acids are described by Fischer (Ber. 1904, 37, 4585; 1907, 40, 2048), *chloroacetylasparagine*, m.p. 148°–149° (corr.); *glycylasparagine*, m.p. 216°, $[\alpha]_D -6{\cdot}4°$ at 20°; *anhydroglycylasparagine*, decomposing at 274°; d-*leucyl*-l-*asparagine*, decomposing at 230° (corr.), $[\alpha]_D -53{\cdot}6°$ at 20°; l-*leucyl*-d-*asparagine*, m.p. 228° (corr.), $[\alpha]_D +17{\cdot}8°$; *asparagylaspartic acid*, decomposing at 120°. Sasaki (Beitr. Chem. Physiol. Path. 1907, 10, 120) describes a *benzoylpolypeptide* of asparagine $C_{19}H_{24}O_8N_6$, decomposing at 210°, and giving the biuret reaction.

Benzyl hydrogen asparaginedithiocarboxylate

$$CO_2H\ C_2H_3(CONH_2){\cdot}NH{\cdot}CS_2{\cdot}CH_2Ph$$

has m.p. 180°. The barium salt crystallises in slender needles (Siegfried and Weidenhaupt, Zeitsch. physiol. Chem. 1910, 70, 152–160).

As regards the alimentary value of asparagine, it has been found that in the case of herbivorous mammals and geese, asparagine has a proteid-sparing action, and under appropriate conditions prevents waste and causes the formation of proteid matter (Weiske, Bied. Zentr. 1879, 744; 1882, 312; Zeit. für. Biol. 15, 261; 20, 276; Landws. Versuchs. Stat. 1888, 34, 303; Rosenfeld, Zeitsch. Ver. deut. Zuckerind 1900, [539] 1055, from. J. Soc. Chem. Ind. 1901, 271). According to Zuntz and Muller (Pflüger's Archiv. 1906, 112, 245), the proteid-sparing action of asparagine is the result of a kind of symbiosis, the bacteria in the paunch of the ruminants decomposing the asparagine in preference to the protein in the food. In the case of omnivora and carnivora, asparagine exerts only a diuretic action (Murok and Voit, Bied. Zentr. 1884, 749; Politis, Zeit. Biol. 1893, 27, 492; Mauthner, *ibid.* 507; Gabriel and Voit, *ibid.* 29, 115, 125; Levena and Kohn, Amer. Jour. Physiol. 1909, 23, 324; *see*, however, Abderhalden, Zeitsch. physiol. Chem. 1911, 74, 481–504; and Nitsche, Beitr. Phys. 1914, 1, 53–89).

Dextro-asparagine was discovered by Piutti (Ber. 1886, 19, 1691) in the young shoots of the vetch (*Vicia sativa*, Linn.) 6500 kilos. of vetch buds yielded 20 kilos. of crude asparagine, from which 100 grams of pure dextro-asparagine was isolated; it is slightly more soluble than the lævo- compound; the solution has an intensely sweet taste, is dextro-rotatory in neutral or alkaline solution $[\alpha]_D + 5{\cdot}41°$ (Piutti, Compt. rend. 1886, 103, 134), and lævo-rotatory in acid solution; it forms large rhombic dextrohemihedral crystals, $a : b : c :: 0{\cdot}4741 : 1 : 0{\cdot}8310$ (Freundler, Compt. rend. 1897, 125, 657). A solution of equal parts of the two optically active asparagines is optically inactive, but the two varieties separate on crystallisation, twinning frequently taking place between the left and right crystals (Piutti, Compt. rend. 1886, 103, 134). *d*- and *l*-Asparagine can be separated by fractional crystallisation from hot water although both have the same solubility at 20°. The solubility of *l*-asparagine, previously heated, is at least doubled after cooling, and only slowly returns to its original value (Erlenmeyer, Biochem. Zeitsch. 52, 439–470). The silver salt of *dl-asparagine* $C_4H_7O_3N_2Ag$, forms wart-like clusters of crystals, m.p. 182°–183° (decomposed) (Abderhalden and Kautzsch, Zeitsch. physiol. Chem. 1912, 78, 115–127).

According to Pringsheim (Zeitsch. physiol. Chem. 1910, 65, 89), the *d*-asparagine found by Piutti in the mother liquors from which the *l*-asparagine had been isolated, was formed by the racemisation of the *l*-asparagine during the process of evaporation of the solutions. The author states that after boiling *l*-asparagine [$[\alpha]_D^{20°} + 36{\cdot}19°$, in $N/10$ hydrochloric acid solution] for 12 hours, with water, and subsequent fractional crystallisation, he obtained a fraction that had $[\alpha]_D^{20°} - 15{\cdot}3°$ in $N/10$ hydrochloric acid solution, and therefore contained *d*-asparagine.

In addition to the two asparagines already described, there is a third form known as *α*-asparagine; it does not occur naturally; is optically inactive, crystallises in the triclinic system, $a : b : c = 1{\cdot}5957 : 1 : 0{\cdot}5668$; $\alpha = 91°19'$; $\beta = 113°/12'$, $\gamma = 83°\ 48'$ (Brugnatelli); and has a sp.gr. 1·454 at 14·8°/4° (Piutti, Gazz. chim. ital. 1904, 34, ii. 36), and is not structurally identical with the optically active or *β*-asparagines. The three asparagines have been synthesised by Piutti (Gazz. chim. ital. 1887, 17, 126; 1888, 18, 457) by the following methods, that leave no doubt as to the constitution of the compounds. By the reduction of the oxime of oxalacetic ester $CO_2Et{\cdot}CH_2{\cdot}C(NOH){\cdot}CO_2Et$ with sodium amalgam and partial saponification of the product, Piutti obtained two different ethyl hydrogen aspartates, melting at 165° and 200° respectively. The ester melting at 165° is identical with the compound obtained by reducing Ebert's (Annalen, 1885, 229, 45) monoethyl ester of oximinosuccinic acid, which has the formula $CO_2H{\cdot}CH_2{\cdot}C(NOH){\cdot}CO_2Et$, since on heating it loses CO_2 and forms oximinopropionic ester $CH_3{\cdot}C(NOH){\cdot}CO_2Et$. It follows, therefore, that the ethyl hydrogen aspartate melting at 165° is the monoethyl *α*-aspartate $CO_2H{\cdot}CH_2{\cdot}CH(NH_2){\cdot}CO_2Et$, and the ester melting at 200° must be the monoethyl *β*-aspartate $CO_2H{\cdot}CH(NH_2){\cdot}CH_2{\cdot}CO_2Et$. When these esters are treated with alcoholic ammonia, they are converted into the corresponding asparagines; the ester m.p. 165° gives inactive *α-asparagine* $CO_2H{\cdot}CH_2{\cdot}CH(NH_2){\cdot}CONH_2$, and the ester m.p. 200° yields a mixture of *d*- and *l*- *β*-asparagines $CO_2H{\cdot}CH(NH_2){\cdot}CH_2{\cdot}CONH_2$. From silver ethyl *γ*-oximinosuccinate

$$\mathrm{OH{\cdot}N}\left\langle\begin{array}{l}\mathrm{CH{\cdot}CO_2Et}\\ \ |\\ \mathrm{CH{\cdot}CO_2Ag}\end{array}\right.$$

Piutti (Gazz. chim. ital. 1890, 20, 402) obtained a mixture of the three asparagines, the *α*-asparagine readily gave up its water of crystallisation in a vacuum, and fell to powder; and the *d*- and *l*- *β*-asparagines could then be separated by hand sorting. A mixture of the three asparagines was also obtained by the action of alcoholic ammonia on the ethyl hydrogen ester of inactive aspartic acid (Piutti, Gazz. ital. chim. 1887, 17, 126; 1888, 18, 457). Körner and Menozzi (Gazz. ital. chim. 1887, 17, 171, 226) effected the synthesis of the *d*- and *l*- *β*-asparagines from ethyl bromosuccinate, from ethyl fumarate or ethyl maleate, by the action of alcoholic ammonia; and similar results were obtained by Piutti (Ber. 1896, 29, 2069) with *l*-bromosuccinamic acid or maleic anhydride.

β-Ethylasparagine $CO_2H{\cdot}CH(NH_2){\cdot}CH_2{\cdot}CO{\cdot}NHEt$, m.p. 258°–260°, with decomposition, and *β-allylasparagine* $CO_2H{\cdot}CH(NH_2){\cdot}CH_2{\cdot}CO{\cdot}NH{\cdot}C_3H_5$, melting and decomposing at 258°–261°, prepared by the action of the corresponding alkylamine on *β*-ethylaspartic acid, yield optically inactive solutions (Piutti, Gazz. chim. ital. 1888, 18, 478). M. A. W.

ASPARAGUS. The shoots of this plant (*Asparagus officinalis*) are used as a table vegetable.

	Water	Protein	Fat	Carbo-hydrates	Ash
Average composition	94·0	1·8	0·2	3·3	0·7

The nitrogenous matter of asparagus consists largely of *amino-succinamic acid* $CO(NH_2){\cdot}CH_2{\cdot}CH(NH_2){\cdot}COOH$, a substance known (from its discovery, in 1805, in asparagus shoots) as *asparagine* (*q.v.*).

Coniferin and vanillin have also been found in the sap and cellular tissue (Lippmann, Ber. 1886, 18, 3355); Tanret (Compt. rend. 1909, 149, 48) describes two new carbohydrates as occurring in approximately equal quantities in asparagus roots—*asparagose* $(C_6H_{10}O_5)_n{\cdot}H_2O$, where $n = 15$ or 16, crystallising in microscopic needles, soluble in water, insoluble in absolute alcohol, m.p. 198°–200°, gives no colouration with iodine, and does not reduce Fehling's solution; and *ψ-asparagose*, a white, hygroscopic substance more soluble than asparagose. Both substances are hydrolysed by invertase, yielding dextrose and lævulose.

The seeds of asparagus were examined by Peters (Arch. Pharm. 1902, 240, 53), and were found to contain water 11·5, woody fibre 8·2, nitrogen 3·0, and oil 15·3 p.c. Starch was not present, but a reserve cellulose (mannan), capable of yielding *d*-mannose on boiling with dilute hydrochloric acid, occurred; 37·5 p.c. of the weight of the seeds, of mannose was obtained. The oil was reddish yellow, had a sp.gr. of 0·928 at 15°, and an iodine number of 137·1. H. I.

ASPARTIC ACID. *Aminosuccinic acid* $CO_2H{\cdot}CH_2{\cdot}CH(NH_2){\cdot}CO_2H$, found in young sugar cane and in molasses of sugar beet (Scheibler, J. 1886, 399), in young shoots of the gourd (Schulze and Barbieri, Ber. 1878, 11, 710), and in mulberry leaves (Mimuroto, J. Agric. Tokyo, 1912, 5, 63–65), has been observed in diseased liver (Taylor, Zeitsch. physiol. Chem. 1901, 34, 580), and occurs in certain glands of *Tritonium nodosum*, the posterior portion of the gland when stimulated secretes an acid fluid from which aspartic acid immediately crystallises. As aspartic acid is soluble in sea-water, it is probably employed by the animal in destroying the calcareous shells of the other shellfish that form its food (Henze, Ber. 1901, 34, 348).

Aspartic acid is prepared by hydrolysing asparagine by means of hydrochloric or sulphuric acid, lime, baryta, lead oxide or potash (Plisson, Ann. Chim. Phys. [2] 35, 175; 37, 81; 40, 303; Schulze, Landsw. Versuchs. Stat. 29, 233); it is one of the degradation products of proteid matter, and is obtained when casein or proteid is heated with (1) dilute sulphuric acid (Kreussler, J. pr. Chem. 1869, 107, 239; Ritthausen, *ibid.* 218; Fischer, Zeitsch. physiol. Chem. 1901, 33, 151; 1902, 35, 70; 36, 462); (2) bromine or with stannous chloride (Hlasiwetz and Habermann, Annalen, 1871, 159, 325; 1873, 169, 162). Aspartic acid is produced by the oxidation of conglutin with potassium permanganate (Pott, J. pr. Chem. 1873, [2] 6, 91), by the pancreatic digestion of fresh blood fibrin at 40°–50° (Radziejewski and Salkowski, Ber. 1874, 7, 1050), or of gluten (Knieriem, Zeitsch. f. Biol. 1876, 11, 198); and is one of the acid constituents of Kühne's 'antipeptone' (Kutscher, Zeitsch. physiol. Chem. 1898, 25, 195; 26, 110).

The naturally occurring aspartic acid is lævo-rotatory and the same *l-aspartic acid* is obtained by hydrolysis of *lævo*-asparagine (Schiff, Ber. 1884, 17, 2929); it crystallises in rhombic prisms, m.p. 270°–271° (Michael, Ber. 1895, 28, 1629), is sparingly soluble in water, 100 grams of water dissolve y mg. of the acid at t°, where

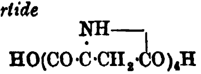
$$y=372+14{\cdot}1t-0{\cdot}18124t^2+0{\cdot}0053t^3$$

(Engel, Compt. rend. 1888, 106, 1734). A solution containing 1·873 p.c. of acid is feebly dextro-rotatory below 75°, but lævo-rotatory above that temperature; $[\alpha]_D 5{\cdot}87°$ (Wood, Chem. Soc. Trans. 1914, 105, 1992); in alkaline solutions the substance is strongly lævo-, and in acids strongly dextro-, rotatory, and dextrorotatory in aqueous solutions of certain inorganic salts (Becker, Ber. 1881, 14, 1028). The rotatory power in acid and alkali reaches a maximum value under definite conditions of concentration (Wood, *ibid.* 1914, 105, 1992; Clough, Chem. Soc. Trans. 1915, 107, 1510). The heat of combustion is 387·2 Cals., the heat of formation 231·9 Cals. (Berthelot and André, Compt. rend. 1890, 110, 884); the heat of dissolution at 16° is −7·25 Cals., heat of neutralisation by sodium hydroxide +3·0 Cals. for the first, and +3·5 Cals. for the second equivalent (Berthelot, Compt. rend. 1891, 112, 829). Aspartic acid is readily soluble in aqueous solutions of certain mineral salts; for this reason Schiff (Ber. 1886, 17, 2929) recommends that in its preparation from asparagine by boiling with hydrochloric acid, the minimum quantity (2 mols.) of acid be employed, and the excess afterwards neutralised by ammonia (1 mol.); by adopting this precaution, a yield of 90 p.c. of the theoretical is obtained. For the estimation of aspartic acid in the hydrolysis products of proteid, *see* Foreman (Bio-Chem. J. 1914, 8, 463).

Aspartic acid forms salts with acid and bases, the copper salt $C_4H_5O_4NCu,4\frac{1}{2}H_2O$ or $C_4H_5O_4NCu,5H_2O$, forms pale-blue needles almost insoluble in cold water (Engel, *l.c.*; Abderhalden and Weil, Zeitsch. physiol. Chem. 1911, 72, 23). The calcium salt can be precipitated quantitatively by means of alcohol (Foreman, *ibid.* 471). The mono-silver salt melts 216°–217° with decomposition (Abderhalden and Kautzsch, Zeitsch. physiol. Chem. 1912, 78, 123). A uranyl salt $UO_2(C_4H_5O_4N)_2,3H_2O$ is formed by double decomposition (Mazzucchelli and D'Alceo, Atti. R. Accad. Lincei, 1912, [5] 2, 11, 620–626). Aspartic hydrochloride $C_4H_7O_4N{\cdot}HCl$, softens with gas evolution at 178°, and then does not alter up to 280° (Philippi and Uhl, Monatsh. 34, 717–731). Aspartic acid is oxidised by hydrogen peroxide to the semi-aldehyde of malonic acid which breaks up into acetaldehyde and carbon dioxide (Dakin, J. Biol. Chem. 1909, 5, 409); it is capable of furnishing the nitrogen required for the development of *B-coli communis* in presence of mannitol and glucose, becoming reduced to ammonium succinate (Harden, Chem. Soc. Trans. 1901, 623), and by enzyme action it is decomposed into formic, propionic, and succinic acids (Neuberg and Cappezzuoli, Biochem. Zeitsch. 1909, 18, 424; Borchardt, Zeitsch. physiol. Chem. 1909, 59, 96; Abderhalden and Fodor, Zeitsch. physiol. Chem. 1913, 85, 119, 130). On heating it with glucose under pressure Bauer and Barshall obtained succinic acid, and suggest that aspartic acid is the source of the succinic acid found in meat extract (Chem. Zentr. 1911, 2, 1367). When aspartic acid is heated at 190°–200° for 20 hours, and the product boiled with water, two sparingly soluble anhydrides, *octoaspartide*

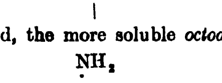
$$\mathrm{HO(CO\cdot\underset{|}{\overset{\overset{NH—}{\cdot}}{C}}\cdot CH_2\cdot CO)_8H}$$

and *tetraspartide*



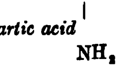
$$\mathrm{HO(CO\cdot\underset{|}{\overset{\overset{NH—}{\cdot}}{C}}\cdot CH_2\cdot CO)_4H}$$

are obtained, the more soluble *octoaspartic*



$$\mathrm{HO(CO\cdot\underset{|}{\overset{\overset{NH_2}{\cdot}}{C}}\cdot CH_2\cdot CO_2H)_8H}$$

and *tetraspartic acid*



$$\mathrm{HO(CO\cdot\underset{|}{\overset{\overset{NH_2}{\cdot}}{C}}\cdot CH_2\cdot CO_2H)_4H}$$

can be isolated from the filtrate (Schiff, Ber. 1897, 30, 2449). Dimethyl or diethyl sulphate and *l*-aspartic acid in alkaline solution give fumaric acid and alkylated ammonia derivatives (Novák, Ber. 1912, 45, 834–850). The following alkyl esters of aspartic acid are described: *Monoethyl asparate hydrochloride*, m.p. 199°; *diethyl* and *dimethyl aspartate hydrochlorides*, deliquescent solids (Curtius and Koch, Ber. 1885, 18, 1293; Wegscheiden and Frankl, Monatsh. 1906, 27, 487), *ethyl β-aspartate* $CO_2H{\cdot}CH(NH_2){\cdot}CH_2{\cdot}CO_2Et$, m.p. 200°; *ethyl α-aspartate* $CO_2H{\cdot}CH_2{\cdot}CH(NH_2)CO_2Et$, m.p. 165° (Piutti, Chem. Zentr. 1888, 1459). The methyl, ethyl, allyl, propyl, *iso*propyl, butyl, *iso*butyl, and *iso*amyl hydrogen esters are dextro-rotatory at ordinary and lævo-rotatory at higher temperatures, and form sparingly soluble copper salts (Piutti and Maghi, Gazz. chim. ital. 1906, 36, ii. 738). *l*-Diethylaspartate has b.p. 126·5°/11 mm. pressure; sp.gr. 1·089 at 17° and $[\alpha]_D^{20°} = -9·46°$ (Fischer, Sitzungber, Akad. Wiss. Berlin, 1900, 48, 1062), or b.p. 126°–127°/10 mm., 150°–152°/25 mm. pressure, and forms a yellow *picrolonate* $C_8H_{15}O_4N,C_{10}H_8O_5N_4$, m.p. 290° (Schmidt and Widman, Ber. 1909, 42, 497). Aspartic acid and ethyl metaphosphate yield a derivative of the composition $C_8H_{12}O_7NP$ (Langheld, Ber. 1911, 44, 2076–2086).

Of the *acyl* derivatives of aspartic acid, the *benzenesulphonyl* derivative $SO_2Ph·NH·C_2H_3(CO_2H)_2$ melts at 170° (Hedin, Ber. 1891, 23, 3196); the *hippuryl* derivative $NHBz·CH_2·CO·NH·C_2H_3(CO_2H)_2$, m.p. 191° (Curtius and Curtius, J. pr. Chem. 1904, (ii.) 70, 158); *benzoyl l-aspartic acid*, m.p. 184°–185° (corr.); has $[\alpha]_D^{20°} + 37·4°$, *leucyl aspartic acid* $CH_2Pr^\beta·CH(NH_2)·CO·NH·C_2H_3(CO_2H)_2,H_2O$ decomposes at 180°–182° (corr.) (Fischer and Koenigs, Ber. 1904, 37, 4585); and the *picryl* derivative $C_{10}H_8O_{10}N_4$ has m.p. 137°; *diethylchloracetyl aspartate*

$$COOEt·CH_2·CH·NH(CO·CH_2Cl)COOEt$$

(Fischer and Koenigs, Ber. 1904, 37, 4585; Bornwater, Rec. trav. chim. 1917, 36, 281) has m.p. 46°–47°; k.p. 139°; *aspartic diamide* $C_2H_3(NH_2)(CONH_2)_2$, m.p. 131°, has $[\alpha]_D - 7°$, and gives the biuret reaction (Fischer and Koenigs, *l.c.*). Aspartic acid resembles asparagine in its physiological action (Salkowski, Zeitsch. physiol. Chem. 1904, 42, 1207; Andrlík and Velich, Zeitsch. Zuckerind. Böhm, 1908, 32, 313).

d-Aspartic acid, obtained by hydrolysis of *d*-asparagine (Piutti, Ber. 1886, 19, 1694), or from *l*-bromosuccinic acid and aqueous ammonia at −40°, a Walden rearrangement taking place (Fischer and Raske, Ber. 1907, 40, 1051); is also obtained from a solution of the racemic acid [(*d*+*l*) aspartic acid] which has been innoculated with a mould grown on *l*-aspartic acid (Engel, Compt. rend. 1887, 106, 1734). *Benzoyl d-aspartic acid*, obtained by Fischer (Ber. 1899, 32, 2451), by the resolution of the racemic compound, through the brucine salts, has m.p. 181°–182°, $[\alpha]_D^{20°} - 37·6°$ in alkaline solution.

Inactive, *(d+l)-aspartic acid*, prepared by the action of boiling hydrochloric or nitric acid on the product obtained by heating the ammonium salts of malic, maleïc, or fumaric acids (Dessaigne, Compt. rend. 1850, 30, 324); by heating an aqueous solution of the hydrochloride of *l*-aspartic acid at 170°–180° for some hours (Michael and Wing, Ber. 1884, [1] 2984); by heating *d*- or *l*-aspartic acid with 2 mols. HCl (sp.gr. 1·107) at 170°–180°, or from an aqueous solution of equal parts of the *d*- and *l*- acids; the racemic acid crystallises out (Piutti, Ber. 1886, 19, 1694); by reducing and hydrolysing the sodium salt of ethyl oximino-oxalacetate (Piutti, Chem. Zentr. 1888, 68). (*d*+*l*)-Aspartic acid forms small monoclinic prisms; 100 grams of water dissolve *y* mg. of the acid at *t*°, where

$$y = 517 + 21·693t - 0·165t^2 + 0·0079t^3$$

(Engel, Compt. rend. 1888, 106, 1734). The copper salt $CuC_4H_5O_4N,4\frac{1}{2}H_2O$ is dark-blue (Engel, *l.c.*). *dl-Aspartic acid picrolonate* forms long slender crystals with square ends decomposing at 130° (Levene and Slyke, Bio-Chem. J. 1912, 12, 127–139). The *benzoyl* derivative has m.p. 164°–165° (corr.), and can be resolved into its active components by crystallising the brucine salt (Fischer, Ber. 1899, 32, 2451).

M. A. W.

ASPHALT. *Compact bitumen*, *Mineral pitch*, *Jews' pitch*, *Bitumen of Judæa.* (*Judenpech*, *Erdpech*, *Bergpech*, Ger.; *Goudron minéral*, Fr.) A name given to the solid varieties of bitumen. In its purest form asphalt presents the appearance of a black or brownish-black solid substance, possessing a bright conchoidal fracture. It melts at 100°, burning with a brilliant flame and emitting a bituminous odour. Sp.gr. 1·0–1·68. Asphalt is insoluble in alcohol and water, soluble in about five times its weight of naphtha, and in benzol. It is dissolved by alkalis and alkaline carbonates.

By dry distillation a yellow oil, Asphalt oil, is obtained. It consists of hydrocarbons mixed with a small quantity of oxidised matter. It begins to boil at 90°, but the boiling-point gradually rises to 250°. The portion boiling below 200° has the sp.gr. 0·817 at 15°; that above 200° has a sp.gr. of 0·868 at 15°. Both portions gave by analysis about 87·5 p.c. carbon, 11·6 p.c. hydrogen, and 0·9 p.c. oxygen, which is nearly the composition of oil of amber (Völckel, Annalen, 88, 139). Nitric acid converts it into a resin, having the odour of musk and the taste of bitter almonds.

Boussingault obtained from the asphalt of Bechelbrunn a pale-yellow oil, *petrolene*, having a faint taste and bituminous odour, of sp.gr. 0·891 at 21°, and boiling at 280°.

By heating asphalt to 250° for 48 hours, the volatile oils are driven off; a black solid substance, *asphaltene*, is obtained. It becomes soft and elastic about 300°.

The purest asphalt is found on the shores of the Dead Sea and in the pitch lakes of Trinidad and Mexico. Rocks more or less impregnated with bitumen, to which the name earthy or crude asphalt is given, are found at the Poldice mines, Cornwall; near Matlock, Derbyshire; at Haughmond Hill, Shropshire; at the Hotwells, near Bristol; in the limestone near Glasgow; the freestone near Edinburgh; and generally throughout the Orkneys. Large deposits occur also at Seyssel, Dépt. de l'Ain; at Bechelbrunn and Lobsann, Lower Rhine; at Bastennes and Dax, in the Dépt. des Landes; in the Val de Travers, Neuchatel, in Kentucky, and other places.

Asphalt is separated from the minerals with which it is associated either by melting the mass, allowing the earthy matters to subside and removing the bitumen; or by boiling with water, which causes the bitumen to run out in the melted state; or by the action of hydrochloric acid, which dissolves the calcium carbonate and leaves the asphalt; or with oil of turpentine, which dissolves out the bitumen. Murrie (J. Soc. Chem. Ind. 3, 182) describes the methods used in Italy for the extraction of bitumen from crude asphalt.

The Val de Travers asphalt contains about 20 p.c. of bitumen, and it only requires the addition of 6 to 8 p.c. of mineral or coal tar to convert it into a plastic, workable mastic of good quality for pavements and hydraulic works.

The modern method of laying down asphalt pavement is to first prepare a foundation of concrete the surface of which is carefully flattened. On this even surface, when thoroughly dry, the melted asphalt is spread with a wooden trowel, and the surface is finally smoothed over. The liquid Val de Travers, Limmer's, and Barnett's asphalts used for this purpose are all mixed with grit or sand, and so present rougher surfaces than those pavings which consist of asphalt alone. Brande (D. R. P. 4993, 1878) mixes ground slag with the asphalt instead of sand.

Another method of paving is to break up the bituminous ore, and heat the fragments till they crumble to powder. A layer of this hot powder, from 16 to 20 inches thick, is laid on the dry concrete and compressed by stamping with hot irons.

Artificial asphalt, or gas-tar asphalt, is a mixture of chalk, sand, or limestone with the thick, pitchy residue obtained by evaporating the more volatile portions of gas tar. The mineral substance must be heated to expel moisture and adhering air, and then added to the strongly heated pitch.

In addition to the use of asphalt for pavements, water-tight tanks, and coatings for iron tubes used for conveying gas or water, &c., it is used in photography, in photo-lithography, and photo-engraving, owing to the asphalt becoming insoluble in turpentine after exposure to light. In the latter case copper plates are covered with a thin coating of pure asphaltum, or bitumen of Judæa, dissolved in benzene or chloroform. When dry, the plate is exposed behind a film to bright sunlight for half an hour, and then developed by first softening the soluble portion of the asphaltum with olive oil, to which subsequently a little turpentine is added. As soon as the lines are bare the turpentine and oil must be washed away by the action of water.

For the preparation of American supplies of asphalt from petroleum, *see* Day (Min. and Eng. World, 1913; J. Soc. Chem. Ind. 1913, 32, 1057).

Methods for preparing asphalt for paving and other purposes are described by Dagusan (D. R. P. 4999, 1878; Dingl. poly. J. 232, 547); Kalilbetzer (D. R. P. 5646, 1878); Zadig and Neuberg (D. R. P. 5678, 1878; Dingl. poly. J. 233, 490); Clark (Eng. Pat. 8036, 1884; J. Soc. Chem. Ind. 5, 183); Kettmann (Eng. Pat. 12425, 1884; J. Soc. Chem. Ind. 4, 675); Richter (Siefenseid Zeit. 23, 272; J. Soc. Chem. Ind. 2, 474).

On the effect of sulphur in producing hard bitumen, *see* Brooks and Humphrey (J. Soc. Chem. Ind. 1917, 997). On the effect of exposure to air on different bitumens, *see* Reeve and Lewis (*idem*. 998).

Native asphalt can be distinguished from artificial asphalt by extracting with carbon disulphide, filtering, evaporating to dryness, and heating the residue till it can be ground to a fine powder; 0·1 gram is treated with 5 c.c. of fuming sulphuric acid for 24 hours, and is then mixed, with continuous stirring, with 10 c.c. of water. If pitch or coal tar be present, the solution will be of a dark-brown or blackish tint; if not, the solution will be of a light-yellow colour (*v.* PITCH).

For the detection of petroleum- or coal-tar pitch in natural asphalt, *see* Marcusson (Chem. Rev. Fett u. Harz-Ind. 1911, 18, 47; J. Soc. Chem. Ind. 1911, 30, 480; Zeitsch. angew. Chem. 1913, 26, 91; J. Soc. Chem. Ind. 1913, 32, 223); Pailler (J. Ind. Eng. Chem. 1914, 6, 286); Loebell (Chem. Zeit. 1914, 18; Marcusson, *ibid.* 1914, 38, 813, 822).

ASPHODEL. The tuberous roots of *Asphodèle de Sardaigne*, of *Asphodelus ramosus* (Linn.), and other species of the same genus, contain a fermentable substance from which alcohol may be prepared (*cf.* Rivière and Bailhache, Compt. rend. 1895, 121, 659). By drying and coarsely grinding the tubers, Landerer obtained a powder which, mixed with water, formed a strong glue. Badoil and Lienders obtain tannin from the pulp left after the extraction of the alcohol.

ASPIDIN, ASPIDINOL *v.* FILIX-MAS.

ASPIDOSAMINE, ASPIDOSPERMATINE, and **ASPIDOSPERMINE** *v.* QUEBRACHO ALKALOIDS.

ASPIRATORS. Aspirators are used to draw air or other gases through any apparatus connected with them, and were probably first employed by Brunner in his analyses of air, 1830–1840 (Pogg. Ann. 20, 274; 24, 569; 31, 1). The process of aspiration or inhaling of air is, however, most common, being necessary to the life of animals and to the ventilation of buildings, mines, &c., to change the air so that it may support life. In other analyses of air by Dumas and Boussingault, an exhausted globe or jar was used as an aspirator (1841, Ann. Chim. Phys. [3] iii. 257). When a vessel is emptied of liquid, air must enter to take its place, and the common aspirator, in its various forms, is a vessel with two openings, the lower to serve as outlet for the water or liquid, and the upper as inlet for the air or gas to be aspirated. With suitable fittings a siphon may be used instead of the lower opening, or the apparatus may be modified into a bell-jar standing over a basin or large jar, the air being drawn in through the neck of the bell-jar. This is Mohr's aspirator, which is sometimes poised like a gasholder to facilitate filling and emptying of the bell-jar (Mohr, Lehrbuch der Titrirmethode, 1855, Brunswick).

From their introduction, aspirators were used not only to draw in gases through apparatus and reagents employed, at a regulated rate, but also to measure the gases so manipulated by simply measuring or weighing the liquid run out of the aspirator. For approximate readings aspirators of glass may be graduated, and those of metal may be provided with gauge glasses.

Numerous forms of the simple aspirator have been invented by Brunner, Regnault, Mohr, and others. Fig. 1 is perhaps the form in most frequent use, and is generally of glass, plain or graduated. Fig. 2 is a very convenient form, described by Clemens Winkler (Industrie-Gase, 1877, 39-41) constructed of zinc plate and supported on a wooden tripod. The second tap below, on the side tube, is useful in filling the aspirator with water. Fig. 3 is the form often used in testing the gases from chemical works. It is simply a cubical or rectangular box made of sheet lead, with a graduated gauge glass, and can be opened at A to fill it with water.

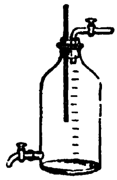


FIG. 1.

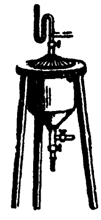

FIG. 2.

Double aspirators. In short operations the simple aspirator requires no refilling nor special attention after the taps are adjusted. To obviate the inconvenience of stopping to change or refill that would be necessary in longer operations, Brunner, Boisgiraud, Dancer, Muencke, and others have contrived double aspirators so connected that each vessel is alternately above and below, and one or other always ready for use. The aspirating bottles may be mounted on a common axis as in Dancer's swivel aspirator Fig. 4 (Chem. News, 1864, 10, 295). These swivel aspirators are very convenient, but the difference of water-level in the two bottles is not under the control of the operator and varies between the height of one bottle and a very small minimum.

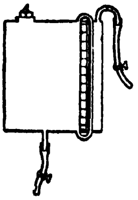

FIG. 3.

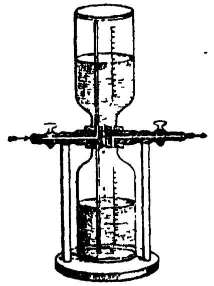

FIG. 4.

Figs. 5 and 6 show an arrangement devised by the author, which has certain advantages. The bottles A and B are connected as shown, being raised and lowered alternately. The four-way tap C (shown larger in Fig. 6) has its index I turned towards the upper bottle in aspirating and towards the lower bottle in blowing. It is made from a good gas tap by boring up the centre of the plug at F, leading out the hole at G. A small piece of metal H is then fitted and soldered diagonally where the holes cross, a piece of tubing K soldered on to the socket of the tap, and an index I above the plug.

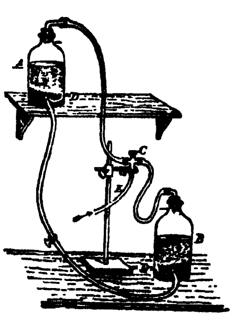

FIG. 5.

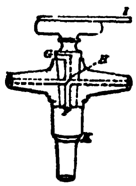

FIG. 6.

Paraffin wax is used to adjust the bottles for exact measurement, and to obtain a fine adjustment below at D, as well as above, by a mark on the neck of the bottle. The proper quantity of melted wax is run through a wide tube into the warm bottle slightly tilted. A passage from the tubulure to D at the side of the bottle is secured by pushing an indiarubber tube through the tubulure and fixing it in the proper position before the wax is run in, and after the wax is quite solid this tube is drawn out. The passage should be curved, so that on emptying the bottle of water the water runs out to the mark at D. The bottles are then adjusted by weighing their content of water between the marks and adding or removing paraffin till at the standard temperature and pressure they hold the exact quantity of water corresponding to the volume required. In successive weighings of bottles so adjusted the differences should not exceed 0·1 gram. To avoid loosening of the wax from direct contact with the glass, the bottles should be preserved from changes of temperature and from mechanical vibration, &c.

Constant or automatic aspirators. Instruments of this class have been invented by Guthrie (Phil. Mag. [4] 15, 64) and by Bonny (Winkler's Technical Gas Analysis, trans. by Lunge, 17). In each of them a pipe from the water supply leads a constant stream of water into a vessel, which, when full, is emptied by a siphon, whose tube is of larger size than the supply pipe. The arrangement thus acts on the principle of the intermittent siphon, and the vessel is filled and emptied at regular intervals. In Bonny's instrument these are registered by a simple mechanism, and the total volume passed is known on measuring the volume passed in one operation.

The Sprengel and injector pumps may be used as constant aspirators (*v.* FILTER PUMPS). By means of a collecting box attached below the pumps to allow the gas and water to escape at different levels, the gas may be measured by passing it through a small gas meter (Davis, J. Soc. Chem. Ind. 211).

J. Grossman (Winkler's Industrie-Gase, 218) has invented a small mercurial aspirator, on the principle of the Geissler pump, with two reservoirs, which are alternately raised and lowered. It is fitted with registering apparatus.

In testing air and gases from confined places, works, &c., Angus Smith, Davis, and others have used small pear-shaped aspirators of indiarubber. These are emptied by simply squeezing in the hand. The air escapes by a valve, of which the simplest is a small slit in the rubber connecting tube, opening outwards like a Bunsen's valve. The rubber recovering its form draws a certain volume of gas through the testing apparatus, and it is easy to ascertain approximately the total volume of gas corresponding to any given number of times the aspirator has been filled. Another larger aspirator of this class is of bellows form, like a concertina, the folding part being of indiarubber. This aspirator is frequently used for filling by displacement jars or bottles with gas to be tested. The common single-barrel air pump or apparatus, on the same principle, is also applied in this manner as an aspirator.

At the British Association Belfast meeting, 1874, the late Prof. Andrews showed how an ordinary wet gas meter could be converted into an aspirator by applying motive power to the hollow axis of the drum, thereby causing it to suck in air at the inlet side and at the same time to measure the air on the meter index. Using mercury as liquid in a cast-iron meter, a similar arrangement forms the basis of the Barr and Stroud air pump applied in the evacuation of bulbs for electric lighting lamps (J. Soc. Chem. Ind. 1896, 640; Eng. Pat. 13188, July, 1895).

T. F.

ASPIRIN. Trade name for acetyl salicylic acid $C_6H_4(COOH)O\cdot CO\cdot CH_3$, used as an antirheumatic, and in the treatment of headaches, feverish colds, &c. Is hydrolysed in the intestine forming sodium salicylate.

ASPIROPHEN. Trade name for amino acetphenetide acetyl salicylate.

ASQUIRROL. Trade name for mercury dimethoxide.

ASSAYING. Assaying, 'the trial of metals,' a term originally applied only to the testing of gold and silver, is now usually extended to the determination of the quantity of the valuable metal in an ore or metallurgical product. It is also sometimes taken to include the estimation of any element which may prejudicially affect the value of the ore, but it is more usual to discuss this together with such work as the complete analysis of ores, slags, furnace materials, fuel, &c., under the heading of 'metallurgical analysis.' A brief account of some of these sections is given below.

The art of assaying is of great antiquity. The use of the touchstone for testing gold in India was referred to by Mathuranatha (Hist. of Hindu Chemistry, by Ray, ii. 231), and was probably known in the Greek world at least as early as B.C. 700, when the first electrum or gold-silver coins were manufactured. At any rate the touchstone found its way into Greek mythology. The testing of gold alloys by cementation was described by Pliny, by Strabo, and in the eighth century A.D. by the Arabian Geber, who was also familiar with the method of cupellation, and is reputed to have discovered nitric acid. The parting assay of gold with the aid of this acid is referred to in a decree of Philippe de Valois in the year 1343, confirming its use in the French Mint. Alloys of silver with copper were tested by observing the degree of blackening caused by heat in the Roman Mint under the Republic (Rochon, Essais sur les Monnoies, 17, 1792).

It is probable that ores were not valued except by inspection until the Middle Ages. The first clear references to ore-assaying are to be found in the anonymous little books entitled Probierbüchlein, which were published in Germany early in the sixteenth century, and in the writings of Biringuccio, Agricola, and Ercker in the same century, but the art was evidently regarded by these authors as already ancient at the time at which they wrote. Ercker, writing at Frankfort in 1580, describes the fire-assays not only of several different kinds of gold and silver ores, but also of the ores of copper, lead, tin, antimony, iron, mercury, and bismuth. Assaying by means of 'wet methods,' volumetric, gravimetric, and electrolytic, is of comparatively recent introduction (excepting the parting assay of gold), but has now in great part superseded the ancient processes involving the use of furnaces.

Sampling.—Whether the material to be assayed is a portion of a vein underground, a heap of broken ore, pigs of metal, or a delicate piece of jewellery, in every case a representative sample must be obtained. In the case of ore *in situ* underground, pieces are taken from a number of different points and either mixed or examined separately. Ore which can be moved is reduced in bulk either by hand or by machinery, and is generally crushed finer between each successive reduction in bulk. Every second, fifth, tenth, or twentieth shovelful or car-load may be set aside as a sample, or the whole heap may be made into a perfect cone, which is flattened and divided into four quarters along two diameters. Two opposite quarters are removed and mixed, and the process of 'coning and quartering' repeated as often as necessary. A heap or vat of ore or tailings, which must be sampled without being moved, is pierced at regularly spaced intervals by a sampling tube which resembles a cheese-taster, and withdraws a cylindrical sample extending to the bottom of the vat or heap.

In automatic sampling machines, which are much used in Western America, the crushed ore is made to slide down an inclined plane or rotating cone, and a portion of the stream of ore is deflected and set aside as a sample. Those machines are preferred which momentarily take the whole stream of ore at regular intervals of time. A stream of pulp is sampled by the passage through it from side to side or from top to bottom, at regular intervals of time, of a receptacle which is large enough not to overflow while the sample is being intercepted. The pulp sample is then filtered and dried. Further reduction in the laboratory is effected by coning and quartering or by a machine such as the *riffle* or *sampling tin*, which consists of a series of metal troughs arranged side by side and fastened at equal distances from each other. A stream of ore let fall on it is in part retained by the troughs and in part passes through.

The final grinding of the ore is effected by means of an iron pestle and mortar, or of a large hammer with a curved face sliding on an iron plate (or *buckboard*), or by some form of rolling or grinding mill. The crushed ore is passed through a sieve, the fineness of which varies according to the ore and the method of assay. If a panning test is required, a 20-mesh sieve (*i.e.* one with 20 holes to the linear inch) suffices. For most fusions, *e.g.* dry lead assay, a 60-mesh sieve is used. Gold ores are crushed through an 80- or 100-mesh sieve, and in the case of tin ores and of telluride ores of gold, the best results are obtained by using 120-mesh sieves. Before it can be passed through a fine sieve, the ore must be dried, so that the *moisture* is determined on coarsely crushed ore by drying at 100° on a water-bath, or, if the dry material is not likely to be affected in any way by a somewhat higher temperature, it is heated on a sand-bath. In crushing rich gold and silver ores, mint sweepings, &c., pieces of metal are found which become flattened out and are caught on the sieve. These 'metallics' are treated separately, and the value calculated on the weight of ore from which they were derived.

The dried and crushed sample is thoroughly mixed by means of a spatula in a basin, or on rubber-cloth, before the portion required for assay is weighed out. If stored in a bottle or tin, the movement of the vessel causes the heavy particles to settle, so that the material at the bottom becomes richer than that at the top.

Ingots of metal are sampled by cuts taken from the corners or edges, as in the case of refined gold and silver, or by drillings from a number of different spots, as is sometimes done in the case of iron and steel and of unrefined gold and silver Pigs of argentiferous lead are sometimes sampled by drillings or saw cuts. Base gold and silver ingots, and in many cases ingots of steel and pigs of lead, are melted and stirred, and a portion dipped out and granulated by pouring into water, or cast into a little ingot. Coins are sampled in various ways, silver coins being seldom uniform in composition. The simplest method applicable to all is to roll them out and cut them into a large number of little pieces, so that all parts of the coin may be represented in the portion taken for assay. This method is adopted in the Philadelphia Mint, but is not in general use, other more complicated methods being preferred. Gold and silver wares are usually pickled, and are richer on the surface than in the interior. In sampling them, it is accordingly necessary to remove the outside by scraping and then to scrape off a portion of metal for assay.

The *preliminary examination* of ores includes careful inspection, which is all the more useful if some comparatively large pieces are included in the sample. The proximate constituents, such as quartz, pyrites, magnetite, galena, &c., are thus observed, and the proportions in which they are present roughly estimated, this information being required in making-up furnace charges. Frequently a concentration test is made in a miner's pan (a flat-bottomed sheet-iron pan about 20 inches in diameter, and 3 or 4 inches deep, with sloping slides) or a vanning shovel, or in any basin, pan, or even clock-glass available. For this purpose a portion of 25 grams or more is weighed out, stirred and shaken with water by a circular motion on the shovel, and the lighter particles rinsed away and caught in a basin. Finally by a combination of the circular motion, and a series of jerks, the denser particles are thrown up and the lighter ones washed down the shovel. The concentrates are examined with a lens or separated, dried, and weighed, or treated with acid, or examined by means of the blowpipe, or in other ways, in order to determine the presence or absence of elements likely to interfere with the method of assay chosen. The vanning shovel is used particularly with tin ores, but may be applied to any others. Panning tests are especially useful in the examination of gold ores, but are also required to determine the nature of the 'mineral' or compounds of the heavy metals in almost all ores. The test may be applied to half a gram of ore in a watch-glass, if no more can be spared.

The furnaces used by assayers are the muffle furnace, and the melting or wind-furnace.

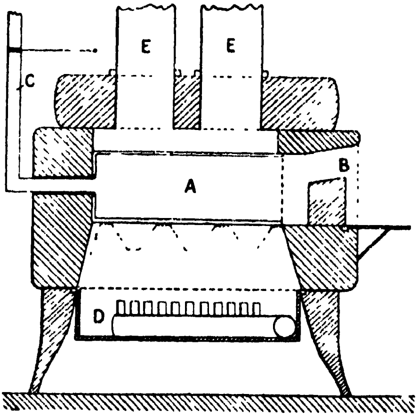

FIG 1.

The *muffle furnace* consists of a small oven or muffle of refractory fireclay open at the front, and having an arched top. It is heated by coal, coke, oil, gas, or electricity. Muffles vary in size according to the amount of work to be done, but those used at the Royal Mint may be considered full size. Sectional views of one of these furnaces are shown in Figs. 1 and 2. The muffle A is 14½ inches long, 8¼ inches wide, and 5 inches high, inside measurements, with walls about ⅜ inch thick. The mouth is closed by the firebrick B and by a sliding plate resting on B. Air enters through holes in the sliding

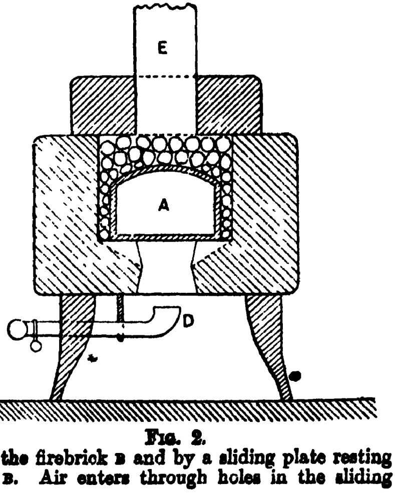

FIG. 2.

plate and passes out at the back through the tube O, which has a sliding damper and leads into the main flue. The fuel is ordinary gas, supplied by a row of bunsen burners D, and complete combustion of the gas may be aided by clay fireballs surrounding the muffle. The flues E E carry off the waste gases. The furnace walls consist of firebrick bound with iron and covered with a thick layer of magnesia and asbestos to check radiation. No chimney stack or forced draught is required for this furnace.

A *melting furnace* adapted for the use of coke as fuel and suitable to make fusions in assay operations, is shown in section in Fig. 3, in which A is the fireplace, B the flue, C the ashpit, D the damper, and E the firedoor. The most useful size of the fireplace is about 9 inches square, and about 10 inches in depth from the firebars to the flue. The furnace is built of brick and lined with firebrick. It is bound with angle iron or covered with iron plates bolted together and furnished with tie rods. Gas-melting furnaces with natural draught or using a blast of air are less common. Fluxing crucibles consist of fireclay or, in the assay of galena, of wrought iron. They are of different sizes and shapes, the best-known being the Battersea (round, Cornish, and triangle), French, Hessian, and Colorado crucibles, the last-named being used for making fusions in the muffle, a common practice in America. Most crucibles require careful annealing before being used. Roasting dishes made of fireclay are for the roasting of ores; fireclay scorifying dishes or scorifiers are used in the process of scorification; cupels of various shapes and sizes are made of compressed bone-ash or magnesia, and are required in the assay of the precious metals. The bone-ash cupels may be made by the assayer, and must be carefully dried before use. Magnesia cupels are usually bought ready-made.

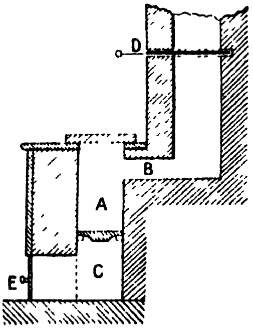

FIG. 3.

The *reagents* used in fire assay may be classed as fluxes, agents for reducing, oxidising, sulphurising, and desulphurising, and covers to protect the contents of the crucible from the action of the air, furnace gases, &c. Generally speaking, an ore consists of compounds of a heavy metal or metals (the mineral), together with a quantity of earthy materials, such as quartz, silicates, &c. (the gangue). It is required to reduce the valuable constituent to metallic form, and to incorporate the remainder of the ore in a fusible slag, through which the particles of metal may settle to the bottom, where they collect in the form of a button. Sometimes a regulus or matte (sulphide of a heavy metal) or a speise (arsenide of a heavy metal) forms a separate layer between the metal and the slag, and a cover, say, of common salt, may be provided which is lighter than silicate slags and floats on the top. On breaking open a cold crucible in which a fusion has been made, there are, therefore, frequently four layers.

The principal fluxes used are sodium carbonate, which forms fusible mixtures with acid (siliceous) ores, and also acts as a desulphuriser, converting pyrites into a mixture of sulphides of iron and sodium which does not form a regulus, but is dispersed through the slag. Carbonate of soda is now generally used in the anhydrous form, Na_2CO_3, but the bicarbonate, which gives up half its carbonic acid without fusion is also suitable. Soda crystals give up their water of crystallisation with ebullition, and are not suitable unless previously dried. Basic ores require borax, which forms fusible mixtures with oxides of iron, lime, &c.; and increases the fluidity of most charges. Crystallised borax powder on heating swells up enormously, gives up its water and fuses into a glass. The swelling may occasion loss in the assay if the crucible is too full. To avoid this, borax glass may be used, which is equivalent to about double its weight of ordinary borax. Litharge is a useful flux, especially for oxides of iron, copper, &c., but attacks and corrodes the crucibles. Fluorspar is sometimes used, especially for phosphates. Sand is often required to protect the crucible from attack by basic ores.

The reducing agents are carbon (charcoal powder or lampblack), flour, tartar or argol (crude hydrogen potassium tartrate), and occasionally potassium cyanide. One part of charcoal is about equal to two parts of flour or five of tartar, but tartar also acts as a flux, being converted by heat into carbon and potassium carbonate. Black flux is a reducing mixture made by deflagrating one part of nitre with two and a half parts of argol.

The chief oxidising agents, which are also desulphurisers, are hot air, litharge or red lead, and nitre. Iron is often used as a desulphurising agent. The ordinary materials used as covers are borax and common salt.

The *balances and weights* do not differ, as a rule, from those used in ordinary chemical analysis, the most notable exception being in the case of those used in the assay of gold and silver. The proportion of these metals present in ores is reported in troy ounces, pennyweights, and grains per ton, or sometimes in ounces and decimals or in pennyweights and decimals. The weight of ore taken for assay accordingly contains as many milligrams as there are ounces troy in a ton (29,166 in a ton of 2000 lbs., and 32,666 in a ton of 2240 lbs.). This weight of 29·166 grams is called an *assay-ton* (or A.T.), and boxes of weights made up of assay-tons and decimals are used by many assayers. Then the gold extracted from the sample of ore is weighed in milligrams, and can be reported without calculation. In the assay of gold bullion the weights commonly range from '1000' downwards, where 1000=0·5 gram or some other unit such as 5 grains. Much tedious calculation is avoided by thus marking the weights so that their face-value gives at once the result of the assay. Again, in assaying silver by precipitation as chloride

(India Mint method, see p. 419), since 18·815 grains of pure silver are contained in 25 grains of chloride, it follows that if 18·815 grains of an alloy be always taken for assay, and the resulting chloride be weighed out with a series of weights the largest of which is marked 1000, and is equal to 25 grains, and the others are marked correspondingly, then the subsidiary weights of this series will indicate the result of the assay without calculation. A similar series can, of course, be arranged for any special purpose.

The balances used for weighing gold and silver in bullion assays are light and delicate, taking about 2 grams as their maximum of weight, and turning to one hundredth of a milligram. Usually, one division of the ivory scale is made equal to 0·05 mg. Balances for weighing the parted gold in ore assays are still more delicate. The maximum weight which they can carry is only 1 gram or even less, and they turn with one-hundredth or in some cases only one five-hundredth of a milligram. Milligram and half-milligram riders are used, but the final reading is always based on the deflection from the zero position of the pointer, measured by the number of divisions on the ivory scale covered by the swing. At the present day short beams of 6 inches, 4 inches, and even 8 cm. in length, are in use, so that the balances are very rapid in action in spite of their sensitiveness.

In quantitative blowpipe work on gold and silver, it has been found possible to dispense altogether with a delicate balance, and to use an ivory scale (Plattner's scale), by which the diameter of the bead of metal is accurately measured. The principle has been extended in the assay of poor materials, and beads of microscopic dimensions are placed on the stage of a microscope and measured by means of a micrometer eyepiece. In this way L. Wagoner (Trans. Am. Inst. Mining Eng. xxxi. 1901, 798) obtained a close approximation to the weight of beads of silver of 0·02 mm. in diameter, which weighed about 0·00004 mg.

The above summary has special reference to the requirements of a laboratory for making dry or fire assays. For wet assays, the apparatus and reagents are those of the ordinary analytical laboratory (*v.* ANALYSIS).

In all methods of assaying, wet or dry, time must be considered as well as accuracy. It is sometimes important to arrive at a result in the course of an hour or less, and some of the methods described are intended for such emergencies, when extreme accuracy must be sacrificed. It is also necessary to observe that assay methods are intended to be comparative, and wherever it is possible check assays on similar materials of known composition should be made side by side with the assays of ores or other bodies requiring examination, and a correction applied to the results. In the following pages, only methods in common use in assay offices are described. The methods of ordinary analysis are generally omitted or made the subject of brief reference.

Aluminium. There are no special methods of assaying the ores of this metal. The silicates are broken up, and the silica removed as usual, and the acid solution of the bases is treated so as to separate the metals contained in it. Aluminium is precipitated and weighed as phosphate $AlPO_4$, or oxide Al_2O_3. It is sometimes weighed as oxide together with oxide of iron Fe_2O_3, and also P_2O_5, if these constituents are present in the ore. The last mentioned constituent is of course combined as phosphate. The phosphorus and iron are then determined, aluminium being estimated by difference (Low's Technical Methods of Ore Analysis, 1st ed. 22).

Antimony. The antimony in ores may be determined by fusion with cyanide of potassium or with iron (avoiding excess) and black flux, but the results are unsatisfactory. The sulphide of antimony in an ore may also be approximately determined by charging 500 grams of ore broken to nut-size into a clay crucible with a perforated bottom. This crucible is fitted into another of about the same size, and the joint carefully luted. A cover is also luted on, and the whole is slowly raised to a red heat. The sulphide of antimony fuses and liquates into the lower crucible, from which it can be detached when cold, and weighed. The fused sulphide of antimony, if pure, contains 71·7 p.c. of the metal. The valuation of antimony sulphide ores is usually effected, according to Bedford McNeill (Berenger's Assaying, 11th ed. 226), by having recourse to the ordinary smelting operation, which is to be used in treating the ore on the large scale. Charges of about 20 kilos. of ore are used for the valuation.

The wet methods of estimation of antimony in ore are far more accurate than those referred to above. The ore is fused with sulphur and sodium carbonate, and then digested with water. A solution of an alkaline sulpho-compound of antimony is thus obtained, from which a mixture of antimony and arsenic sulphides and free sulphur is precipitated by the addition of dilute hydrochloric acid. After the arsenic has been separated, the antimony sulphide is weighed or is oxidised by fuming nitric acid, and weighed as Sb_2O_4. Ores may also be attacked by hydrochloric acid. The antimony in the separated sulphide may be estimated volumetrically, dissolving the sulphides in hydrochloric acid and chlorate of potash, warming to expel the chlorine, adding an excess of potassium iodide, and titrating with thiosulphate of soda (J. Soc. Chem. Ind. xv. 255).

Arsenic. The determination of arsenic in ores and metallurgical products is usually made by Pearce's method, which consists in fusing about 0·5 gram of the ore with 5 grams of a mixture of equal parts of sodium carbonate and nitre, dissolving out the soluble arsenates of the alkalis and precipitating the arsenic in a neutral solution by means of silver nitrate. The precipitated brick-red silver arsenate Ag_3AsO_4 is filtered off, dissolved in nitric acid, and the silver in it determined by Volhard's thiocyanate method. The amount of arsenic present can then be calculated (Low's Ore Analysis, 41). Small quantities of arsenic in metals and minerals may be separated by distillation with ferric chloride and calcium chloride in a hydrochloric acid solution, the distilled arsenious chloride being condensed in a vessel of cold water (Berenger's Assaying, 384). (For arsenic in steel, see p. 417.)

Bismuth, if present in an ore in the metallic state, may be determined by liquation, the method of procedure being similar to that used in liquating sulphide of antimony (*q.v.*). The bismuth in an ore may also be determined by fusing it with fusion mixture, common salt, and cyanide of potassium. These methods are inexact, and bismuth is usually determined by being weighed as Bi_2O_3 after precipitation as carbonate, or as BiOCl on a weighed filter or a Gooch crucible after being dried at 100°. Bismuth in metallic lead is precipitated and weighed as BiOCl, and in metallic copper it is detected by the colour given to lead iodide. (For estimation of bismuth in copper, *see* p. 414.)

Chromium occurs in chrome-iron ore and sometimes in other iron ores, in pig-iron and in steel. Small quantities of chromium in iron ores, after separation from other metals and earths, are precipitated by lead acetate in an acetic acid solution, and weighed as $PbCrO_4$, or, in the alternative, reduced by sulphurous acid and the chromium precipitated from the green solution by means of ammonia and weighed as Cr_2O_3. Chrome-iron ore is assayed by a volumetric method based on the oxidation of ferrous iron by chromium in the form of chromate. The chromium is oxidised by fusion with peroxide of sodium (J. Iron and Steel Inst. xlviii. 153). The ferrous iron is added in the form of a weighed amount of ferrous ammonium sulphate or of a weighed amount of metallic iron dissolved in sulphuric acid. The excess of ferrous iron present in the solution containing the chromium is titrated with permanganate. Chromium in steel is precipitated and weighed as chromium phosphate (Chem. News, lvii. 1888, 153), or as chromic oxide Cr_2O_3.

Cobalt. *See* **Nickel**, p. 418.

Copper. The principal ores of copper are (*a*) native copper; (*b*) sulphide ores, copper pyrites or yellow ore, erubescite or purple ore, grey copper ore, &c.; (*c*) oxidised ores, malachite, silicate of copper, &c. The treatment of copper ores results in the production of copper matte or regulus containing from 30 to 50 p.c. of copper, and cement copper or copper precipitate, containing 70 p.c. or more of metallic copper. In addition to these materials, ordinary commercial standard copper, refined copper, and the alloys of copper require to be assayed.

The chief methods in use are as follows:—

(1) *Dry or Cornish assay*, long used in connection with the sale of copper ores, but applicable chiefly to mattes and rich sulphide ores. It is especially unsatisfactory when dealing with poor ores, but gives low results in all cases, the loss, according to Beringer, ranging from 2 p.c. of the copper present in the richest materials to 33 p.c. of the copper in 2 p.c. ore. It consists in fusing the calcined regulus for metallic copper and refining the copper. Rich oxidised ores are fused for metal at once. The amount of ore taken for assay is 400 grains, but with rich material only 200 grains or even 100 grains are taken. The fluxes vary with the nature of the ore, in which there may be too much sulphur and iron, as in copper pyrites, &c., or too little, as in grey copper. The following are examples of the charges:—

	A. Copper pyrites	B. Grey copper ore
Ore	200 grains	100 grains
Nitre	50 ,,	—
Lime	200 ,,	200 ,,
Fluorspar	200 ,,	200 ,,
Glass	150 ,,	150 ,,
Borax	150 ,,	150 ,,
Hæmatite	—	15–20 ,,
Sulphur	—	25–30 ,,
Argol	—	30 ,,

The charge is fused in a 'large copper' crucible at a low red heat, which is gradually raised. After about 15 minutes the charge is poured into a conical mould, and, as soon as the slag is solid, it is taken up by tongs, dipped into water, and allowed to dry. When treated in this way, the slag breaks up readily. The regulus is detached by a hammer and crushed to powder in an iron mortar. It should be reddish-brown in colour and contain about 50 p.c. of copper and 20 p.c. of iron. It is roasted in a Cornish crucible in the melting furnace or in a roasting dish in the muffle, at a low but increasing temperature, with continuous stirring at first. When 'sweet,' *i.e.* not smelling of sulphur, at a full red heat, it is mixed with a little charcoal powder, and re-roasted to decompose sulphates. It is then crushed again, if necessary, and fused in the same crucible with argol, borax, and sodium carbonate. A high temperature is required, and the charge is poured in about 15 minutes. The slag is detached and cleaned by a second fusion with more argol and sodium carbonate. The 'coarse copper' obtained in this way is refined by being charged into a very hot crucible and melted. The impurities are oxidised by the air and form a ring of oxides round an eye of copper. Then refining flux, which consists of a deflagrated mixture of nitre, argol, and common salt, is added, and 2 minutes later the copper is poured, and if it is found to be at 'tough pitch,' it is weighed. The slag contains copper, and must be cleaned. (For full details of the method, *see* Percy's Metallurgy, i. 1861, 454–478.)

(2) *Electrolytic assay of copper.* The weight of ore taken for assay depends on its richness, a convenient amount of metallic copper for electro-deposition being from 0·1 to 0·5 gram. When using this method or any of the other wet methods, the copper must first be brought into solution and usually separated from other metals. Oxidised ores may require merely to be treated with hydrochloric acid. Sulphide ores, mattes, copper precipitate, &c., are attacked by nitric acid, evaporated to dryness, and taken up by hydrochloric acid. Copper slags are fused with sodium and potassium carbonate (fusion mixture), and a little nitre, and are then digested with water and hydrochloric acid. The copper is precipitated from its hydrochloric acid solution by means of sulphuretted hydrogen or (after evaporation with sulphuric acid) by sodium thiosulphate, and the sulphides are filtered off and redissolved in nitric acid. The copper may also be separated from other metals by adding sulphuric acid to the nitric or nitrohydrochloric acid solution and boiling off the volatile acids. The solution is cooled, diluted and filtered, and the copper precipitated at a boiling temperature with aluminium foil. For the electrolytic assay, the

solution obtained in one of these ways is diluted, warmed, and filtered into a 200 c.c. flask, and made up to about 100 c.c., of which from 2·5 to 5 p.c. should be nitric acid. Platinum electrodes (spiral and weighed cone or cylinder) are then placed in position, and a current from two Daniell cells in series is passed through for 16 or 17 hours. The cylinder is removed from the colourless solution, washed with water and afterwards with alcohol, dried in a water-oven, and weighed. The copper precipitate should be salmon-red in colour. The solution still contains a little copper, which is estimated colorimetrically, ammonia being added, and the colour, after filtration, compared with those of standard solutions containing known amounts of copper. Silver, mercury, bismuth, arsenic, and antimony interfere with the process, being deposited with the copper. Mercury, however, is separated on dissolving the sulphides in nitric acid. Bismuth turns the copper dark grey, but is not deposited until most of the copper has been thrown down. Arsenic and antimony darken the copper deposit, but may be driven off by heating to dull redness. Lead is deposited at the anode as a dark-coloured coating of PbO_2, and may be weighed in that form. The electrolytic assay is suitable for all materials containing copper (*cf.* ELECTROLYTIC ANALYSIS).

By rapidly rotating the cathode a coherent deposit can be obtained even when a strong current of 10 to 12 amperes per 100 sq. cms. of cathodic area instead of the usual current of 0·5 to 1·0 ampere is used. The time required for the deposition of the copper may thus be shortened to a few minutes (Amer. J. Sci. 1903, xvii. 320, xviii. 56; J. Amer. Chem. Soc. xxv. 896; Chem. Soc. Trans. xci. 373).

(3) *The volumetric assay of copper.* There are two main processes—the potassium cyanide and the iodide methods. Both are in wide use in the assay of ores, alloys, &c. In preparing to use these methods, the copper is brought into solution, and may be separated from other metals, &c., as already described, with any further precautions necessary to remove special impurities. With ordinary pyritic ores, however, containing no zinc, silver, nickel, or cobalt, it is sufficient, in preparing for the cyanide process, to heat the ore gently with concentrated nitric acid to which a little sulphuric acid has been added. It is then diluted, an excess of ammonia or of Na_2CO_3 added, the bulk made up to some convenient amount such as 300 c.c., and the solution titrated with potassium cyanide. The blue solution is decolourised, and when overdone changes to a straw-yellow colour. The results are affected by time, temperature, degree of dilution, and by the amounts of ammonia and of ammonium salts. The conditions of the check assays on pure copper and those on ores, &c., must therefore be identical, and ferric hydrate, for example, must be present either in both or in neither. If, however, the solution is free from ammonia and ammonium salts, and is made alkaline with sodium carbonate, the effects of time, temperature and degree of dilution are much reduced, while ferric salts do not affect the result unless present in such amount as to mask the end reaction. The standard cyanide solution, which decomposes somewhat rapidly, contains about 42 grams KCy to the litre, and 100 c.c. of this is equivalent to 1 gram of copper. The reaction, according to Beringer, is represented by the equation:

$$CuSO_4+4KCy=2KCy\cdot CuCy_2+K_2SO_4.$$

The quantity of copper usually present in an assay is about 0·5 gram. At the finish the effect of an addition of 0·5 c.c. of cyanide is readily observable. Zinc, silver, nickel, and cobalt interfere with the assay, and must be removed before titration.

In the iodide method, the alloy or the sulphide of copper separated from the ore is dissolved in nitric acid, evaporated almost to dryness in order to expel nitrous fumes, and diluted. The nitrous products may also be destroyed by urea. The solution is then filtered if necessary, and carefully neutralised with sodium carbonate, avoiding excess. One c.c. of acetic acid is then added, which should be enough to redissolve the precipitated copper. Next, after cooling the flask, an amount of about 5 grams of potassium iodide crystals is added (or not less than ten times the weight of the copper present); the solution is diluted to a fixed amount, say 50 c.c.; and the liberated iodine is at once titrated with a solution containing 39·18 grams sodium thiosulphate (equivalent to 10 grams of copper) to the litre. The reactions are represented by the equations:

$$2CuSO_4+4KI=Cu_2I_2+2I+2K_2SO_4$$
$$2Na_2S_2O_3+2I=2NaI+Na_2S_4O_6.$$

When the yellow colour is almost discharged, 2 c.c. of fresh starch solution is added, and the addition of the thiosulphate continued drop by drop until the blue colour disappears and does not return within 2 or 3 minutes. The effect of one drop or 0·05 c.c. of standard solution, equivalent to 0·5 mg. copper, is observable. The solution is standardised with pure electrolytic copper. Ferric acetate, arsenic, lead, and large quantities of sodium acetate may interfere with the titration. According to J. W. Westmoreland (Beringer's Assaying, 441), sodium acetate counteracts the interference of arsenic and bismuth, and the bad effect of large quantities of sodium acetate is removed by doubling the amount of potassium iodide added. Iron, if present, is precipitated by ammonium phosphate (J. Soc. Chem. Ind. v. 48). Instead of neutralising with sodium carbonate and acidifying with acetic acid, an addition of 20 c.c. of a saturated solution of zinc acetate may be made (A. H. Low). In order to dispense with the large quantities of expensive potassium iodide required in the ordinary method, Moir proposes (J. Chem. Met. and Mng. Soc. of S.A., vol. xviii., Nov. 1917, p. 133) to add a slight excess of sodium thiosulphate to the usual very faintly acid solution of cupric acetate, and to titrate back with *N*/10-iodine, of which only a small quantity will be required.

The colorimetric method of assaying copper is sometimes used in the case of very poor ores, or generally whenever the quantity of copper present is small. Reference has been made to it above.

Examination of commercial copper. Electrolytic and Lake copper are generally nearly pure, but some of the metal sold contains as much as

2 or 3 p.c. of impurities. The most important of these are arsenic, lead, nickel, oxygen, and phosphorus; but antimony, bismuth, cobalt, gold, iron, selenium, silver, sulphur, and tellurium may also be present. The impurities to be looked for in copper which has passed a high conductivity test are mainly bismuth, selenium, and tellurium. Arsenic and phosphorus are separated as iron arsenate and phosphate mixed with acetate. Gold and antimony are separated by dissolving the copper in nitric acid, and silver is precipitated as chloride or bromide from a nitric acid solution. It may be collected in a precipitate of lead sulphate Nickel is left in solution by precipitating copper electrolytically, or by sulphuretted hydrogen in an acid solution. Lead is detected by the blackening of the anode in the electrolytic assay, and is estimated as sulphate or chromate.

The methods of determining oxygen may be classified in two groups (J. Inst. Metals, vii. 1912, 232):—

1. The estimation of cuprous oxide.
2. The estimation of total oxygen.

In Hampe's method (Zeitsch. anal. Chem. xiii. 1874, 215) of estimating the amount of cuprous oxide in copper, the copper is dissolved in cold dilute silver nitrate solution free from acid. The equations are as follows:—

$$Cu+2AgNO_3=Cu(NO_3)_2+2Ag$$

$$3Cu_2O+6AgNO_3+3H_2O$$
$$=2Cu(NO_3)_2+2Cu_2(HO)_3NO_3+6Ag$$

The copper existing as Cu_2O is found by multiplying the copper in the precipitate by $\frac{3}{2}$. The results are satisfactory.

Total oxygen is estimated by heating thin strips or bright turnings of copper to redness in a stream of hydrogen and weighing the water produced, or, better still, the residual copper. In the latter case, as mirrors of arsenic, antimony and bismuth may be formed, it is necessary to weigh the tube and copper together.

Bismuth is separated, according to Beringer, by precipitation by sodium bicarbonate. After redissolving in sulphuric acid, it is boiled with sulphurous acid and potassium iodide, and the bismuth in the yellow solution estimated colorimetrically. Tellurium and selenium (J. Amer. Chem. Soc. xvii. 280) are precipitated as iron tellurite and selenite by additions of iron nitrate and ammonia. The precipitate is redissolved in HCl, tartaric acid and potash added, and a current of sulphuretted hydrogen passed. The selenium and tellurium are subsequently precipitated by a current of sulphurous acid in a hydrochloric solution, and parted by boiling with potassium cyanide.

Gold. Gold is generally in the metallic state in its ores, either in the form of grains, scales, pellets, &c., in loose alluvial gravels, or in various forms embedded in quartz or other gangue in veins. It is frequently associated with iron pyrites, blende, &c., but the only native compounds are the tellurides. Besides these, the auriferous materials to be assayed comprise tailings or residues of ores after treatment, copper bottoms, pig lead, unrefined bullion, which contains silver, copper, and other metals, fine (*i.e.* refined) gold, and the commercial alloys used for coinage, plate, &c. The assay of gold ores and alloys is made with greater exactness than other assays, owing to the high value of the metal.

A *panning assay*, or concentration test is carried out as described on p. 409. The concentrates consist of 'black sand' or oxides of iron, titanium, &c., sulphides and arsenides, and sometimes grains of platinum. Free gold is sometimes visible, and is collected by grinding in a mortar with mercury, panning out the amalgam, and recovering the gold by distilling off the mercury or dissolving it in nitric acid. In either case the gold must be parted from the silver as described on p. 416. The panning assay of alluvial gold deposits is usually reported in grains of fine gold per cubic yard, which weighs about 3000 lbs., or 1½ short tons. In the panning assay, from 60 to 90 p.c. of the gold in the ore is usually recovered.

Ordinary gold ores are assayed by (1) the fusion or crucible method, or (2) the scorification method. In the *crucible assay*, the ore, crushed through an 80-mesh or finer sieve, is mixed with litharge or red lead, charcoal, or argol, and the necessary fluxes, and, fused in the melting furnace or, as in Western America, in the muffle. The amount of ore taken is usually 1 A.T. (assay-ton, see p. 410), but is sometimes only ½ A.T., and, in the case of poor tailings in which there are only a few grains of gold per ton, as much as 12 A.T. is taken and fused in several charges, the gold being finally collected into one lead button. The fluxes vary with the nature of the ore. The following are typical charges subject to very large variations to meet special cases:—

—	A. Silicious ore (grey or white with a little pyrites, &c.)	B. Basic oxidised ore (red or brown)	C. Pyritic ore
Ore . .	1 A.T.	1 A.T.	1 A.T.
Litharge or red lead	1 „	1 „	1 „
Charcoal .	1·2–1·5 grams	2·0 grams	0–1 gram
Sodium carbonate	1¼ A.T.	25 „	1 A.T.
Borax .	5–10 grams	10 „	10 grams

Sand is added to B and C if necessary for the protection of the crucible from corrosion. The borax is usually not mixed with the charge, but is added as a cover or charged in after the fusion has begun. The charge is well mixed and put into a cold crucible, which it must not make more than two-thirds full, and pieces of hoop iron or two or three tenpenny nails are embedded in the mixture. The crucible is gradually heated, a red heat beginning to appear after about 10 minutes, and a dull red heat not being attained for 30 minutes or more. Tranquil fusion results in 40 or 50 minutes from the time of charging in. The pot is then lifted out of the furnace, the nails removed, and the charge poured into a conical mould or allowed to cool in the pot, which is afterwards broken. When cool, the lead button is detached from the slag by hammering. The button should weigh at least 25 grams. If less than this amount of lead is reduced, a fresh charge is made up containing more charcoal, and any change is made in the fluxes which may seem desirable from the appearance of the slag. If the lead is hard or brittle, owing to the presence of impurities, it is usually scorified, sometimes with the addition of fresh lead, before being cupelled, as otherwise the loss of gold is increased.

The slag will contain gold and *a fortiori* silver if the conditions during fusion are favourable to oxidation of the metals. For this reason it is better to reduce almost all the litharge than to leave some of it in the slag, and the more readily oxidised metals—iron, manganese, &c.—must be reduced to their lowest oxides, ferrous oxide, &c. Practically all the copper, nickel, and other readily reducible metals will then be in the lead button. In the case of ores containing much copper, this is a disadvantage, entailing loss of gold in cupellation, and the copper may be removed from the ore by treatment with acid before fusion (with some loss of silver) or large quantities of litharge (6 A.T. of PbO to 1 A.T. of ore) may be added, and only a small part of it reduced. In the latter case the slag contains gold and silver, and is cleaned by a second fusion, with the reduction of more lead. A similar method of fluxing is used for telluride ores, an excess of litharge in the slag preventing tellurium from entering the lead button. Antimonial and arsenical gold ores are sometimes roasted with coal-dust in a reducing atmosphere, in order to remove the antimony or arsenic as a sulphide before fusion. An alternative method is to fuse with much litharge and enough nitre to oxidise the antimony with the formation of antimoniates. Sulphides may be roasted in air before fusion.

The lead button, rounded by hammering, is placed on a hot cupel in the muffle (*see* p. 10.)), which is kept at a full red heat. The lead melts and oxidises, and the litharge and other oxides are absorbed by the cupel, the gold and silver being left as a bead (or 'prill') on the surface. If the bead is large and contains much silver, it must be cooled gradually to prevent it from 'spitting' on solidification, by which part of the metals might be lost. The bead is cleaned, weighed, flattened, and parted by dissolution in boiling nitric acid in a porcelain crucible or test-tube. If less than two parts of silver are present to one of gold, the metals are not parted completely, silver being left in the gold, and it is convenient to have a greater proportion of silver present. It is, therefore, often necessary to melt the bead with more silver, the proportion varying with the size of the bead, as follows:—

Weight of gold	Silver required for parting
10 milligrams	40 milligrams
1 „	6 „
0·2 „ or less	2 „

A little extra silver is permissible, but if too much silver is present, there is a tendency for the gold to break up into very fine particles, which are difficult to wash without loss. The separation of these minute particles is avoided by dropping the bead into boiling acid, sp.gr. 1·2, when the parting will be completed in a few seconds. The parted gold is washed free from silver nitrate, &c., and is made firm and coherent for weighing by being annealed at a red heat. (For weights, balances, &c., *see* p. 410.) The silver is estimated by difference. The litharge, fluxes, &c., must be tested for silver and gold by running blank charges without ore.

In *scorification* about 0·1 or 0·2 A.T. of ore is mixed with 30 or 40 grams of granulated lead, and transferred to a dry scorifier. The charge is covered by a similar amount of granulated lead, and from 0·5 to 1 gram of borax is sprinkled on last. The scorifying dish is then charged into a muffle, which has been raised to a temperature of 1000°-1100°, or considerably above that required for cupellation, and the muffle is closed. As soon as the charge is melted down, the muffle is opened. The lead now oxidises, and the litharge, forming a ring of slag round the scorifier, oxidises the sulphides, &c., and slags off the earthy materials in the ore. As oxidation proceeds, the litharge encroaches on the 'eye' of metal, and at length covers it over. A pinch of charcoal powder is then added in tissue paper, and when the fusion is again tranquil, the charge is poured into a mould, and the slag detached. The lead is cupelled, and the assay finished as before.

In cupellation some gold and silver is carried into the cupel with the litharge, especially if tellurium, selenium, copper, &c., are present. The gold and silver are usually recovered by fusing the crushed cupel with litharge, charcoal, sodium carbonate, borax, and fluorspar, and cupelling the button of lead (see Lodge's Notes on Assaying, 112-169).

Assay of gold bullion and alloys. A piece of the metal to be examined is adjusted by cutting and filing to correspond in weight with a standard weight marked '1000,' which varies with different assayers between 5 and 10 grains, but is usually 0·5 gram. To the assay piece is added a piece of silver (free from gold) equal in weight to 2½ times (at the Royal Mint 2·1 times) that of the gold estimated to be present in the alloy, which, if not already known, can be ascertained by a rough preliminary assay or by the touchstone (*see* p. 416). The whole is wrapped in sheet lead, the weight of which depends mainly on the amount of copper to be removed, and varies from 8 to 32 times the weight of metal taken for assay. The lead packets are then transferred by means of tongs to cupels already raised to a bright red heat in the muffle, the current of air through the muffle is carefully regulated and the heat maintained. In from 10 to 20 minutes, a rapid passage of brilliant iridescent bands of colour over the surface of the button is observed to take place, and the buttons then appear to become colder, no longer glowing brightly with the oxidation of the lead. A few minutes later the muffle is closed to allow the buttons to set without loss by spitting. If copper is present in the assay pieces, however, this is not to be feared, and the charge can be drawn while the buttons are still molten. At the Royal Mint a charge consists of 72 assay pieces, which are charged in simultaneously by means of a divided metal tray with a sliding bottom and withdrawn simultaneously while still molten by means of a tray made of a mixture of graphite and clay, on which the cupels are placed. The buttons are cleaned by brushing, flattened on an anvil, annealed in the muffle or before a blowpipe, and reduced to a thickness of about 0·2 mm. by passage through a small pair of flatting rolls. The 'fillets' are again annealed and coiled into a spiral or 'cornet' by the finger and thimb.

The parting in nitric acid is effected either in glass parting flasks or in a platinum boiling apparatus. If parting flasks are used, an amount of about 2 oz. of nitric acid of sp.gr. 1·2 is heated in the flask almost to boiling, and the cornet is then dropped in and boiled until 2 or 3 minutes after the red fumes have disappeared. The acid is then poured off, and the gold, after being washed twice with boiling water, is boiled for a further 15 minutes with nitric acid of sp.gr. 1·2 or stronger. The acid must be free from silver, chlorine, &c.

The gold is again washed, and is then transferred to a porous crucible or 'annealing cup' by filling the flask with water, placing the cup over its mouth, and inverting it. The gold falls into the cup, and the flask is removed without agitating the water in the cup. The gold is then dried, annealed by heating to redness, and weighed. If no more than three parts of silver are present to one of gold, the cornet does not break up; and if enough is known previously of the composition of the bullion to make sure of this in the cupelled button, a platinum tray, containing a number of little platinum cups may be used. A cornet is placed in each cup, and the whole tray is immersed in nitric acid, and subsequently washed by dipping in and out of hot water. Less acid is used per assay piece by this method, and the boiling is more prolonged, 30 minutes in each of two acids of sp.gr. 1·23 being used at the Royal Mint.

In each batch of assays, two or more check assays on pure gold are made to determine the 'surcharge' or net sum of the losses of gold and the gain in weight due to the retention of silver. With alloys boiled separately in flasks, check assays are of comparatively little value (see Rose's Metallurgy of Gold, 5th ed. 470–498).

Alloys of gold and silver If the alloy contains enough silver to be parted by nitric acid, no difficulty arises. The silver is dissolved, precipitated by hydrochloric acid, and weighed either as chloride or as metal. If the silver is deficient in quantity, the alloy is melted with two and a half times its weight of cadmium under a cover of potassium cyanide and parted with nitric acid. The silver is precipitated and weighed as chloride, or determined volumetrically in solution by means of sulphocyanide. Sometimes the silver is determined by difference, the alloys being cupelled and weighed, and subsequently cupelled again with the addition of silver, and parted.

(For alloys containing *gold and platinum, see* p. 418.)

Assay by the touchstone. This ancient method consists in comparing the colour of the streak produced by a sample of gold of unknown composition on a black surface with those from a series of alloys of known compositions, after all have been treated alike with nitric acid. Any abrading surface on which the acid is without action can be employed for this purpose.

Iridium occurs alloyed with platinum, and finds its way into gold bullion. In the latter case, it is found with the gold cornet obtained in the bullion assay, adhering in the form of black scales or powder to that side of the gold which was originally nearest to the cupel. It can be estimated by dissolving the gold in *aqua regia*, the iridium remaining undissolved.

Iron. The dry assay of iron, made by fusing ores with fluxes in carbon-lined (brasqued) crucibles, is obsolete, and need not be described. The wet methods are volumetric, based on the oxidation of iron from the ferrous to the ferric state or on the converse reduction. Either the bichromate or the permanganate method is generally used to determine the total amount of iron in ores or the amount of iron present in the ferrous condition. The stannous chloride method is used for measuring the amount of iron present in the ferric state in an ore.

For the determination of the total amount of iron, the ore is passed through an 80-mesh sieve, and attacked by acids as usual. Most ores are oxides, carbonates, &c., and the iron in them is easily dissolved by hydrochloric acid.

Titaniferous ores are fused with acid potassium sulphate and dissolved in water and hydrochloric acid. If nitric acid is present in the acid solution, it is destroyed by evaporating to dryness with hydrochloric acid and taking up with hydrochloric acid and water, and the iron is then reduced by zinc, which gives a stream of hydrogen or (if titanium is present) by crystals of sodium sulphite in a neutral or slightly acid solution. As soon as the solution is colourless, the excess of zinc is removed, or the sodium sulphite decomposed by boiling with hydrochloric acid, and titration is carried out in a porcelain basin by means of a solution prepared by weighing out 4·39 grams of potassium bichromate to the litre, equivalent to 5 grams of iron according to the equation:

$$6FeCl_2+K_2Cr_2O_7+14HCl \\ =3Fe_2Cl_6+Cr_2Cl_6+2KCl+7H_2O.$$

Potassium ferricyanide (0·1 p.c. solution, freshly prepared) is used as an indicator, a drop from the assay solution being mixed with a drop of the test solution on a white glazed tile, from time to time. The end-point is reached when a colour is no longer produced. The solution of bichromate is standardised by means of piano wire, which contains about 0·4 p.c. of impurities.

The permanganate method is carried out in a sulphuric acid solution, the equation being:

$$10FeSO_4+K_2Mn_2O_8+8H_2SO_4 \\ =5Fe_2(SO_4)_3+2MnSO_4+K_2SO_4+8H_2O.$$

The standard solution is prepared by weighing out 2·82 grams of potassium permanganate per litre, which is equivalent to 5 grams of iron. The end reaction, the appearance of a pinkish tinge in the solution in the flask, is very sharp.

When the amount of ferrous iron only in the ore is required, the ore is dissolved in hydrochloric or sulphuric acid with exclusion of air. The ferric iron may be determined by difference, or, as a check, the stannous chloride method may be used, in which the yellow solution of ferric iron in hydrochloric acid is decolourised. The standard solution (20 grams of commercial stannous chloride per litre, acidulated with hydrochloric acid) is run into a boiling-hot solution of iron, and is standardised by means of a solution of ferric chloride free from nitric acid.

Analysis of iron and steel. The elements requiring estimation are carbon (graphite, combined carbon and total carbon), silicon, manganese, sulphur, phosphorus, arsenic, and, in special steels, chromium, nickel, tungsten, molybdenum, vanadium, &c. The total carbon is estimated by combustion, usually after removal of the iron by a cupric salt. The graphite is estimated by combustion of the residue after dissolving the iron in hydrochloric acid, by which the combined carbon is removed in combination with the hydrogen evolved, or more advantageously in nitric acid, by which the combined carbon is oxidised and retained in solution. The combined carbon is determined by the colour of a nitric acid solution compared with the colour of certain standard solutions containing known amounts of carbon. Silicon is weighed as silica after dissolution of the iron by acids or iodine. Sulphur is weighed as barium sulphate, after the iron has been dissolved in *aqua regia*, or it is evolved as sulphuretted hydrogen, which is absorbed by caustic soda, and decomposed by a standard solution of iodine. The excess of iodine is estimated by sodium thiosulphate.

Manganese is separated by precipitation with bromine in an ammoniacal solution after removal of the iron as basic acetate. The precipitated hydrated peroxide is heated strongly in a muffle and weighed as Mn_3O_4. There is also a colorimetric estimation, the steel being dissolved in nitric acid and the solution boiled with lead peroxide. The colour of the permanganate produced is compared with those of standard solutions. Phosphorus is precipitated by ammonium molybdate or magnesia mixture. Arsenic is separated by precipitation as sulphide in an acid solution, converted into arsenic acid and determined by precipitation by magnesia mixture.

(For the determination of the metals in special steels, *see* under the headings *Chromium*, *Nickel*, &c. For full details of the analysis of iron and steel and also of the complete analysis of iron ores, *see* Blair's Chemical Analysis of Iron, Campredon's Guide Pratique du Chimiste Métallurgiste et de l'Essayeur, 438–634, and Brearley and Ibbotson's Analysis of Steel Works Materials.)

Lead. Both dry and wet methods of assay are used. The dry assay is only applicable to rich ores and to concentrates, and even with these is less accurate than the wet methods. The ore is crushed through a 60-mesh sieve, mixed with sodium carbonate and argol, and fused in a wrought-iron crucible or in a clay pot with hoop-iron. Galena is reduced by the iron, and any oxides, sulphates, &c., of lead are reduced by the argol. Borax is sometimes added as a cover. The following are examples of the charges recommended by Percy:—

	1. Rich galena	2. Any galena, esp. poor ores	3. Phosphate ore	4. Cerussite
Ore . .	500 grs.	500 grs.	300 grs.	500 grs.
Sodium carbonate .	500 ,,	350 ,,	350 ,,	500 ,,
Argol (tartar)	50 ,,	100 ,,	100 ,,	100 ,,
Borax . .	—	150 ,,	30 ,,	30 ,,

The iron crucible is made red hot, cleaned, and allowed to cool. The charge is then transferred to it, care being taken to avoid loss by dusting, and the borax, or, if none is used, part of the sodium carbonate is added as a cover. A clay lid is also placed on the crucible. The charge is slowly heated for about 20 minutes, and is then poured into a mould, provided that all signs of effervescence have disappeared, and the mixture is seen to be in a state of tranquil fusion. The lead is found at the bottom. It is detached from the slag with a hammer, and is cleaned and weighed. The slag is examined for lead beads before being thrown away. Clay crucibles are used for phosphate and carbonate ores.

When the ore contains arsenic, a speise is formed which is found adhering to the upper surface of the lead, below the slag. It must be removed with great care to avoid loss of lead. The lead should be soft and malleable. The silver and gold in the ore are determined by cupellation and parting (*see* p. 415). The method gives results with pure ores which are about 1 or 2 p.c. too low. When the ore contains antimony, bismuth, copper, &c., these metals are in part reduced with the lead, and are weighed with it. If the lead button is hard, it is necessary to estimate the lead in it by weighing it as lead sulphate or otherwise, or to adopt wet methods of assaying the ore.

(For details of the dry assay of lead, see Percy's Metallurgy of Lead, 103–119.)

In the wet methods, oxidised ores are attacked by hydrochloric acid, followed by nitric acid, if necessary. Sulphide ores are treated direct with nitric acid. The lead is determined either as sulphate or volumetrically, by means of ammonium molybdate (Alexander's method). In the latter method (Eng. and Mng. J. April 1, 1893, 298), the mixture of nitric acid and ore is evaporated with sulphuric acid, diluted, boiled, and filtered. The lead sulphate in the residue is dissolved in hot ammonium acetate, acidified with acetic acid, raised to boiling, and titrated with a standard solution of ammonium molybdate, containing, according to Low, 4·25 grams per litre. The solution is standardised with pure lead foil. Tannin is used as an indicator, giving a yellow colour to a drop of the solution on a white glazed tile when the ammonium molybdate is in excess. If iron and calcium are present, it is better to separate the lead as sulphide and redissolve before titration (Low's Ore Analysis, 113).

Lead may also be determined in a feebly acid solution by adding an excess of potassium chromate and estimating the amount of excess by means of a standard solution of ferrous chloride. The reaction is the same as in the bichromate assay of iron, but in this case the end is marked by the appearance of a green colour in the test drops on the plate (Beringer's Assaying, 214).

Manganese occurs as MnO_2 in pyrolusite. Spiegeleisen, ferromanganese, and steel are also assayed for manganese. Either the ferrous sulphate assay or Volhard's volumetric process is generally used. In the latter method the manganese is precipitated by potassium permanganate in a boiling neutral solution. The precipitate, as far as numbers are concerned, is represented by the equation:

$$K_2Mn_2O_8+3MnSO_4+2H_2O$$
$$=K_2SO_4+5MnO_2+2H_2SO_4$$

About one gram of the ore or spiegeleisen is dissolved in hydrochloric and nitric acids, heated with sulphuric acid, and neutralised by the addition of an emulsion of zinc oxide in slight excess. All the iron is precipitated, and, after violently shaking the mixture, it is made up to 500 c.c., allowed to settle, and 100 c.c. of the clear supernatant liquid is drawn off, heated to boiling, and titrated. The end point is marked by the appearance of a pinkish tinge. (For the estimation of manganese in steel, *see* p 417.)

Mercury. The wet methods of assay are not satisfactory, and one of the distillation methods is usually employed. When a large percentage of mercury is present, a combustion tube of 18–20 inches long is used. It is sealed at one end and magnesite powder placed in it first, to a depth of 3 or 4 inches. Next a layer of ·2 inches of unslaked lime is added and then 5 or 10 grams of ore well mixed in a mortar with 10 grams of lime. The mortar is cleaned with more lime and the rinsings added to the tube and covered with clean lime to a depth of 3 or 4 inches. Finally, a loosely fitting plug of asbestos is inserted and the unoccupied portion of the tube is drawn out almost to a point and bent over at right angles, care being taken that no hollow in the glass is formed which might collect some of the mercury. The tube is placed in position in a combustion furnace and tapped until the mixture settles and leaves a free passage for gases throughout its length. The narrow opening is made to dip into a beaker of water, and the tube is heated, beginning with the asbestos plug and finishing with the magnesite, which yields enough carbon dioxide to sweep out the vapours of mercury. The time required for heating is about 30 minutes. While the tube is still red hot throughout its length, its end is cut off and dropped into the beaker. The mercury collects in the water, and is dried by blotting-paper and then in a desiccator and weighed in a porcelain crucible.

When only small quantities of mercury are present, Eschka's method is used (Dingl. poly. J. cciv. 74), in which the mercury is condensed on a weighed piece of gold. This is in the form of a basin made of thin sheet gold, used as the cover of a porcelain crucible and filled with water to keep it cool. The basin projects beyond the rim of the crucible, and usually weighs about 10 grams. From 0·2 to 2·0 grams of ore is mixed with 1–4 grams of iron filings, and heated in the crucible for 10 or 20 minutes, the flame being kept from heating the upper part. This may be done by fitting the crucible into a hole in a piece of sheet asbestos. The gold basin is then dried without the agency of heat, and weighed, the increase of weight representing the mercury.

Molybdenum in ores is estimated by precipitation as mercurous molybdate in a very slightly alkaline or neutral solution by means of mercurous nitrate. The precipitate is ignited in a porcelain crucible, either alone or with litharge, until the mercury is expelled. The increase in the weight of the crucible is taken as MoO_3, but if chromium, vanadium, tungsten, phosphorus, or arsenic is present in the ore, the ignited MoO_3 must be purified by further treatment or separated before precipitation. Molybdenum in steel is precipitated as ammonium phospho-molybdate.

Nickel and cobalt occur together in ores, the former more commonly and in greater proportion than the latter. They are usually assayed together. In the fire assay, the ore is roasted sweet and then fused with arsenic to form a speise. This is heated in air on a little clay dish in the muffle, and the metals oxidised successively, iron passing into the slag first, cobalt next, and then nickel, copper being left until last. The changes in colour of the borax slag show the progress of the assay. The slag is coloured brown while iron is passing into it, blue by cobalt, sherry-brown by nickel, and blue by copper. Gold is added to the speise after the elimination of cobalt if copper is present. The speise is weighed after each metal has been removed. The slag must be frequently examined and renewed, and great care and experience are needed to attain even approximate results.

The method is easier to carry out if copper is absent, and this metal is sometimes removed by precipitation with sulphuretted hydrogen in an acid solution before the speise is formed. If cobalt is absent, a weighed amount may be added, as otherwise it is difficult to observe the point at which nickel begins to pass into the slag after the removal of the iron. The arsenides in the speise have the formulæ Fe_2As, Co_2As, Ni_2As, and Cu_3As (Rhead & Sexton's Assaying, 187).

In the wet methods it is usual to roast the ore as a preliminary in order to remove the arsenic, sulphur, &c., and then to separate the nickel and cobalt from the iron, manganese, zinc, &c., by suitable methods. The nickel is precipitated as hydrate and weighed as NiO. Cobalt is often included in the nickel, but is separated if present in large quantities. A volumetric method depends on the interference by nickel in the titration of cyanide with a standard solution of silver nitrate. An alkaline solution containing caustic soda is used, and a little potassium iodide added as an indicator. An excess of a standard solution of potassium cyanide is added to a solution of nickel sulphate made alkaline (and precipitated) by caustic soda. The excess of cyanide is titrated by a standard solution of silver nitrate (Beringer's Assaying, 255). The reactions are represented by the equations:

$$4KCy+NiSO_4=K_2NiCy_4+K_2SO_4.$$
$$2KCy+AgNO_3=KAgCy_2+KNO_3.$$

Nickel and cobalt are also sometimes estimated by electrolysis, and for this purpose must be separated from zinc and other metals, dissolved in nitric acid, and precipitated in an ammoniacal solution.

Nickel is separated from cobalt by precipitation with dimethylglyoxime, and may be estimated in that way. (*See* ANALYSIS.)

Nickel in steel is precipitated by bromine water and caustic soda, after removal of the iron as basic acetate. It is weighed as NiO.

Platinum in alluvial deposits is concentrated by panning, as in the case of auriferous sands. In all cases platinum can be collected in lead by the same methods as those described under the assay of gold ores. The lead buttons are sometimes cupelled at a very high temperature, but it is difficult to remove the whole of the lead in this way, as the 'prill' freezes on the cupel when only part of the lead has been oxidised, unless a weighed amount of gold or silver is added in order to produce an alloy of lower melting point than pure platinum.

Cupellation may be finished in the oxygen-gas blowpipe flame, but the loss of platinum is then large. It is more usual to dissolve the lead button in dilute nitric acid and to filter off the platinum and gold residue, which is parted by dissolving in *aqua regia*, and precipitating the gold with oxalic acid. The platinum is estimated by difference or by precipitation as $(NH_4)_2PtCl_6$.

Platinum in alloys or in rich alluvial concentrates may be estimated by melting with six parts of pure lead, and grinding in a mortar the brittle alloy freed from slag. Portions of the alloy are scorified with fresh lead and dissolved in nitric acid.

Alloys containing gold, silver, and platinum are difficult to assay, as they are insoluble in *aqua regia*. The method adopted is first to cupel the alloy to remove copper, &c., these metals being estimated by difference. The alloy is then inquarted by cupellation with twice its weight of silver and parted by boiling in sulphuric acid. The residue contains the gold and platinum. These may be parted by again inquarting with silver and dissolving in nitric acid, provided that the amount of gold present is at least ten times that of the platinum. If the proportion of gold present is less than this, part of the platinum remains undissolved, and it is therefore necessary to add gold in many cases. The parted gold is weighed and the platinum estimated by difference (6ème Rapport des Monnaies, 1901, p. xxix.; Rose's Precious Metals, 272).

Silver. The ores of silver are assayed in the same way as those of gold of a similar kind, the scorification method being used far more frequently than in the case of gold ores. The slags and cupels must be examined usually, as silver is more readily lost than gold. The temperature of cupellation is kept as low as possible, to check the loss of silver by volatilisation (see Lodge's Notes on Assaying, 37–111).

Silver bullion and alloys are assayed by cupellation, by the Gay Lussac or the Volhard volumetric processes, or by weighing the chloride (India Mint method). In cupellation, the 'base' or oxidisable metals are removed in the muffle, and the silver prill is cleaned and weighed. The weight of silver taken is usually 10 grains. The amount of lead required varies from six times the weight of the silver for alloys of high standard to twelve times for silver 700 fine. The method is not suitable for alloys containing less than 70 p.c. of silver. The muffle is kept at a lower temperature than that required for gold cupellation, but must be raised to above the melting-point of pure silver (962°) at the finish, to prevent the metal from setting in the furnace before all the lead has been removed. When the cupellation is complete, the mouth of the furnace is closed with great care to exclude draughts, and the furnace is allowed to cool slowly to prevent loss of silver by spitting. The solidified prills are cleaned and weighed. The loss of silver in cupellation varies from 5 to 15 parts per 1000, and check assays on pure silver are placed in all parts of the furnace to measure this loss. Any gold that may be present is weighed as silver. The process is very ancient, and clear reference is made to it in connection with a trial of the Pyx in the Black Book of the Exchequer, written in the reign of Henry II.

In the Gay Lussac process, the volume is measured of a standard solution of common salt or sodium bromide required for the precipitation of a little more than a gram of silver in solution as nitrate. No indicator is used, and the end of the operation is judged from the appearance of a faint cloud of chloride in a solution from which almost all the silver has been precipitated. It is the most accurate method of assaying silver bullion. The standard solution of common salt (usually called the 'normal solution') contains about 5·416 grams of NaCl per litre, so that 100 c.c. will precipitate 1 gram of silver. A weight of silver bullion containing about 1·003 gram of silver is weighed and dissolved in nitric acid, and 100 c.c. of the salt solution added to it from a pipette. The chloride is agglomerated by a shaking in a stoppered bottle, and the clear supernatant liquid is tested by 'decinormal' solutions of common salt and, if necessary, of silver nitrate. The appearance of the cloud of silver chloride shows the amount of silver left in solution. Further shakings are resorted to if required, and the final reading is taken after waiting for about 5 or 10 minutes. Check assays on fine silver are used with every batch to test the strength of the solution, which varies with the temperature, &c. Mercury interferes with the method, and is detected by the colour of the precipitated silver chloride, which does not darken if mercury is present. Acetate of soda corrects the error if the quantity of mercury present is small. The Gay Lussac method can be used only in cases where the approximate assay is already known (Percy's Silver and Gold, 282; Riche et Forest, L'Art de l'Essayeur, 183).

In the India Mint method, the silver alloy is dissolved in nitric acid and precipitated by a slight excess of hydrochloric acid. The silver chloride is then collected by shaking in a stoppered bottle, and, after being washed, is transferred to a porous cup, dried, and weighed while warm. The chloride is washed by decantation, but the drying is tedious, and is expedited by breaking up the crust with a glass rod. Any gold that may be present is weighed as silver chloride. This is the best method for alloys containing less than 70 p.c. of silver (Trans. Inst. Mng. & Met. xvii. 334).

The Volhard method is largely used in this country. The nitric acid solution of the silver is freed from nitrous acid by boiling, and is then diluted and titrated with a solution containing 7·04 grams of ammonium thiocyanate per litre. As this salt is deliquescent, it is usual to weigh out about 7·3 grams per litre. Iron alum is used as an indicator, giving a red colour when all the silver has been precipitated. Time is saved and the accuracy of the method increased by taking for assay an amount of alloy containing about 1·003 gram of silver, and running in 100 c.c. of the standard solution of thiocyanate from a pipette. After shaking the liquid in a flask, the titration is finished by adding the thiocyanate a drop or two at a time. Check assays on fine silver are used (Trans. Inst. Mng. & Met. xvi. 154).

Tin. Tin ore is concentrated on a vanning shovel with the production of 'black tin' in order to determine what yield may be expected when the ore is treated on the dressing floors. The ore is crushed and sampled, and about 30 grams (or less with rich ores) are thoroughly mixed with 30 or 40 c.c. of water on the vanning shovel, to prevent, as far as possible, the loss of 'float tin.' The ore is then collected by a vigorous circular motion of the water, and the slimes are poured off, a process which is repeated until the water remains clear after being left to settle for a few seconds. A smaller quantity of water is used for the subsequent operations. By means of a circular motion of the shovel, combined with a series of jerks, the tin oxide is now separated from the lighter material, which is carried down by the descending wave. The tailings are sometimes saved and washed over again until they yield no more tin, and are then crushed by rubbing with a hammer and again washed. The concentrates are dried and roasted and dressed once more after being rubbed down with a hammer. Sometimes they are washed quite clean from worthless material, and sometimes left impure with oxide of iron, &c., according to the nature of the ore and the custom of the operator. Sometimes they are purified by boiling in hydrochloric acid or *aqua regia*, which, according to J. H. Collins, causes a loss of tin. The residue is usually reported in pounds of black tin to the long ton of ore. The losses of cassiterite in vanning vary considerably, and may be reckoned as 30 to 40 p.c.

The black tin obtained by vanning may be assayed for metallic tin by reduction with anthracite (Cornish method) or by fusion with potassium cyanide. In the Cornish method 100 grams of tinstone are heated with 20 grams of anthracite in a plumbago crucible at a white heat for 15 or 20 minutes before pouring. The excess of anthracite contains beads of tin, which are separated by sieving and vanning. In the cyanide process, 10 grams of tinstone are fused with 40 grams of impure cyanide (containing potassium carbonate), and poured at a red heat. The German process consists in reducing a mixture of 5 grams each of tinstone and cupric oxide with 15 grams of black flux (a mixture of carbon and potassium carbonate, obtained by heating tartar) and 1·25 grams of borax with a cover of common salt. The reduced metal is compared in weight with that of the copper reduced from cupric oxide alone. The most trustworthy of these methods is the fusion with cyanide. The reduced tin, however obtained, is usually impure (Beringer's Assaying and Kerl's Metallurgische Probirkunst).

Tin is also estimated volumetrically. A satisfactory method described by Beringer Text-Book of Assaying, 11th ed. 285) is to reduce the solution of stannic chloride to stannous chloride by means of nickel foil, and to titrate with a standard solution of iodine in an atmosphere of carbonic acid gas. Starch is used as an indicator. In all wet methods, tin oxide must be reduced to metallic tin before it can be dissolved. Beringer prefers reduction by means of zinc vapour acting on ore mixed with oxide of zinc. The alloy of zinc and tin thus produced is dissolved in hydrochloric acid, to which crystals of permanganate are added. In Pearce's method (Low's Technical Analysis. 261) the ore is fused with caustic soda and charcoal powder, and the mass dissolved in hydrochloric acid; the reduction of the stannic to stannous chloride is then effected with iron rods.

Titanium in ores is generally in the form of titanic oxide, which is insoluble in acids. Titanates, however, are somewhat soluble, so that on attacking ores with acid, titanium will be found partly in the residue and partly in the solution. The metals of the iron group with titanium are precipitated from the solution as basic acetates, which are fused with potassium bisulphate and extracted with water. The titanic acid is precipitated from the solution by means of prolonged boiling with sulphurous acid. The residue left by the attack on the original ore with acids is similarly treated, after the silica has been removed by heating with sulphuric and hydrofluoric acids (Beringer's Assaying, 293).

Tungsten in wolfram, steel, &c., is estimated by weighing as tungstic acid WO_3. The ore is boiled with hydrochloric acid followed by *aqua regia*, when the tungsten separates as insoluble yellow tungstic acid. After thorough washing, this is dissolved in ammonia, filtered, and recovered by evaporating the solution to dryness, and gently igniting the residue to decompose the ammonium tungstate. Nearly pure tungstic acid remains. Any silica that may be present may be removed by hydrofluoric acid. The tungstic acid may also be precipitated from solution by neutralising with nitric acid and adding a solution of mercurous nitrate (Beringer's Assaying, 13th ed. p. 297 d.). In attacking ores with acid, some WO_3 is dissolved in the presence of fluorides, arsenic or phosphorus, but this is corrected by the addition of cinchonine. The ores may be attacked by fusion with caustic soda and sodium peroxide, or by digesting with soda solution instead of by boiling with acid (Hutchin and Tonks, J. Inst. Mng. and Met. 18, 1909, 425).

Uranium. The mineral is evaporated with nitric acid and taken up with HCl. After separation of the other metals as sulphides and carbonates, the uranium is precipitated by ammonia and weighed as U_3O_8, or it is precipitated by microcosmic salt in the presence of acetic acid and ammonium acetate. The precipitate consists of ammonium uranyl phosphate $UO_2NH_4PO_4$ which is washed, ignited gently and weighed or converted into uranyl pyrophosphate $(UO_2)_2P_2O_7$, for greater accuracy (Low's Technical Ore Analysis, 201). This precipitation is also the basis of a volumetric method, a boiling solution of uranium being titrated with a standard solution of phosphate, until ferrocyanide no longer gives a brown colour.

Vanadium in steel is estimated by titrating with potassium permanganate. The steel is dissolved in HCl and evaporated to dryness with a little nitric acid. The residue is fused with nitre and fusion mixture, boiled in water and filtered, and the filtrate evaporated with H_2SO_4, reduced by sulphur dioxide and titrated. One atom of iron is equivalent to one of vanadium in the titration (Rhead and Sexton's Assaying, 270).

Zinc. The old dry method of assay of ores based on the loss of weight due to the volatilisation of zinc at a white heat is obsolete. Certain alloys of zinc with tin and copper, *e.g.* coinage bronze, are assayed for zinc by heating to 1200° for two hours in carbon crucibles (J. Soc. Chem. Ind. 33, 1914, 270). The loss of weight gives the zinc together with any cadmium or oxygen present. Check assays on trial plates of known composition are necessary Zinc is usually weighed as oxide after precipitation as carbonate, or it is titrated with sodium sulphide or potassium ferrocyanide. An amount of 1 or 2 grams of ore is weighed out and dissolved in hydrochloric acid or *aqua regia*. The silica and metals other than zinc are removed as usual. All the precipitates will contain zinc if they are bulky, and must be redissolved and reprecipitated. The alkaline filtrate may be diluted to 200 c.c. and used for the sodium sulphide titration, which is carried out at 50°–60°. A flake or two of freshly precipitated ferric hydrate is used as an indicator, turning from red to black as soon as sodium sulphide is in excess. One c.c. of the standard solution of sodium sulphide should be equal to 0·01 gram zinc. Instead of ferric hydrate, sodium nitroprusside may be used as an indicator on a white tile. This gives a purple colour with sodium sulphide.

For titration with potassium ferrocyanide, the pure ammoniacal solution of zinc obtained as above is acidified with hydrochloric acid, boiled and titrated hot. The standard solution of ferrocyanide is made up by dissolving 41·25 grams of the pure salt in a litre of water. The test solution consists of 0·5 gram of uranium acetate dissolved in 20 c.c. of water. A drop of this solution gives a brown colour on a white tile with a drop of the zinc solution as soon as the ferrocyanide is in excess. It is advisable to confirm the end reaction by adding 5 c.c. of a standard solution of zinc in hydrochloric acid, containing 10 grams of zinc per litre, and again titrating (Chem. News, lxxvi. 6).

The assay of zinc-dust for metallic zinc is made by acting on the sample with dilute sulphuric acid, and collecting and measuring the hydrogen which is evolved.

Commercial metallic zinc contains lead, cadmium, and iron, and may also contain arsenic, copper, antimony, tin, &c. By dissolving in dilute sulphuric acid, the lead and the greater part of the copper, tin, cadmium, &c., are left undissolved. The residue is attacked with nitric acid, and the metals separated as usual. Iron in zinc is titrated in the sulphuric acid solution without being separated. Arsenic and antimony are passed with the hydrogen evolved by sulphuric acid into a solution of silver nitrate (Campredon, Guide Pratique, 760; Eliot and Storer, Amer. Acad. Arts & Sciences, viii. 57).

Coal. The assay of coal usually comprises the determination of moisture, total ash, sulphur, coking properties, and calorific power. The coal is broken down and sampled as in the case of ores (see p. 408), and the sample is passed through an 80-mesh sieve.

The moisture is determined by drying 1 gram in a water-oven for 30 minutes and weighing. The coal is then again warmed for 15 minutes and reweighed, and the process is continued until the weight is constant or begins to increase.

For sulphur, 2 grams of coal are mixed with 3 grams of a mixture of two parts of calcined magnesia and one part of potassium carbonate, and heated to dull redness for an hour in a porcelain or platinum crucible, with occasional stirring. After cooling, the charge is transferred to a beaker and digested with water and 1 c.c. of bromine. It is then acidulated with hydrochloric acid, the bromine boiled off, and the sulphur, now in the form of sulphate, precipitated by barium chloride. The sulphur may also be oxidised by heating the coal with a mixture of nitre and common salt. Phosphorus in coal, if determined at all, is estimated in the ash, which may require complete analysis.

The coking qualities of coal are examined by heating 50 grams of coarsely crushed coal in a 'large copper' crucible covered with a closely fitting lid. The evolution of gases is completed after 15 or 20 minutes at a full red heat. After cooling, the coke is turned out and weighed, the loss of weight giving the amount of volatile matter.

The calorific power of coal is determined by igniting 2 grams of the finely powdered sample with 20 grams of a mixture of six parts of potassium chlorate and one part of nitre. The coal and deflagrating mixture are ground together in a mortar and ignited in a Thompson calorimeter. The error due to loss of heat by escaping gases, &c., is always taken as one-tenth of the total evolved. The calorific power reported is the weight of water that could be evaporated at 100° and 760 mm. pressure by a unit weight of the fuel (*v.* FUEL).

Cyanide solutions. In gold mills, these solutions are in wide use, and require frequent analysis. Free cyanide is estimated by means of a solution of silver nitrate prepared by dissolving 13·04 grams of crystallised $AgNO_3$ in a litre of water. One c.c. of this solution is equivalent to 0·01 gram of KCy, the end of the titration being denoted by the solution becoming milky from the precipitation of AgCy. The reaction is represented by the equation:

$$AgNO_3+2KCy=KAgCy_2+KNO_3.$$

The amount of cyanide solution taken for assay may be from 10 c.c. to 100 c.c., according to its strength. Alkalis and other compounds which may be present dissolve silver cyanide, and accordingly it is usual to add potassium iodide as an indicator. Turbid cyanide solution must be filtered before titration. If soluble sulphides are present, they prevent the assay from being carried out. They are removed by agitating the solution with freshly precipitated lead carbonate. If zinc is present in the solution, part of the cyanide contained in the double cyanide K_2ZnCy_4 is estimated as free KCy.

The 'total alkali' in a cyanide solution is estimated (J. E. Clennell, Chemistry of Cyanide Solutions, 62) by titration with a standard solution of sulphuric acid, using methyl orange as an indicator. 'Protective alkali' (*op. cit.* 63) is determined by adding a slight excess of silver nitrate together with a little phenolphthalein solution, and titrating with sulphuric acid until the pink colour disappears. The 'reducing power' of cyanide solutions is determined by acidification and subsequent titration with potassium permanganate, until the pink tint becomes permanent, or by adding an excess of permanganate followed by an excess of potassium iodide and estimating the amount of iodine liberated (*op. cit.* 71).

Gold and silver in cyanide solutions are determined by evaporation on lead foil, which is afterwards cupelled, or by evaporation with litharge, which is fused for lead. A more rapid method is to precipitate the gold and silver with zinc-dust and sulphuric acid, filter, and scorify or fuse the residue. The latter method is especially suitable for treating large samples of poor solutions containing very little gold and silver. In all these methods, a button of lead is obtained which is cupelled and the gold and silver parted as usual.

Silica. The silica in ores is partly free and partly combined. The white sandy residue left after careful extraction with acids is sometimes nearly pure silica, and is often reported as 'silica and silicates insoluble in acids.' It may be tested with sulphuric and hydrofluoric acids. The usual method with ores, slags, &c., is to fuse 1 gram with 5 grams of fusion mixture and a little nitre in a platinum crucible or dish. It is extracted with warm water and a little hydrochloric acid and evaporated to dryness on a water-bath. The bases are dissolved out with hydrochloric acid, and the silica filtered off. The filtrate is again taken to dryness and dissolved in hydrochloric acid to separate the remainder of the silica. If the ore contains a large percentage of sulphides, oxides, &c., which are soluble in acids, these are removed before the fusion. In this case the acid solution may contain silica, which is removed by evaporating to dryness, taking up with hydrochloric acid and filtering. The purity of the silica is tested by evaporating two or three times with water, sulphuric acid and hydrofluoric acid. The silica is volatilised (J. Amer. Chem. Soc. xxiv. 1902, 362).

Sulphur. A rapid method of determining the sulphur in ores given by Furman (Manual of Practical Assaying, 5th ed. 91) is to fuse 5 grams of the ore with 15 grams of borax, 3 grams of charcoal, and one or two nails in a hot fire. The time required for fusion is about 15 minutes. The nails are then withdrawn and the charge poured. As soon as the slag is cool, the matte is detached from it with a hammer and weighed. If the matte were pure FeS, it would contain 36·3 p.c. of sulphur. By analysis, Furman finds that the nearest approximation is to take the sulphur as 30 p.c. of the matte. The method, though inaccurate, is sometimes useful, as it can be completed in less than half an hour.

The more accurate methods consist in oxidising the sulphur by *aqua regia* or nitric acid and potassium chlorate, or by fusion with a mixture of nitre and sodium carbonate, and weighing it as barium sulphate. A good method for ores and slags consists in fusion with caustic alkali, extracting with water, and oxidising with bromine. After separation of the silica, the sulphur is precipitated by barium chloride (Chem. News, l. 1884, 194). If lead is present, the solution is boiled with ammonium carbonate.

T. K. R.

ASTATKI. A Russian term, signifying 'dregs,' applied to the residue left in the distillation of Baku petroleum after the volatilisation of the kerosene, and now largely used as fuel in the Caspian region (*v.* PETROLEUM).

ASTERIA (*Star Sapphire*) *v.* CORUNDUM.

ASTERIN *v.* ANTHOCYANINS.

ASTEROL. A combination of the mercury salt of *p*-phenol-sulphonic acid (hydragyrol) and ammonium tartrate

$$C_{12}H_{10}O_8S_2Hg,4[C_4H_4O_6(NH_4)_2],8H_2O,$$

used as an antiseptic in surgery.

ASTRALINE. Russian petroleum oil, used for burning (*v.* PETROLEUM).

ASTRALITE. A glass resembling aventurine, but containing crystals of a cupreous compound which by reflected light exhibit a dichroic iridescence of dark red and greenish-blue. Made by fusing and allowing to cool slowly a mixture of 80 pts. silica, 120 lead oxide, 72 sodium carbonate, 18 borax, with either 24 pts. scale oxide of copper, and 1 pt. scale oxide of iron, or with 5 pts. lime, 26 copper oxide, and 2 iron oxide.

ASTROLIN. Trade name for antipyrine-methyl-ethyl glycollate $C_5H_{10}O_3,C_{11}H_{12}ON_2$, m.p. 64°–65·5°. A colourless powder, with a slight smell and pleasant taste, readily soluble in water and alcohol.

ASUROL. Sodium-mercuri-amido-oxy*iso*-butyrosalicylate.

ASYPHIL. Trade name for a *mercury salt of p-aminophenylarsinic acid*

$$(NH_2C_6H_4AsO(OH)O)_2Hg$$

(*v.* ARSENICALS, ORGANIC).

ATACAMITE. Hydrated oxychloride of copper $CuCl_2{\cdot}3Cu(OH)_2$, occurring in the Atacama region of Chile, sometimes in sufficient amounts for use as a copper ore (Cu 59·4 p.c.). Large quantities have also been mined at Wallaroo in South Australia. Orthorhombic crystals of a bright-green colour and with brilliant faces are not uncommon. Sp.gr. 3·76. Before the days of blotting-paper, it was used, under the name of arsenillo, as a writing sand for absorbing ink (*v.* COPPER).

L. J. S.

ATELESITE. A bismuth arsenate containing iron phosphate found at Schneeberg in Saxony: Bi_2O_3, 57·15; $Fe_2P_2O_8$, 12·50; As_2O_3, 30·35 (Frenzel, J. M. 1873, 785).

ATHAR or **ATTAR**, Indian name for volatile oil of roses (*v.* OILS, ESSENTIAL).

ATISINE, *v.* ACONITINE

ATLAS DYNAMITE *v.* EXPLOSIVES.

ATLAS POWDER *v.* EXPLOSIVES.

ATLAS SCARLET *v.* AZO- COLOURING MATTERS.

ATMOSPHERE. The gaseous envelope surrounding any liquid or solid body; more particularly the gaseous envelope which surrounds the earth, and which is commonly known as air. The thickness of this aërial envelope is not known even approximately, but it is quite certain that it exceeds 45 miles measured from the earth's surface, which was the limit assigned to it by Wollaston. Secchi calculated that air exists even at a height of 300 kilometres above the earth's surface. From the ratio of decrease of density with elevation, the atmosphere at a height of 50 miles cannot exert any measurable pressure. The mass of the atmosphere forms, like the earth itself, an oblate spheroid, the polar axis of which is much shorter than the equatorial axis, the ratio of the two axes being, according to Laplace, as 2 to 3.

The pressure of the atmosphere at any particular spot may be measured in terms of the height of a column of mercury which it is capable of sustaining. It follows from the law of Boyle that the density of the air rapidly diminishes with the height. For air of constant temperature, its density, or, what comes to the same thing, the height of the mercurial column, should diminish in geometric progression, whilst the distance from the earth increases in arithmetic progression. The pressure, even at the same place, is continually varying from a variety of causes, and hence the height of the barometer, as the mercurial column was first termed by Boyle, is practically never absolutely constant. The average height at any one spot at the sea-level is mainly dependent upon the great movements of air which result from the effect of the earth's motion upon the gaseous envelope, combined with variations in the density of the aerial mass due to solar action.

According to Regnault, 1 litre of dry air, free from carbonic acid and ammonia, measured at 0° and 0·76 mm. pressure, at Paris (lat. 48° 50′) and at a height of 60 metres above the sea-level, weighs 1·293187 grams. Lasch found that 1 litre of pure air at standard temperature and pressure weighs at Berlin (lat. 52° 36′) 1·293635 grams.

Guye found 1·2930 grams at Geneva, and concluded that it may vary, on the same day, from place to place to the extent of several tenths of a milligram (Guye, Kovacs and Wourtzel, Compt. rend. 1912, 154, 1584). The mean of the most recent determinations gives the value 1·2928 grams as the weight of a normal litre of air. Guye considers that the most probable explanation of the variations in density observed from time to time is based on the presence in the air of varying quantities of dust, invisible under the ultramicroscope.

The Bureau Internat. des Poids et Mesures adopts for the weight of 1 litre of dry air, containing 0·04 p.c. carbonic acid, at the normal temperature, and under the normal barometric pressure at lat. 45° and sea-level,

$$P_{t,t}=\frac{1{\cdot}293052}{1+0{\cdot}00367}\times\frac{1}{760},$$

on the assumption that 0·00367 is the expansion coefficient of air at constant pressure for a normal degree. According to Leduc the mean composition of air at Paris, purified from aqueous vapour and gases absorbable by alkali, is as follows:

	Oxygen	Nitrogen	Argon	Neon
By volume	0·2100	0·7806	0·0094	15×10^{-6}
By weight	0·2321	0·7549	0·0130	$8{\cdot}4\times10^{-6}$

	Helium	Hydrogen	Krypton	Xenon
By volume	$0{\cdot}5\times10^{-6}$	1×10^{-6}	50×10^{-9}	6×10^{-9}
By weight	$0{\cdot}7\times10^{-6}$	$0{\cdot}07\times10^{-6}$	140×10^{-9}	30×10^{-9}

For such air at 0° and a pressure of 76 cm. of mercury at Paris the mass of 1 litre is found to be 1·2932 grm. Under normal pressure (76 cm. of mercury at 0°; $g=980{\cdot}665$) the weight is 1·2928. In other terms, taking the sp.gr. of mercury as 13·5951 and the value of g at the 4th story of the Sorbonne as 980·97, the mass of a litre of air under the pressure of a megabar is 1·2759 grm. For purposes of ordinary chemical calculation it may be assumed with sufficient accuracy that 1 gram of air measures at standard temperature and pressure 773 c.c.

The total weight of the atmosphere is about 11 trillions of pounds, or about 5 trillion kilograms and the relative amounts of the chief constituents may be assumed to be—

	Trillions kgm.
Nitrogen (argon, &c.) .	4·041200
Oxygen	1·218040
Carbonic acid . .	0·003156
	5·262396

Herschel calculated that, allowing for the space occupied by the land above the sea, the mass of the atmosphere is about $\frac{1}{1200000}$ part of that of the earth.

The unit of pressure adopted by engineers and others, and styled an *atmosphere*, is an amount equal to the average pressure of the atmosphere at the sea's level. In British measure an atmosphere is the pressure equivalent to 29·905 inches of mercury at 32° F. at London, and is about 14·73 lbs. on the sq. inch. In the metric system it is the pressure of 760 mm. (29·922 inches) at 0° C. at Paris, and is equal to 1·033 kilos on a sq. centimetre. Hence the English 'atmosphere' is 0·99968 that of the metric system.

The specific heat of air at constant pressure is 0·239 (Hercus and Laby). Its coefficient of thermal expansion between −30° and 200° is 0·003665 for 1°. Its thermal conductivity is $5{\cdot}22\times10^{-5}$ cal./cm. sec. deg. (Hercus and Laby, Proc. Roy. Soc. 1918, A, 206). Its viscosity $(N_0\times10^4)=1{\cdot}733$.

By the application of sufficient cold and pressure, air may be liquefied.

Comparatively little of the sun's heat is absorbed in its direct passage through the air. According to Tyndall, a column of air 1 metre long absorbs 0·088 p.c. of the heat which passes through it. According to Violle, and also Lecher and Pernter, the amount is not greater than 0·0070 p.c. This absorption is mainly due to aqueous vapour, and, in a lower degree, to carbonic acid and suspended organic matter. The air mainly gets its heat by conduction from the earth, and hence, as a rule, it is hottest near the ground. The law of the decrement in temperature corresponding to height is not accurately known; it is usually stated to be about 0·56° per 100 metres, but the rate is liable to very great variations.

Air is not perfectly transparent. Its particles reflect and scatter light in sufficient quantity to obscure the light from the stars. The blue colour of the sky is due to the fact that the most refrangible rays are most widely scattered (*cf* Rayleigh, Phil. Mag. 1899, 47, 375). Strutt has devised a method of showing the scattering of light by dust-free air and of artificially reproducing the blue colour of the sky (Proc. Roy. Soc. 1918, 94 A, 453; *see* also Cabannes, Compt. rend. 1915, 160, 62). In the higher regions of the atmosphere, where the amount of reflected light becomes less and less, owing to the decreased density of the air, the sky appears to grow gradually darker. Brewster first proved that the blue light from the sky, as well as the white light from the clouds, was due to reflected light, by the fact that it was polarised.

Suspended matter, dust, smoke, aqueous vapour in a state of partial precipitation, &c., greatly diminish the transparency of air. Wild gives the following numbers as representing the transparency coefficient of 1 metre of air:—

Dry air (free from dust) . . . 0·99718
Air of a room (dry, but containing dust) . . . . 0·99520
Air free from dust, but saturated with aqueous vapour . . . . 0·99328

The refractive indices of dry air at standard temperature and pressure for the Fraunhofer lines A, B, C, D, E, F, G, H, are, according to Kettler (Pogg. Ann. 124–401), as follows:—

$nA = 1{\cdot}00029286$
$nB = 1{\cdot}00029345$
$nC = 1{\cdot}00029383$
$nD = 1{\cdot}00029470$
$nE = 1{\cdot}00029584$
$nF = 1{\cdot}00029685$
$nG = 1{\cdot}00029873$
$nH = 1{\cdot}00030026$

The emission spectrum of air has been mapped by Huggins (Phil. Trans. 154, 139) and Angstrom (Pogg. Ann. 94, 141), and the spectrum of lightning by Kundt (Pogg. Ann 135, 315), who has shown that forked lightning gives a line spectrum, whereas sheet lightning gives a band spectrum. The absorption spectrum of air was first mapped by Brewster and Gladstone, and has been further examined by Janssen, Cornu, and Chappuis (Compt. rend. 91, 988).

Air, owing to the oxygen it contains, is a magnetic substance. The diurnal variation in magnetic declination has been alleged to be due to the varying magnetic potential of the oxygen owing to alterations in temperature

Air is a mixture of nitrogen, oxygen, aqueous vapour, argon, carbon dioxide, with minute quantities of ozone, hydrogen peroxide, ammonia, nitrous and nitric acids, hydrocarbons, helium, neon, krypton, xenon, hydrogen, &c. That the air is not a chemical compound of its component gases is proved by the facts: (1) that these gases are not present in any constant ratio; (2) that air can be made by simply mixing its constituents in the proportion indicated by the analysis of air, without contraction or any thermal disturbance resulting; (3) that on treating air with water and expelling the dissolved air by boiling, the proportion of the oxygen to the nitrogen is found to be increased, and in amount corresponding with the law of partial pressures; (4) that the constituents of the air can be mechanically separated by processes of diffusion; and (5) that the refractive power of the air is equal to the mean of the refractive powers of its constituents, whereas in compound gases the refractive power is either greater or less than the refractive power of the elements in a state of mixture.

The amount of **oxygen** in air may be ascertained by measuring the diminution in volume which a known bulk experiences when in contact with some substance capable of absorbing or combining with oxygen gas. Among the substances which may be conveniently used for this purpose are:

1. *Phosphorus.* A fragment of phosphorus on the end of a platinum or copper wire is exposed to a measured volume of air standing over water or mercury until no further decrease of volu[illegible]ed (Berthollet) Lindemann (Zeitsch anal Chem 1879, 18, 158) employs thin sticks of phosphorus for the same purpose in the Orsat apparatus (*v.* GAS ANALYSIS). At a temperature below 7° the oxidation of the phosphorus ceases. Watson (Chem. Soc. Trans. 1911, 99, 1460) has described an accurate method of ascertaining the amount of oxygen in air by the use of yellow phosphorus. A modification of the apparatus for estimating the oxygen content of air from the upper atmosphere has been suggested by Aston (Chem. Soc. Trans. 1919, 472).

2 *Pyrogallol in Alkaline solution.* Chevreul, in 1820, first suggested the use of this reagent. The absorption is apt to be accompanied by the formation of notable quantities of carbon monoxide if the amount of oxygen is large or the alkaline solution very concentrated. According to Hempel (Ber. 20, 1865), the best proportions are 5 grams pyrogallol dissolved in 15 c.c. water mixed with 120 grams caustic potash dissolved in 80 cm. of water. Practically no carbon monoxide is formed with this solution. The absorption is very rapid (Hempel, Ber. 18, 267 and 1800). Guye and Germann have described a volumeter by which it is possible to analyse accurately very small quantities of air (0·25 c.c.) (Compt. rend. 1914, 159, 154).

3. *Metallic Copper.* A spiral of copper wire is heated to redness in dry air free from carbonic acid and of known pressure until the whole of the oxygen has combined with the metal to form cupric oxide. The pressure of the residual gas is then determined, whereby the amount of nitrogen is ascertained, and hence the amount of oxygen. An apparatus on this principle was suggested by Jolly (W. N. S. 6538); it is seen in Fig. 1.

The glass vessel A, of about 100 c.c. capacity, is exhausted by the mercurial pump, and is replenished with the air under investigation. This is then cooled to 0 by surrounding A

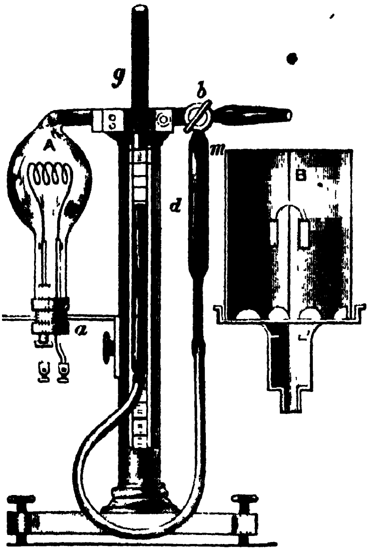

Fig 1

with the metallic cylinder B, which is filled with melting ice. The tension of the confined air is measured by the height of mercury in the glass tubes *g* and *d*, which are connected together by caoutchouc tubing. The tube *g* is movable in the clamp *f*, the position of *d* being fixed with reference to A. By turning the three-way stop-cock *b*, A and *d* may be alone brought into connection, or both may be made to connect with the outer atmosphere. The cock is now so turned that A and *d* are alone in connection; the tube *g* is now raised until the level of the mercury in *d* just touches the point *m*, when the tension of the air is read off on the graduated scale behind *g*. The copper spiral in A is next heated to redness by an electric current, whereby the heated metal rapidly combines with the oxygen. The cylinder B is once more placed round A, the residual nitrogen cooled down to 0° by means of melting ice, and its tension measured by adjusting the level of the mercury to *m*, and reading off the height of the mercury in *g*. If, for example, the pressure before abstracting the oxygen was 702·56 mm., and after the abstraction was 555·70 mm., then 1 volume of the air would be reduced to $=\frac{555\cdot70}{702\cdot56}=0\cdot79096$ vol., or, expressed centesimally, the composition of the air would be:

Nitrogen (argon, &c.) . . .	79·096
Oxygen	20·904
	100·000

Kreusler has shown that unless the air be carefully dried before being heated with the copper spiral, the proportion of oxygen will be apparently too low.

Dumas and Boussingault (Ann. Chim. Phys. [3] 3257), as far back as 1841, made use of the fact that heated metallic copper combines with oxygen, in order to determine the gravimetric composition of air. Air deprived of moisture and carbonic acid was passed through a weighed tube containing metallic copper heated to redness, whereby all the oxygen was absorbed, the nitrogen being collected in a vacuous glass globe also previously weighed. At the conclusion of the experiment the tube containing the metallic copper was again weighed; the increase in its weight gave the amount of absorbed oxygen, together with the weight of the nitrogen which it also contained. The nitrogen was then removed by the air pump and the tube again weighed; the difference between the first and third weighings of the tube containing the copper gave the weight of absorbed oxygen, and the weight of nitrogen was obtained by adding the difference between the second and third weighings of the tube to the increase in the weight of the glass globe. As the mean of a large number of experiments made by this method, the precentage composition by weight of air free from water and carbonic acid was found to be

Oxygen	23·00
Nitrogen (with argon, &c.) .	77·00
	100·00

Leduc has shown that this proportion of oxygen is too low, as an average; the amount is about 23·2 p.c. by weight as calculated from the known density of air and of its constituent gases (Compt. rend. 1896, 12, 1805; 1898, 126, 413).

4. *Explosion with hydrogen.* A measured volume of air is mixed with a known volume of hydrogen in excess, and the mixture is exploded by the electric spark, when the oxygen combines with the hydrogen in the proportion of 1 vol. of the former to 2 of the latter to form water. One-third of the contraction resulting from the explosion represents, therefore, the amount of oxygen in the air under examination. This method, first suggested by Volta, was perfected by Bunsen. Modifications of the method have been made by Regnault and Reiset, Williamson and Russell, Frankland and Ward, and others. These methods are extremely accurate, and have afforded us all the exact knowledge we have respecting the variations in the amount of oxygen in atmospheric air. Thus Bunsen, in a series of analyses made in the winter of 1846, found that the percentage amount varied from 20·97 to 20·84. Regnault made a large number of analyses of air collected from all parts of the world. In 100 analyses of air collected in Paris the minimum amount of oxygen was 20·913, the maximum 20·999. Air collected in various parts of Europe, from above the Atlantic Ocean, from the summits of the Andes and from the South Polar Sea, contained an amount of oxygen varying from 20·86 to 21 p.c. Many hundreds of analyses were made by Angus Smith, of air collected in various towns in England and Scotland, and also of air collected in the country. The oxygen in London air varied from 20·857 to 20·95, less oxygen as a rule being found in the air of streets than in that of the parks and open spaces. A series of 30 analyses of Glasgow air showed variations from 20·887 in the closer parts to 20·929 in the more open spaces. Even wider extremes were found by Leeds in the air of New York, viz. from 20·821 to 21·029 p.c. According to E. W. Morley, the diminished proportion of oxygen may be caused by the down-rush of air from the higher regions of the atmosphere, which probably contain a less relative amount of oxygen. Regnault's experiments afford some evidence for the belief that the air of the tropics contains slightly less oxygen than that in northern latitudes (*v.* also Jolly, W. N. F. 61, 520). A similar conclusion has been drawn by Hempel (Ber. 20, 1864) from the analysis of a large number of analyses of air collected simultaneously at Tromsö, Dresden, and Para. The mean results were:

	Oxygen.
Tromsö	20·92
Dresden	20·90
Para	20·89

From the results of 203 analyses of air collected at five different spots and analysed by three independent methods, it follows that the most probable mean percentage amount of oxygen is 20·95. Numerous determinations by Pettersson and Högland of the air of Stockholm during October, November, and December, 1889, gave O=20·94 (Ber. 22, 3324; Hempel, Ber. 20, 1864; Kreusler, Ber. 20, 991). More recent work by Durius and Zuntz, Watson (Chem. Soc. Trans. 1911, 99, 1460), and Benedict (Carnegie Inst. Report, 166), indicates that such small variations as occur are not traceable to meteorological conditions. The mean percentage of oxygen (20·952) found by Benedict from 1909 to 1912 corresponds closely with that found by Morley (20·955) in 1881.

Air from various parts of France, the Alps, and Algiers, taken both in spring and winter, was found by Leduc to show on an average 23·20–23·21 p,c. of oxygen by weight, the extreme values being 23·05 and 23·25 p.c. The percentage is slightly lower in the north and at sea-level than elsewhere, and is less in London than in Paris. Samples of the upper air are less rich in oxygen than air at the level of the earth, although the differences are much less than are indicated by the law of Laplace.

Ozone is always present in minute quantity in normal air. Air over marshes contains little or no ozone. No ozone can be detected in the air of large towns or in inhabited houses. Atmospheric ozone is probably formed by the action of electricity on air. Most of the information we at present possess concerning the distribution of atmospheric ozone has been obtained by the use of so-called ozone papers. Of these the best known is Schönbein's, which is based on the fact that ozone liberates iodine from potassium iodide, and thereby renders starch blue. To prepare them, unsized paper is immersed in a solution of 15 parts starch and 1 part potassium iodide in 200 parts of water and dried in the dark. To make a determination of ozone the paper is freely exposed to the air for some hours and moistened with water, and the depth of tint produced compared with a standard scale of colour. The method has no pretensions to scientific accuracy. Houzeau (Ann. Chim. Phys. 4, 27, 5) determines the relative amount of ozone by exposing red litmus paper previously dipped in 1 p.c. sol. of potassium iodide and dried, to the action of the air. The ozone liberates iodine and the free alkali turns the paper blue. Thallium salts are turned brown by the action of ozone, and hence papers soaked in solution of these salts have been used for the recognition of ozone. Paper soaked in a very dilute solution of neutral gold chloride is turned a deep violet colour by ozone (Böttger, Chim. Zentr. 1880, 719).

Attempts have been made to estimate ozone by aspirating large volumes of air through dilute solutions of hydriodic acid and determining the amount of the liberated iodine by iodometric analysis. Also by leading the air through a mixed solution of potassium arsenite and potassium iodide, whereby the liberated iodine converts the arsenite to arsenate. The liquid through which the air had passed was then mixed with a few drops of ammonium carbonate solution and starch paste, and a standard solution of iodine (1 : 1000) added until the blue colour was permanent. A precisely similar experiment was made on equal amounts of distilled water, iodine, arsenite, &c., used, and from the difference in the amount of iodine solution needed the amount of oxidised arsenite and hence the quantity of ozone was determined.

According to David (Compt. rend. 1917, 164, 430) the ozone in air may be estimated by adding 5 c.c. of $N/100$-ferrous ammonium sulphate acidified with sulphuric acid to a vessel of 1 litre capacity, and then titrating back with $N/1000$ potassium permanganate.

Pring (Proc. Roy. Soc. 1914, A 90, 204), by observations on the action of ozone on aqueous solutions of potassium iodide, with the formation of hypoiodite and free iodine, finds that the average amount of ozone in the atmosphere is 2·5 vols. per million of air, and that this amount varies very little with the altitude between 5 and 20 kilometres. In the Alps a mean value of 2·5 vols. was observed at 2100 metres, and 4·7 vols. at 3580 metres. Pring regards ozone as a contributing factor in determining the blue colour of the sky. The use of potassium iodide as an agent for the estimation of atmospheric ozone is deprecated by Usher and Rao (Chem. Soc. Trans. 1917, 111, 799), who have devised a method in which the air to be examined is shaken with a dilute standard solution of sodium nitrite made slightly alkaline; and the unchanged nitrite content subsequently determined colorimetrically by the production of the red dye with α-naphthylamine and sulphanilic acid (Griess-Ilosvay method). For particulars the original description must be consulted.

It appears that the amount of ozone varies with the seasons: it is greatest in winter, becomes gradually less during spring and autumn, and is least in summer. Ozone is more frequently observed on rainy days than in fine weather; thunderstorms, gales, and hurricanes are frequently accompanied by relatively strong manifestations of it (*cf.* Thierry, Compt. rend. 1897, 124, 460).

According to Holmes (Amer. Chem. J. 1912, 47, 497) the maximum amount of ozone in the air is only found when 'high' barometric areas are so near that the air from great heights flows rapidly down to the earth. Most of the ozone is produced by the action of the sun's ultraviolet rays on the upper air (*cf.* Strutt, Proc. Roy. Soc. 1917, 94, 260). According to Moore (Proc. Roy. Soc. 1918, B, 90, 158), the 'ozone' odour in air is probably due to oxides of nitrogen formed by the action of sunlight rich in ultraviolet light in the upper layers of the atmosphere on air and water-vapour.

It is highly probable that many so-called ozone manifestations are due to the existence of *hydrogen peroxide* in the air, which was first demonstrated by Meissner in 1863. Schöne found from observations made at Moscow, that it was invariably present in rain, dew, and snow, and was less in winter than in summer; and more in southerly winds than in those from the north. The amounts in all cases were, however, very minute, the maximum being 1·4 c.c., and the mean 0·38 c.c. hydrogen peroxide vapour in 1000 c.c. air.

The quantity of *aqueous vapour* in the air varies with the temperature: thus 1 cm. of air when saturated with water contains:

At −10°	2·284 grams	At +20°	17·157 grams
0°	4·871 „	25°	22·843 „
+ 5°	6·795 „	30°	30·095 „
10°	9·362 „	35°	39·252 „
15°	12·746 „		

The most accurate method of determining the amount of aqueous vapour in the air consists in aspirating a given volume of the air through weighed tubes filled with some hygroscopic substance, such as phosphoric oxide or pumice soaked in oil of vitriol and reweighing the tubes, when the increase of weight gives the quantity of moisture present.

Usually, however, the humidity of the air is estimated by means of hygrometers, the best-known form of which is the psychrometer or wet-and-dry-bulb thermometer of August. The *absolute humidity* of the air is the weight of aqueous vapour contained in 1 c.m. The *relative humidity* denotes the relation between the weight actually present and that which could be theoretically present if the air were saturated; it is usually expressed in per cent. of the maximum humidity. The air is seldom absolutely saturated with aqueous vapour, although in our moist climate saturation is occasionally very nearly attained. With us the most humid month is December, and the driest is July.

The presence of *carbonic acid* in the atmosphere was first indicated by Black in 1752. The quantity in normal air is about 0·03 p.c.; in that of large towns it is slightly greater. Angus Smith gives the following summary of results obtained in London in 1864 and 1869 (Air and Rain, 53–58):—

Over River Thames .	8 expts.	0·0343 p.c.
In the Park . .	5 ,,	0·0301 ,,
In the streets . .	10 ,,	0·0380 ,,

Any circumstance which interferes with the ready diffusion of the products of respiration and of the combustion of fuel will tend to increase the relative amount of carbonic acid in the air of a town: hence during fogs the amount may be as great as 0·1 p.c.

The amount of carbonic acid in the air of the country at night is usually greater than in the day, as the following comparison shows:—

Air in the day-time.

Observer	Year	Place	Amount
Fr. Schulze .	1861–71	Rostock .	0·0292 p.c.
T. Reiset . .	1873–80	Ecorchebœuf	0·0290 ,,
G. F. Armstrong	1879	Grasmere .	0·0296 ,,
Müntz & Aubin .	1881	Vincennes .	0·0284 ,,
A. Levy . .	1877–83	Montsouris .	0·0299 ,,
Petermann .	1892	Gembloux .	0·0299 ,,
Brown & Escombe	1898–1901	Kew . .	0·0294 ,,
Air in the night-time.			
T. Reiset . .	1873–80	Ecorchebœuf	0·0304 p.c.
G. F. Armstrong	1879	Grasmere .	0·0330 ,,

These differences are mainly due to the exhalation of carbonic acid from plants at night, and, to a smaller extent, to the absence of wind and of any decomposition of the gas by the action of sunlight. Over the sea this diurnal variation is not perceived, as the following results indicate:—

Carbonic acid in sea air.

T. E. Thorpe	Irish Channel and Atlantic Ocean	1865–6	Day .	0·0301 p.c.
			Night	0·0299 ,,
			Mean 0·0300	

In cold regions the dissociation pressure of hydrogen carbonates in the sea being low, the proportion of carbon dioxide in the air is below normal. Samples of air collected over the sea at latitudes of 64–70, at temperatures between 1° and 2°, gave a mean value of 2·0524 vols. in 10,000 of air, a distinctly smaller proportion than is met with in warmer regions (Muntz and Lainé, Compt. rend. 1911, 153, 1116).

Carbonic acid in the air of tropical countries.

T. E. Thorpe . .	S. America .	1866	0·0328 p.c.
Müntz & Aubin .	S. and Central America .	1882	0·0278 ,,
		Mean 0·0303	

The pressure exerted by the carbonic acid in air is so small that its amount is not perceptibly diminished by rain. The amount also is not sensibly altered in the higher regions of the atmosphere.

Of the several methods which have been proposed for the estimation of atmospheric carbonic acid, the most generally convenient is that of Pettenkofer. It consists in exposing a known volume (say 50 c.c.) of dilute baryta water of known strength to a measured quantity of air (4–6 litres) contained in a well-closed flask. In about 5 or 6 hours the absorption of the carbonic acid will be complete, provided that the sides of the flask have been moistened from time to time by the baryta solution. The baryta solution is then decanted and allowed to stand in a small stoppered bottle until the barium carbonate has settled, when aliquot portions (say 20 c.c.) of the clear solution are withdrawn and the amount of the baryta still in solution determined by titration with a standard solution of sulphuric or hydrochloric acid, of which 1 c.c. = 1 mgm. CO_2, phenolthalein being used as indicator (*v.* ACIDIMETRY). The difference in the volume of acid needed for the neutralisation of the baryta before and after exposure to the confined volume of air gives the number of milligrams of carbonic acid contained in the air. Blochmann (Annalen, 237, 72) has described a modification of the apparatus which allows of the titration being effected without exposure to the air of the laboratory.

(For other methods, *v.* Haldane and Pembrey, Roy. Soc. Proc. 1889; Cl. Winkler, Chem. Unter. der Industriegase, Freiberg, 1877; Reiset, Chem. Soc. Trans. 90, 1144; Müntz and Aubin, Compt. rend. 92, 247.)

(For Angus Smith's minimetric method, *v.* Air and Rain; compare Lunge, Dingl. poly. J. 231, 331.)

(On the influence of the sea upon the amount of atmospheric carbonic acid, *v.* Levy, Ann. Chim. Phys. [3] 34, 5; Thorpe, Chem. Soc. Trans. 1867; Schloesing, Compt. rend. 93, 1410; Lawes, Phil Mag. [5] 11, 206.)

Minute quantities of ammonia and nitrous and nitric acids are also present in the air. Although many of the published observations are probably inaccurate owing to the imperfection of the methods employed, it appears to be proved that the amount of ammonia, which exists mainly as carbonate, is subject to very great variations. By aspirating from 10 to 20 litres of air through Nessler's solution (an alkaline solution of potassium-mercury iodide) and comparing the depth of colour with that produced by a standard solution of an ammonium salt, H. T. Brown (Roy. Soc. Proc. 18, 286) found that the air of Burton-on-Trent during September, October, and November, 1869, taken 2 metres from the ground, contained from 0·4059 to 0·8732 part $(NH_4)_2CO_3$ in 100,000 parts of air, whereas that of the country taken during December and February contained from 0·5102 to 0·6085 part. The direction of the wind had apparently no influence on the amount; heavy rain seemed to diminish it, but the air was restored to its normal condition in a few hours. Truchot found from 0·93 to 2·79 mgm. per cubic metre in the air of Auvergne, the minimum being found in clear weather and the maximum during fogs (Compt. rend. 77, 1059). Müntz and Aubin, from observations on rain water, found that the upper strata of air contain much less ammonia than air near the ground. Levy (Compt. rend. 91, 94) found that the rain water and snow of Paris contain in mean 1·17 mgm. of ammoniacal nitrogen per litre of water. The amount of ammonia in this meteoric water is least in winter and greatest during the warmer periods of the year. Gilbert and Lawes found that 1,000,000 pts. of rain water collected in the country contained 0·927 to 1·142 pts. of ammonia. Rain water collected in towns always contains large quantities of ammonia. Thus Angus Smith found that rain water collected in the sparsely populated districts in Scotland contained 0·53 pt. per million, whereas the rain water of London contained 3·45, that of Liverpool 5·38, that of Manchester 6·47, and that of Glasgow 9·1 per million. The increased amount in the towns is doubtless due to the influence of animal life and to the constant presence in greater proportion than in the country of readily decomposable nitrogenous organic matter in the air (*cf.* Heinrich, Chem. Soc. Abst. 1898, ii. 114).

The quantities of nitrous and nitric acids in the air are even smaller than that of ammonia. Angus Smith (Air and Rain, 287) has given the following results showing the amount contained in a million pts. of rain water :—

Scotland, inland country places .	0·305
Ireland „ „ „ .	0·370
Scotland, country places . .	0·424
„ towns . . .	1·164
England, inland country places .	0·749
„ towns . . .	0·863

Trieschmann found that the average per million brought down in rain at Mount Vernon, Iowa, over a period of 8¼ months was of free ammonia 0·407; albuminoid ammonia, 0·366; nitrates, 0·255; and nitrates 0·018. Rain was found to be richer in nitrogen contents than snow (Chem. News, 1919, 119, 49).

Occasionally, and more especially in the air of towns, minute quantities of hydrocarbons, sulphuretted hydrogen, carbonic oxide, sulphurous acid, common salt, alkaline sulphates, are met with. Boracic acid and sal ammoniac have been observed in air in the neighbourhood of active volcanos.

The percentage amount by volume of the inert gases in the air may be stated as follows :—

Argon	0·93000 p.c.
Krypton . . .	0·00995 „
Xenon	0·00114 „
Neon	0·00123 „
Helium . . .	0·00040 „

(Moissan, Compt. rend. 137, 600; Ramsay, Roy Soc. Proc. 1908, 80 A, 599.)

Organic matter in greater or less quantity is always present in the air. Much of this is nitrogenous, and apparently readily susceptible to putrefaction, giving rise to products which are alternately transformed into ammonia, nitrous and nitric acids. This form of organic matter reduces silver nitrate and potassium permanganate solutions. A portion of the organic matter consists of micro-organisms which are rapidly deposited in the absence of strong aërial currents. Hesse quantitatively estimates the relative proportions of micro-organisms contained in air by aspirating a given volume of the air through glass tubes coated internally with gelatine peptone, which is then kept at a temperature of about 25° for some days, when the various monad bacilli and micrococci which are arrested and which are capable of growing in the gelatine peptone are recognised by the colonies which they form. By means of this method Percy F. Frankland has made a number of estimations of the micro-organisms contained in the air of towns and in the country and in inhabited buildings. By simultaneously exposing small circular glass dishes partially filled with the nutrient gelatine to the action of the air, a rough estimate was obtained not only of the number of micro-organisms in a given volume of the air, but also of the number which fell during a given time on a definite horizontal area. As the mean of a series of observations made on the roof of the South Kensington Museum between January and June, 1886, it was found that there were 35 organisms in 10 litres of air, whilst 279 was the average number which fell on 1 sq. ft. in 1 minute. Similar experiments made near Reigate and in the vicinity of Norwich showed an average of 14 organisms in 10 litres of air, while 79 fell per sq. ft. per minute. Experiments made in Kensington Gardens, Hyde Park, and on Primrose Hill, gave an average of 24 organisms in 10 litres, and a deposition of 85 per sq. ft. per minute. At St. Paul's Cathedral, 56 organisms were found at the base, 29 in the Stone Gallery, and 11 in the Golden Gallery, in 10 litres of air. At Norwich Cathedral, 18 at the base, 9 at a height of 180 ft. and 7 at 300 ft. In inhabited buildings great variations were observed; as a rule, the number of micro-organisms was less than was found in the open air when the air of the room was undisturbed, but rose rapidly when the air was set in motion by draughts or by the presence of many people (P. F. Frankland, Roy. Soc. Proc. 40, 509).

Experiments made at the Montsouris Observatory have shown that far fewer organisms are present in the air during winter than during spring and summer. The number also seems to be greatly increased after rain. Whilst in the warm months the number of spores in 1 litre of air was 28, after heavy rain it rose to 95 and 120.

Atmospheric dust is made up of both inorganic and organic matter. Tissandier found that 1 c.m of the air of Paris contained on the average 7·5 mgms. of dust; after a period of dry weather (8 days), 23·0 mgms., and after heavy rain, only 6·0 mgms. It consisted of from 27 to 34 p.c. volatile matter, and from

66 to 75 p.c. mineral matter, viz. sulphates and chlorides of the alkalis and alkaline earths, oxides of iron, earthy carbonates and phosphates, &c. (*cf.* J. Aitken, Trans. Roy. Soc. Edin. 35, 37, 39).

Radioactive Constituents of the Atmosphere.

A charged electroscope slowly loses its charge in air, and it has been shown that this is not due to moisture, but that, on the contrary, the leakage is greater in dry than in wet weather. The conductivity of air is lessened by passage through a metal tube or by the presence of a weak electric field. These facts indicate that the conductivity of air is due to the presence of charged ions (Townsend, Proc. Roy. Soc. 1899, 65, 192; Geitel, Naturw. Rundsch. 21, 221). The rate of leakage of electricity from a charged conductor in dust-free air is the same for positive and negative charges, but varies with the pressure. The loss of charge per second corresponds to the production of about 20 ions of either sign in each cubic centimetre of air (Wilson, Proc. Roy. Soc. 68, 151).

Elster and Geitel have shown (Wied. Ann. [2] 39, 321) that ions are produced during the formation of ozone by contact of air with flames or by the slow oxidation of phosphorus, &c., but the mere presence of ozone does not impart conductivity to air (Jorissen and Ringer, Ber. 1906, 39, 2090). Langevin (Compt. rend. 1905, 140, 232) states that in air, in addition to ordinary ions carrying charges equal to that of a hydrogen ion in solution, there exist other ions having a much smaller mobility, but carrying charges fifty times as great.

Nordmann has described (Compt. rend. 140, 430) an apparatus for continuously recording the state of ionisation of the air. Air is caused to circulate between the plates of a cylindrical condenser, and the charge given up by the ions is removed by dropping water. The condenser is connected with an electroscope, the deviations of which are recorded photographically, and are proportional to the number of ions present in unit volume of air. Another apparatus for the same purpose is that of Langevin and Moulin (Compt. rend. 140, 305).

No satisfactory explanation of the ionisation of air was found until Elster and Geitel showed (Physikal. Zeitsch. 1901, 76, 590) that a negatively charged wire suspended in the open air became coated with radioactive matter, the presence of which could be proved by its action upon a charged electroscope, although the quantity present was altogether too small to respond to any chemical test. Rutherford and Allan confirmed this observation, and measured the rate of decay of the deposit (Phil. Mag. 1902, vi. 4, 704). Later, Allan showed that the radioactive matter could be removed from the wire by rubbing it with a piece of felt or by solution in ammonia, and that the ashes of the felt or the residue from the evaporation of the solution showed radioactivity having a period of decay equal to that of the deposit on the wire (Phil. Mag. 1904, vi. 7, 140).

These phenomena are due to the presence in the atmosphere of the gaseous emanations of radioactive elements, probably those of radium and thorium (Bumstead, Amer. J. Sci. 1904, 18, 1). The amount of active matter is not constant, but increases with increased circulation of the air, and is therefore probably due to the presence of radium in the soil (Simpson, Phil. Trans. 1905, A, 205, 61). Balloon observations made by Flemming (Zeitsch. physikal. Chem. 1908, 9, 801) show that radium emanation is present even at a height of 3000 metres. Thorium emanation exists principally in air taken from the soil or the lower layers of the atmosphere (Gockel and Wulf, Physikal. Zeitsch. 1908, 9, 907). That it is not widely disseminated in the air is probably due to its rapid rate of decay (Blanc, Physikal. Zeitsch. 1908, 9, 294). The experiments of Dadourian (Physikal. Zeitsch. 1908, 9, 333) and of Wilson (Phil. Mag. 1909, 17, 321) indicate that air normally contains about 3700 times as much radium emanation as thorium emanation.

By passing air through a copper spiral cooled in liquid air, the emanations are condensed, and may then be volatilised into an electroscope and the amount estimated by their effect in ionising the contained air. Ashman (Amer. J. Sci. 1908, 26, 119) has thus found in Chicago air an amount of emanation per cubic metre equal to that which would be in equilibrium with about $1 \cdot 0 \times 10^{-10}$ gram of radium. By absorbing the emanations in charcoal and then volatilising them into an electroscope, Eve has obtained results of the same order—$0 \cdot 8 \times 10^{-10}$ gram for the radium equivalent of the emanation in the air of Montreal (Phil. Mag. 1907, 14, 724), and has shown by numerous observations that the value is not affected by temperature, but that a deep cyclone with rain causes an increase, whilst anti-cyclonic conditions cause a decrease in the amount of emanation (Phil. Mag. 1908, 16, 622). These results have been confirmed by Satterly (Phil. Mag. 16, 584).

All investigators are agreed that these emanations are the chief cause of the ionisation of air, but Wilson, by experiments on the effect of pressure on 'natural' ionisation of air enclosed in a metal cylinder, has shown (Phil. Mag. 1909, 17, 216) that it is partly due to some penetrating radiation the source of which is not in the soil (Pacini, Atti R. Acad. Lincei, 1909, 18, 123). Both Pacini and Wulf (Physikal. Zeitsch. 1909, 10, 152) have detected a double diurnal periodicity in the state of ionisation of the air.

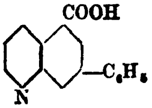
ATOPHAN. Trade name for 2-phenylquinoline-4-carboxylic acid,



Used as a uric acid eliminant and as an analgesic in the treatment of gout and sciatica.

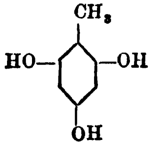
ATOXYL. Trade name for the mono-sodium salt of *p*-aminophenylarsinic acid (Ehrlich and Bertheim). Forms a white crystalline tasteless, odourless powder. So named from its relatively low toxic action (*v.* ARSENICALS, ORGANIC.)

ATRAMENTUM STONE. (*Atramentumstein*, Ger.) A product of the partial oxidation of iron pyrites, consisting of a mixture of ferrous and ferric sulphates with free ferric oxide. Used in the manufacture of ink.

ATRANORIN $C_{19}H_{18}O_8$ is present in the lichens *Evernia vulpina*, *E. prunastri*, *E. furfuracea*, *Lecanora atra*, *L. sordida*, *Parmelia perlata*, *P. physodes*, *P. tinctorium*, *Physcia stellaris*. *Xanthoria parietina*, *Cladonia rangiformis*, *Stereocaulan vesuvianum* and others. It forms colourless prisms, m.p. 195°–197° C. (Zopf), 187°–188° C. (Hesse), easily soluble in hot chloroform, soluble in alkalis with a yellow colour.

According to Paternò, by heating with water to 150°, atranorin gives physciol (methylphloroglucinol) and atraric acid (betorcinolcarboxylic acid methyl ester), and these substances are also obtained when atranorin is heated with acetic acid in a sealed tube (Hesse).

Physciol forms colourless needles, m.p. 104°–105°, gives a blue-green colouration with ferric chloride, and possesses, according to Hesse, the constitution of a methyl-phloroglucinol—

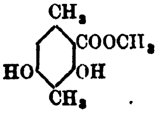


Betorcinol carboxylic acid methyl ester $C_{10}H_{12}O_4$, crystallises in leaflets, m.p. 140°–141° C., and gives a blood-red colouration with calcium hypochlorite solution. Digested with boiling hydriodic acid, it is converted into *β-orcin* (Stenhouse and Groves), $C_8H_{10}O_2$, according to the equation—

$$C_{10}H_{12}O_4+HI=CH_3I+CO_2+C_8H_{10}O_2$$

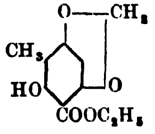
β-orcin (*see* also *barbatic acid*) is 1 : 4-dimethylresorcinol.

The constitution assigned to betorcinol carboxylic acid methyl ester is—



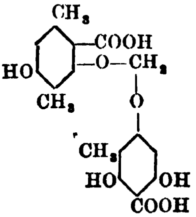
Heated with alcohol in a sealed tube atranorin gives, according to Paternò, *hæmatommic acid* and *hæmatomminic acid*; but the researches of Hesse indicate that these compounds in reality consist of *hæmatommic acid methyl ether* and *betorcinol carboxylic acid methyl ether.*

Hæmatommic acid methyl ether $C_{10}H_{10}O_5$ forms colourless needles, m.p. 147°, soluble in alkaline solutions with a yellow colour. With ferric chloride it gives a purple-red or purple-brown colouration. The *ethyl ether*, $C_{11}H_{12}O_5$, gives colourless needles, melts at 111°–112° (Hesse); 113°–114° (Zopf). It is represented by the formula—

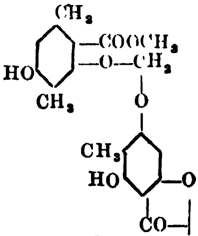


When a solution of atranorin in dilute acetic acid is gently evaporated, *atranorinic acid* (Hesse) is produced. This compound is also present in the *Cladonia rangiformis* (Hesse) when gathered in December, but is absent from the lichen in summer.

Atranorinic acid $C_{18}H_{18}O_9,H_2O$ forms colourless crystals, which are anhydrous at 100°, and then melt at 157°. With ferric chloride it gives a dark brownish-red colouration. With hydriodic acid it gives *β-orcin*, and when heated with alcohol yields carbon dioxide, *physciol* and *β-orcin*. The constitutions assigned to atranorinic acid (1) and atranorin itself (2) are as follows:—



I.



II.

ATROPINE *v.* TROPEINES.

ATROSCINE. *See* HYOSCINE, under TROPEINES.

ATTAR OF ROSES *v.* OILS, ESSENTIAL.

ATYROSYL. syn. for Asyphil.

AUCUBIN *v.* GLUCOSIDES.

AURAMINE. *Iminotetramethyldiparamino-diphenylmethane hydrochloride*, $C_{17}H_{21}N_3,HCl,H_2O$, $NMe_2{\cdot}C_6H_4C(NH){\cdot}C_6H_4{\cdot}NMe_2,HCl,H_2O$ (Graebe), or $Me_2N{\cdot}C_6H_4{\cdot}C(NH_2):C_6H_4:NMe_2Cl,H_2O$ (Stock; Dimroth and Zoeppritz). According to Stock (J. pr. Chem. 47, 401; Ber. 1900, 33, 318), and Dimroth and Zoeppritz (Ber. 1902, 35, 984), the base has the constitution assigned to it by Graebe (Ber. 1899, 32, 1678; 1902, 35, 2615), but the hydrochloride and the other salts have the quinonoid structure $Me_2N{\cdot}C_6H_4{\cdot}C(NH_2){\cdot}C_6H_4:NMe_2Cl$, and are to be regarded as derivatives of triphenylmethane in which an amino- group has replaced one of the benzene residues. (*Cf.* Semper, Annalen, 1911, 381, 234.)

Auramine, the first member of a series of yellow, orange-yellow, or brown dyes, is the hydrochloride of a colourless base obtained by the action of ammonia on tetramethyldiaminobenzophenone, and comes into the market either in the nearly pure form as *Auramine O*, or mixed with dextrin as *Auramine I.* and *II.* (Graebe, Ber. 20, 3264). Fehrmann (Ber. 20, 2847) proposed to restrict the name auramine to the colourless base, but such a change would inevitably lead to confusion; and Graebe (*l.c.*) has consequently adopted the name *auramine-base* for the base itself, using the term auramine in its usual signification.

Preparation.—(1) Auramine was originally prepared from tetramethyldiaminobenzophenone by dissolving it in some indifferent solvent such as chloroform, carbon disulphide, hydrocarbons, &c., treating it with half its weight of phosphorus trichloride or oxychloride, and adding excess of concentrated ammonia to the chlorinated compound thus obtained (B. A. S. F., D. R. P. 27789).

(2) Auramine can be prepared more economically by heating tetramethyldiaminobenzophenone with suitable ammonium salts, such as the chloride, acetate, tartrate, thiocyanate, &c., in the presence of zinc chloride at 200° (B. A. S. F., D. R. P. 29060). Acetamide may be employed instead of ammonium salts (B. A. S. F., D. R. P. 38433), or the dye may be obtained by heating aniline hydrochloride with zinc chloride and carbamide, phenylcarbamide, diphenylcarbamide, or carbanil (Ewer and Pick, D. R. P. 31936); but these alternative methods have no practical importance.

(3) At the present day, auramine is prepared by a method due to Sandmeyer (Eng. Pat. 12549, 1889; 16666, 1890) and Walker (J. Soc. Chem. Ind. 1901, 34), which consists in heating a mixture of tetramethyldiaminodiphenylmethane, sulphur, ammonium chloride, and sodium chloride in a current of dry ammonia. A modification of this method is described by J. Y. Johnson (B. A. S. F., D. R. P. 71320; Eng. Pat. 6249, March 23, 1893), in which the tetramethyldiaminodiphenylmethane is replaced by dimethyl-tetramethyldiaminodiphenylmethane obtained by condensing acetone and dimethylaniline (Ber. 1878, 12, 813). About 14 kilos. of dimethyl-tetramethyldiaminodiphenylmethane are mixed with 120 kilos. of salt, 6 kilos. of sulphur, and 7 kilos. of ammonium chloride, and a stream of ammonia gas is passed through the mixture for eight hours at 175°. The mass is first washed with cold water to dissolve away the salt and ammonium chloride, it is then dissolved in water at 70°, filtered, and the dye salted out, pressed, and dried. Auramine is also prepared by heating dimethylaminobenzamide and dimethylaniline with zinc chloride at 160°–200° (D. R. P. 77329).

(4) Guyot (Compt. rend. 1907, 144, 1219; J. Soc. Chem. Ind. 1908, 679) has synthesised auramines by means of the oxalic esters.

Tetraalkyldiaminodiphenylglycollic esters (J. Soc. Chem. Ind. 1907, 603) form neutral salts with acids, the indigo-blue aqueous solutions of which react with ammonia even when dilute to furnish tetraalkyldiaminodiphenylamino acetic esters, according to the equation:

$$(R_2N{\cdot}C_6H_4)_2CCl{\cdot}CO_2R'+2NH_3$$
$$=NH_4Cl+(R_2N{\cdot}C_6H_4)_2C(NH_2)CO_2R'.$$

These new compounds are *exo*-carboxylic derivatives of the leucauramines, and possess all the properties of the latter. They dissolve in glacial acetic acid with an intense blue colouration, and condense with aromatic tertiary amines to form triphenylmethane derivatives. Thus ethylhexamethyltriaminotriphenyl acetate is produced by heating an equimolecular mixture of dimethylaniline and ethyltetramethyldiaminodiphenylaminoacetate in glacial acetic acid on the water-bath for some minutes:

$$(Me_2N{\cdot}C_6H_4)_2C(CO_2Et){\cdot}NH_2+C_6H_5{\cdot}NMe_2$$
$$=(Me_2N{\cdot}C_6H_4)_2C(CO_2Et)C_6H_4NMe_2+NH_3.$$

When a dilute alkaline solution of the aminoacetic ester is oxidised with dilute potassium ferricyanide solution in the cold, a quantitative yield of the corresponding auramine is produced.

Properties.—Auramine crystallises from water in yellow scales, which seem to consist of six-sided tables, and from alcohol in golden-yellow scales, melts at 267° (Graebe), carbonises at 265°–280° without previous fusion (Fehrmann), and is sparingly soluble in cold but readily soluble in hot water; the temperature of the aqueous solution, however, must not exceed 60°–70°, otherwise decomposition ensues, with the formation of ammonia and tetramethyldiaminobenzophenone. On treatment with mineral acids, the aqueous solution undergoes a similar decomposition either slowly in the cold or very rapidly on heating. Spectroscopically, auramine behaves like most yellow dyes; a hot concentrated aqueous solution, however, shows two bands, one in the red and one in the green, which become broader on dilution and finally coalesce, forming a bright broad band extending from the middle of the red to the commencement of the green (Graebe). On treatment in the cold with ammonia, auramine (crystallised from alcohol) is converted into the colourless base $C_{17}H_{21}N_3$, which melts at 136°, and is characterised by yielding with acids intensely yellow, and for the most part crystalline salts, which dissolve in water and alcohol without fluorescence. Alkaline reducing agents, such as sodium amalgam, slowly decolourise the alcoholic solution of auramine, forming *leucauramine* $C_{17}H_{23}N_3$, a colourless crystalline reduction compound melting at 135°, which dissolves in acetic acid with an intense blue colour owing to its decomposition into ammonia and tetramethyldiaminobenzhydrol.

Auramine dyes wool and silk direct, producing colours which are pure yellow and fairly fast to light and soap. Cotton, for which the dye is chiefly used, requires to be first mordanted with tannin and tartar emetic, and on this account auramine is useful for producing compound shades with other basic colouring matters, such as safranine, benzaldehyde-green, &c., which are fixed by the same mordant. (For further information *v.* Köchlin, Wagner's Jahr. 1884, 1139.)

Salts. *Auramine hydrochloride* $C_{17}H_{21}N_3$, HCl, is sparingly soluble in water, and has μ_∞ 90·4 at 25°; the *palmitate* $C_{17}H_{21}N_3,C_{16}H_{32}O_2$, has m.p. 57°, the *stearate* has m.p. 68° (Gnehm, Röteli Zeit. Angew. Chem. 1898, 487); the *methyl sulphate* obtained by the action of dimethyl sulphate on auramine, has m.p. 225° (Zohlen, J. pr. Chem. 1902, 66, [20] 387).

Substituted Auramines. In addition to auramine, substituted auramines have also been prepared. **Auramine G**, obtained by treating a hot mixture of *sym*-dimethyldiamino-di-*o*-tolylmethane (from methyl *o*-toluidine and formaldehyde) sulphur, ammonium chloride and salt with dry ammonia gas (Gnehm and Wright, U.S. Pat. 488430), has m.p. 120°, the *picrate* has m.p. 234°, the *sulphate* m.p. 182°, the *oxalate* m.p. 210°. *Leucauramine G* has m.p. 208°.

Metaxylylauramine can be obtained by heating an intimate mixture of 10 kilos. of tetramethyldiaminobenzophenone and 23 kilos. of metaxylidine hydrochloride for about 4 hours at 200° in an enamelled vessel provided with a mechanical stirrer. Fusion takes place slowly, and the mass becomes reddish yellow in colour, assuming finally a greenish metallic lustre towards the close of the reaction, which is complete when a test specimen is almost entirely soluble in water. The cooled mass is extracted with hot water, and the dye precipitated in orange-yellow flocks by addition of sodium nitrate to the filtered solution.

Methylauramine $MeN:C(C_6H_4{\cdot}NMe_2)_2$, m.p. 133° (Zohlen, J. pr. Chem. 1902, 66, 387), the *hydrochloride* $C_{18}H_{24}N_3Cl$, has m.p. 225°, the *platinichloride* $(C_{18}H_{24}N_3Cl)_2PtCl_6$, m.p. 190°–200°, the *hydrobromide* $C_{18}H_{24}N_3Br$, m.p. 260°, the *hydriodide* $C_{18}H_{24}N_3I$, m.p. 259°, forms a series of unstable polyiodides: the *trichromate* $(C_{18}H_{24}N_3)_2Cr_3O_{10}$, m.p. 70°, the *thiocyanate* $C_{18}H_{24}N_3CNS$, m.p. 213°–214°, and the *picrate* $C_{18}H_{23}N_3,C_6H_3O_7N_3$, m.p. 225°.

Ethylauramine $EtN:C(C_6H_4{\cdot}NMe_2)_2$, from auramine ethyl iodide and zinc oxide (D. R. P. 136616), m.p. 130°–131°, dyes mordanted cotton a pure yellow.

Phenylauramine $PhN:C(C_6H_4{\cdot}NMe_2)_2$, prepared by heating tetramethyldiaminodiphenylmethane with aniline and sulphur at 200° (Feer, D. R. P. 53614); or by heating dimethylaminobenzanilide with dimethylaniline and phosphorus oxychloride (D. R. P. 44077); has m.p. 172°; the *hydriodide* $C_{23}H_{25}N_3,HI$, has m.p. 242°; the *methiodide* $C_{23}H_{25}N_3,MeI$, has m.p. 214°.

Paraminophenylauramine $NH_2{\cdot}C_6H_4N:C(C_6H_4{\cdot}NMe_2)_2$ (Finckh and Schwimmer, J. pr. Chem. 1894, 50, 401), has m.p. 221°–222°; the *hydrochloride*, m.p. 224°; the *picrate*, m.p. 185°–186° (corr.); the *diacetyl* derivative has m.p. 194°–195°; the *triacetyl* derivative has m.p. 257°–258°; *monobenzoyl* derivative has m.p. 117°; and the *dibenzoyl* derivative has m.p. 180°–181°; *paraphenylenediauramine* $C_6H_4[N:C(C_6H_4{\cdot}NMe_2)_2]_2$, has m.p. 311°–312°.

Orthaminophenylauramine, m.p. 199°–200°, forms a *picrate*, m.p. 220°–221°, and a *benzoyl* derivative, m.p. 236°–237°; *orthophenylenediauramine* has m.p. 305°.

***p*-Tolylauramine**, obtained by heating tetramethyldiaminodiphenylmethane with *p*-toluidine and sulphur (D. R. P. 53614), or from dimethylaminobenzo-*p*-toluidine, dimethylaniline, and phosphorus oxychloride (D. R 44077), has m.p. 178°. **o-Tolylauramine** similarly prepared to the *p*- compound has m.p. 173°–174°, **α-naphthylauramine** $(Me_2N{\cdot}C_6H_4)_2C:NC_{10}H_7$ (D. R. P. 44077), has m.p 225°. **β-naphthylauramine** $(Me_2N{\cdot}C_6H_4)_2C:NC_{10}H_7$ (D. R. P. 44077), m.p. 179°–180°. **Benzylauramine** $C_6H_5{\cdot}CH_2{\cdot}N:C(C_6H_4{\cdot}NMe_2)_2$ (D. R. P. 136616) from auramine benzylchloride and magnesia, has m.p. 116°. **Benzoylauramine** (Fmekh and Schwimmer, J. pr. Chem. 1894, 50, 401) $NBz:C(C_6H_4{\cdot}NMe_2)_2$, has m.p. 179° (corr.).

Methylphenylauramine hydrochloride, *dephenylauramine*, and *pentamethyleneauramine* have been described by Stock (Ber. 1900, 33, 318; J. pr. Chem. 47, 401–413). The following compounds, closely related to the naphthylauramines, form the subject of a patent (D. R. P. 44077): *tetraethyldiaminodiphenylmethylene-α-naphthylamine* $(Et_2N{\cdot}C_6H_4)_2C:N{\cdot}C_{10}H_7$, m.p. 157°–158°; *dimethyldiethyldiaminodiphenylmethylene-α-naphthylamine* $(Me_2N{\cdot}C_6H_4)(Et_2N{\cdot}C_6H_4)C:N{\cdot}C_{10}H_7$, m.p. 177°–178°; *tetraethyldiaminodiphenylmethylene-β-naphthylamine* $(Et_2N{\cdot}C_6H_4)_2C:N{\cdot}C_{10}H_7$, m.p. 155°; *dimethyldiethyldiaminodiphenylmethylene-β-naphthylamine* $(Me_2N{\cdot}C_6H_4)(Et_2N{\cdot}C_6H_4)C:N{\cdot}C_{10}H_7$, m.p. 163°–164°.

The substituted auramines dye silk and wool, and also cotton after mordanting with tannin. The shades produced on cotton are, however, distinctly reddish or brownish-yellow compared with the pure yellow produced by auramine itself; for example, the auramines from orthotoluidine, metaxylidine and cumidine hydrochlorides dye cotton golden-yellow; those from aniline and paratoluidine dye orange-red, that from metaphenylenediamine dyes orange-brown, and those from α- and β-naphthylamine dye brownish-yellow shades (B. A. S. F., D. R. P. 29060; Fehrmann, Ber. 20, 2852).

AURANTIA (*Kaisergelb*) is the commercial name of the ammonium salt of hexanitrodiphenylamine.

Hexanitrodiphenylamine $NH[C_6H_2(NO_2)_3]_2$ is obtained by treating diphenylamine or methyldiphenylamine with nitric acid, and, after the first vigorous action has subsided, heating to complete the reaction. The product is then extracted with water to remove any resin or picric acid associated with it, and finally crystallised from acetic acid.

It forms bright-yellow prisms, melts at 238° with decomposition, but can be sublimed in yellow needles by careful heating, and is almost insoluble in water, more soluble in alcohol, and easily soluble in ether. It readily yields salts, and the *ammonium* salt (aurantia) crystallises in lustrous brown-red needles, although commercially it is obtained as a brick-red powder which dissolves in water and dyes silk and wool a beautiful orange colour (Gnehm, Ber. 7, 1399; 9, 1245; *cf.* Townsend, Ber. 7, 1249; Mertens, Ber. 11, 845). Aurantia is used chiefly as a dye for leather (W. J. 1877, 1002). Like hexanitrodiphenylamine, it is very explosive, but any danger may be avoided by moistening it with glycerol (W. J. 1876, 996). According to Gnehm (Ber. 9, 1246, 1557) and Bayer & Co. (W. J. 1877, 879), aurantia produces skin eruptions; Martius, however, contends that this effect is due to idiosyncrasy, and quotes the opinions of Salkowski and Ziureck in support of his statement (Ber. 9, 1247), and the question appears to have received a solution in this sense in Germany, since the ministerial order of November 8, 1877, prohibiting its manufacture, was cancelled in June, 1880

AURIN and **ROSOLIC ACID** *v.* TRIPHENYLMETHANE COLOURING MATTERS.

AUROCANTAN. Cantharidylethylenediamine aurocyanide.

AUROCHIN. Quinine *p*-aminobenzoate.

AURUM MUSIVUM or **MOSAICUM** *Mosaic gold*. Made by triturating an amalgam of 2 parts tin and 1 of mercury with 1 part sal ammoniac and 1 of sulphur, and subsequently subliming. Used as a bronzing powder for plaster figures (*v.* BRONZE POWDERS).

AUSTENITE. A solid solution of carbon in iron, of variable composition; is a constant constituent of steels containing 1·1 p.c. of carbon or more when cooled rapidly from a temperature of 1100°-1500°. It may be obtained pure by quenching a steel containing 0·93 p.c. carbon and 1·67 p.c. manganese from 1050° in ice-water (Maurer, Métallurgie, 1909, 6, 33). Steels containing 13 p.c. of manganese or 25 p.c. of nickel contain only austenite, and are soft and non-magnetic.

Under the microscope austenite is recognised by its softness as compared with '*martensite*,' with which it is usually associated; by its structureless appearance and by the brightness of an etched, polished section (Le Chatelier, Revue de Métallurgie, 1904)

AUSTRALENE *v.* TURPENTINE.

AUSTRIAN CINNABAR. *Basic lead chromate* (*v.* CHROMIUM).

AUTAN A mixture of solid (polymerised) formaldehyde and the dioxides of barium or strontium, used in the disinfection of living-rooms. On mixing the powder with water, a rapid disengagement of formaldehyde vapour, mixed with oxygen, occurs

AUTOCLAVE An apparatus constructed on the principle of Papin's digester, for heating liquids at temperatures above their boiling points Autoclaves are usually made of cast iron or steel, occasionally of copper, and in some cases of sheet-iron or steel. Cast iron autoclaves are sometimes strapped with steel rings for [illegible] tin, lead, copper, or zinc. Metallic linings are now soldered readily to the [illegible] autoclave. Th[illegible] with a pressure gauge and safety valve, and tubes for the insertion of thermom[illegible] are usu[illegible] by a scr[illegible] cover, working against a wa[illegible] aluminium or copper, and are [illegible] by steam, direct fire, electrical heaters, the circulation of hot oil, or in a bath of molten lead. They are tested before use at (at least) twice their working pressure by means of a hydraulic test pump Occasionally they are provided with agitators working through stuffing [illegible] to

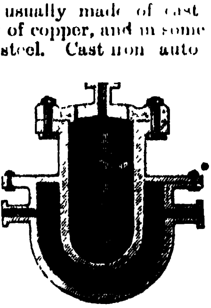

FIG. 1.

ensure thorough mixing of the contents when heated.

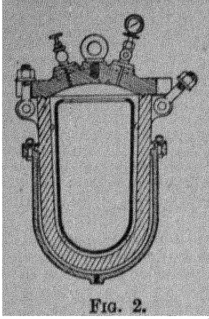

FIG. 2.

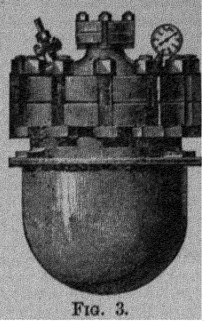

FIG. 3.

Figs 1, 2 and 3 illustrate the types of apparatus for pressures of 20 or 30 atmospheres, but when very high pressures are employed (100 atmos. or more) a tubular design, Fig. 4, is more satisfactory both in cost and ease of manipulation. Autoclaves working at about 10 atmos. are usually of rivetted steel plates, and follow ordinary steam boiler practice. Welding is not as reliable as rivetting, and must always be viewed with suspicion in this class of plant. It is obvious that the ordinary safe working stresses adopted by mechanical engineers are not suitable for designing autoclaves.

Considerations relating to the effect of temperature and chemical action may arise. In the case of cast metal autoclaves the greatest care in design, in selecting the material, and in casting to minimise internal stresses must be taken. When treating liquids, suitable pipes for admission and discharge may make it unnecessary to remove the cover under ordinary circumstances, but when solid substances are charged, the mechanical problem of repeatedly making a tight joint presents itself. Extension of the cover bolts under stress and heat must be considered to avoid leakage under the worst working conditions.

The joint is usually made by means of a tongue in the cover pressing on a soft metal ring in a groove made in the flange of the body. A broad surface is unsuitable and in the case of a copper ring, a bearing area not more than one-eighth inch wide is usually satisfactory at all pressures. Such a joint may be remade hundreds of times without failure. On account of its high elastic limit, nickel steel is the most suitable material for both bodies and bolts of high-pressure autoclaves, and by the use of suitable protective linings can generally be adapted for any chemical process.

When a loose container, as shown in Fig. 2, is employed, the space between the body and the container should be filled with a liquid (paraffin wax is generally most suitable) to improve the rate of heat transference.

J. W. H.

AUTOLYSIS. A physiological term signifying self-destruction, and used to indicate the destructive changes (apart from putrefaction due to micro-organisms) which occur in cells after death or removal from the living body. These changes are due to the action of intra-cellular [illegible] are analagous to those which occur in digestion; indeed the term auto-digestion is sometimes employed. The study of such changes is important be[illegible]lieved that [illegible] after death, w[illegible]ls are still [illegible] a time, a[illegible] with those which occur during life and result in the formation of waste substances, the products of vital activity. During life, however, the destructive changes are counterbalanced by changes in the opposite direction by which the cells build themselves up from food materials to repair their wear and tear. Assimilation of this kind is obviously impossible after death.

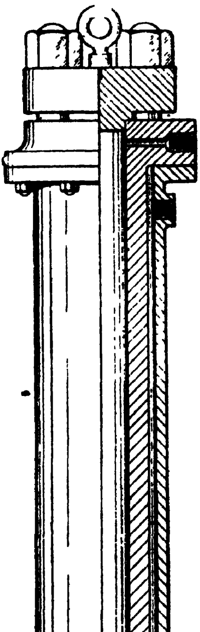

FIG. 4.

AUTUNITE or CALCO-URANITE. A mineral consisting of hydrated phosphate of uranium and calcium $Ca(UO_2)_2P_2O_8 \cdot 8H_2O$, which within recent years has been somewhat extensively mined as an ore of uranium and radium. It is a member of the isomorphous group of minerals known as the 'uranium micas,' which crystallise in square, tetragonal (or very nearly square, orthorhombic) plates with a perfect micaceous and pearly cleavage parallel to their surface. In the orthorhombic autunite the colour is characteristically sulphur-yellow, or sometimes with a greenish tinge, so that this mineral is readily distinguished from the emerald-green torbernite or cupro-uranite. Sp.gr. 3·1; H. 2–2½. It occurs as an alteration product of pitchblende, and is often found as a scaly encrustation on the joint-planes of weathered granite or gneiss. The more important localities are St. Symphorien, near Autun in France (hence the name autunite); St. Just, Redruth, and Grampound Road in Cornwall; Johanngeorgenstadt and Falkenstein in Saxony; Black Hills in South Dakota; Olary and Mount Painter in South Australia; and Sabugal, near Guarda in Portugal. At the last-named locality several mines have recently been opened up; the crude ore is here leached with sulphuric acid, and the extracts sent to Paris for further treatment. L. J. S.

AUXOCHROME *v.* COLOUR and CHEMICAL CONSTITUTION.

AVA or *Kava-kava.* The root of *Piper methysticum* (Forst, f.), growing in the islands of the Pacific. It is taken as an intoxicant by the natives, and is used as a drug on the Continent. It is often adulterated with matico and annatto (Pharm. J. [3] 7, 149).

AVENTURINE or **AVANTURINE.** A variety of quartz found at Capa de Gata, Spain, spangled throughout with minute yellow scales of mica, is known as aventurine quartz. An aventurine felspar or sunstone is found at Tvedestrand, Norway. It is used for ornaments.

Artificial aventurine, or *glass,* or *gold flux,* was manufactured for a long period at the glass-works of Murano, near Venice. It may be prepared by adding to 100 parts of a not too refractory glass, 8 to 10 parts of a mixture of equal parts of ferrous and cuprous oxides, and allowing the mixture to cool very slowly so as to facilitate the formation of crystals.

Aventurine glaze for porcelain, invented by Wöhler (Annalen, 70, 57), is prepared by finely grinding 31 parts Halle kaolin, 43 quartz sand, 14 gypsum, and 12 porcelain fragments; making the whole into a paste with 300 parts water, and adding successively 19 parts potassium dichromate, 47 lead acetate, 100 ferrous sulphate, and sufficient ammonia to precipitate the whole of the iron. After the soluble potash and ammonium salts have been washed out, the glazing is ready for use.

AVIGNON GRAINS. The seeds of *Rhamnus infectorius,* employed in dyeing for the production of yellow colours (*v. Rhamnin,* art. XANTHORHAMNIN).

AVOCADO PEAR or **ALLIGATOR PEAR.** The fruit of *Persea gratissima,* a tropical product. The fruit, which usually weighs from 4 to 6 oz., consists of rind (about 8 p.c.), flesh (67 p c.), and a large 'stone' or 'pit' (about 25 p.c.). According to Prinsen-Geerlings (Chem. Zeit. 1897, 21, 715), the flesh contains:

Glucose	Fructose	Saccharose	Total sugar
0·40	0·46	0·86	1·72

The flesh, which has a nut-like flavour, is usually eaten with pepper and salt. An analysis, made by Jamieson (Chem. News, 1910, 102, 61), gave:

Water	Ether extract	Protein	Sugar	Fibre	Ash
66·9	10·6	5·7	1·1	4·0	2·0

The ether extract was green, and contained about 4 p.c. of resins. After their removal, an oil, resembling that of bergamot, was obtained, which had an iodine value of 29·9, and saponification value of 207. La Forge (J. Biol. Chem. 1916, 24) found that the sugar present in the pulp of the ripe fruit could be extracted with water and crystallises from dilute alcohol in hexagonal prisms, m.p. 152°. It is non-fermentable and not oxidised by bromine, and is probably mannoketoheptose. H. I.

AVOCADO PEAR, OIL OF. An oil obtained from the oleaginous fruit of the *Persea gratissima.* Hofmann stated that for the purposes of the soapmaker this oil would be as valuable as palm oil.

AWAL or *Tarwar.* An Indian drug, the bark of *Cassia auriculata* (Linn.) (Dymock, Pharm. J. [3] 7, 977).

AWLA *v.* AMLAKI.

AXIN. A waxy secretion of a Mexican rhynchotrous insect *Llaveia axinus* which feeds on *Spondias lutea, Xanthoxylum Clava-herculis,* and *X. pentanome:* has the consistence of butter, the smell of rancid fat, and a yellow colour. Melts at 35°, and is soluble in hot alcohol and ether. Rapidly absorbs oxygen from the air, becoming brown, hard and insoluble in alcohol and ether. Is readily saponified, yielding *axinic acid* and glycerol. It resembles Japan lac and forms an excellent lacquer for wood, metals, and pottery (Bocquillon, J. Pharm. Chim. 1910, 2, 406; J. Soc. Chem. Ind. 29, 1320).

AXINITE. A complex borosilicate of aluminium, calcium, iron and manganese. Various formulæ have been proposed: W. E. Ford (1903) gives $R''_7R'''_4B_2(SiO_4)_8$, where R''=Ca, Fe, Mn, Mg, H_2, and R'''=Al, Fe. According to W. T. Schaller (1909) the composition is expressed as isomorphous mixtures of 'ferro-axinite' $4CaO{\cdot}2FeO{\cdot}2Al_2O_3{\cdot}B_2O_3{\cdot}8SiO_2{\cdot}H_2O$, and 'manganaxinite' $4CaO{\cdot}2MnO{\cdot}2Al_2O_3{\cdot}B_2O_3{\cdot}8SiO_2{\cdot}H_2O$. The mineral contains 5–6 p.c. B_2O_3. Crystals are triclinic with a characteristic axe-shaped habit, hence the name. The colour is usually clove brown, but may be yellowish or greenish. D 3·03–3·36, H 6½–7. Axinite occurs in crystalline schists and metamorphic rocks at many localities. Fine crystals, suitable for cutting as gem-stones, are not uncommon from Bourg d'Oisans, Isère, France, and large groups of crystals come from Japan. In the metamorphic rocks surrounding the granite mass of Bodmin, in Cornwall, massive axinite and axinite-rock are of abundant occurrence (G. Barrow, Mineralog. Mag. 1908, xv. 113; Geology of Bodmin and St. Austell, Mem. Geol. Survey, 1909).

Tourmaline (*q.v.*), another complex borosilicate containing rather more boron (B_2O_3 9–11 p.c.), is also of common occurrence under the same conditions in Cornwall. It is possible that these occurrences may be of use as a source of boron. L. J. S.

AZADIRACHTA, *Margosa,* or *Nim.* The bark of the nim tree, *Melia indica* (Brandis) [*M. Azadirachta*], is commonly used in India as a tonic and febrifuge. It contains a bitter resin. An oil, used in medicine and for burning is expressed from the seeds, which on saponification yielded 35 p.c. of fatty acid melting at 30°, and 65 p.c. melting at 44°.

AZAFRAN or **AZAFRANILLO.** The root of a plant obtained from Paraguay, belonging to the family of the *Scrophulariaceæ,* used to colour fats. Contains about 1 p.c. of a dye (*azafrin*) easily extracted by boiling benzene. Forms orange-red crusts of microscopic needles, m.p. 214°. Does not contain nitrogen or methoxy- or ethoxy- groups; one hydroxyl group is shown by Zerewitinoff's method. Dyes wool yellow, and forms yellow to orange lakes with Scheurer's mordants; wool extracts the whole of the dye from a hyposulphite vat. Gives a fine blue solution in concentrated sulphuric acid, which becomes violet on adding alcohol (Liebermann, Ber. 1911, 44, 850). It is not identical with bixin, as conjectured by van Hasselt, in spite of the similarity in their reactions. The acid reactions of azafrin afford a good example of halochromism. Methyl-azafrin, obtained by the action of dimethyl-sulphate, gives a series of salts parallel with those of the parent substance (Liebermann and Schiller, Ber. 1913, 46, 1973).

AZELAIC ACID. *Lepargylic acid.* $CO_2H\cdot(CH_2)_7\cdot CO_2H$. It is obtained by oxidising Chinese wax (Buckton, J. 1857, 303), cocoanut oil (Wirz, Annalen, 104, 261), or castor oil (Arppe, Annalen, 124, 86) with nitric acid; by the oxidation of oleic acid with potassium permanganate and caustic potash (Ehmed, Chem. Soc. Trans. 1898, 627), and by the oxidation of keratin (horn shavings) with permanganate (Lissizin, Zeitsch. physiol. Chem. 1909, 226). It is formed together with other products when fats or oleic acid become rancid (Scala, Chem. Zentr. 1898, i. 439). It has been synthesised from pentamethylene bromide and sodium acetoacetate (Haworth and Perkin, Chem. Soc. Trans. 1894, 86), and has been obtained by decomposing the ozonide of oleic acid (Molinari and Soncini, Ber. 1906, 2735; Harries and Thieme, *ibid.* 1906, 2844; Molinari and Fenaroli, *ibid.* 1908, 2789). It is best prepared by oxidising with potassium permanganate an alkaline solution of ricinoleic acid obtained by the hydrolysis of castor oil (Maquenne, Bull. Soc. chim. 1899, (iii.) 21, 106; Hazura and Grüssner, Monatsh. 9, 475). Azelaic acid crystallises in colourless plates, m.p. 106·2° (Massol, Bull. Soc. chim. [3] 19, 301), and is readily soluble in alcohol, less soluble in water or ether. By heating azelaic acid with soda lime, *azelaone* (*cyclononanone*) $C_8H_{14}O$, b.p. 205° (*circa*), is obtained (Miller and Tschitschkin, Chem. Zentr. 1899, ii. 181); Harris and Tank (Ber. 1907, 4555) have shown that a complex mixture of cycloketones is obtained by distilling the calcium salt of azelaic acid. *Azelaic anhydride* is obtained by heating azelaic acid with 7–8 pts. of acetyl chloride. It melts at 56°–57° (Étaix, Ann. Chim. Phys. [7] 9, 399).

AZELAONE *v.* AZELAIC ACID.

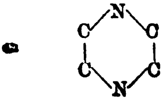
AZIDINE BLACK, -BLUE, -BORDEAUX, -BROWN, -FAST RED, -FAST SCARLET, -GREEN, -ORANGE, -PURPURINE, -YELLOW, -VIOLET, -WOOL BLUE *v.* AZO- COLOURING MATTERS.

AZIMINOBENZENE *v.* DIAZO COMPOUNDS.

AZIMINONAPHTHALENES *v.* DIAZO COMPOUNDS.

AZINES (Quinoxalines). Azonium bases, and colouring matters derived from them.

Definition.—The term 'azines' has been given to a group of organic bases, which contain in their molecule as an intrinsic part of their constitution a heterocyclic hexagonal ring, built up of four carbon and two nitrogen atoms, arranged in such a manner that the nitrogen atoms stand in para-position to each other, whilst the four carbon atoms are disposed in two pairs between them, thus:



The term 'azine,' first proposed by Merz, is not happily chosen, and is even misleading, as it enters into the names of other nitrogen compounds of a different constitution, such as the hydrazines.

The name 'quinoxaline' was given by Hinsberg to compounds which also correspond with the above definition. It was, therefore, considered for some time as synonymous with the word 'azine,' which latter was, however, more frequently used. In later years it has become customary to distinguish between the two terms, and to use them for the two tautomeric forms in which these bases occur (*see Theory*).

The name 'azonium bases' has been given by Witt to a class of organic bases, derived from the azines by the linking of an organic radicle to one of the nitrogen atoms, whereby this atom passes from the trivalent into the pentavalent state, a process which results in a very marked change of the properties of the substance.

Both the azines and azonium bases possess the nature of powerful chromogens, the heterocyclic ring above mentioned being endowed with strong chromophoric properties. Being highly basic and capable of assuming a quinonoid structure (*see Theory*), they, and especially the azonium bases, possess to some extent the nature of dyestuffs, which is, however, much more strongly developed by the introduction of separate auxochromic groups. A very large number of powerful colouring matters of great intensity, variation, and purity of shade may thus be obtained, some of which have acquired considerable practical importance. According to their constitution, which is in almost all cases completely cleared up, they have been classified into groups, which have received the names **eurhodines**, **eurhodols**, **safranines**, **safranols**, **aposafranines**, **indulines**, and **fluorindines**.

The investigation of the azines and their derivatives, which was accomplished by a number of chemists during the last 20 years of the nineteenth century, has been of considerable importance in the development of our present views on the constitution of colouring matters, and especially in the adoption of the modern quinonoid structural formulæ for the great majority of them.

History.—The two simplest and most typical members of the azine group, diphenazine and dinaphtazine, have been known for many years as 'azophenylene' (Claus and Rasenack, 1873; Annalen, 168, 1) and 'naphtase' (Laurent, 1835; Ann. Chim. Phys. 59, 384), but their constitution was not properly understood and their importance not recognised. Merz (1886, Ber. 19, 725) finally proved the constitution of the former, which had been insufficiently substantiated by Claus, and proposed for it the name diphenazine; Witt (1886, Ber. 19, 2791) determined the true nature of 'naphtase.' In 1884 Hinsberg (Ber. 17, 319) described a general method for preparing his quinoxalines, which proved most fruitful in the further development of the subject. Other general methods were discovered by Witt, Merz, Japp, Ullmann, and others.

The first eurhodines were prepared by Witt in 1879 and 1885. He recognised that they formed a new class of dyestuffs, and also that they were related to the safranines. He determined their constitution in 1886 (Ber. 19, 441) by showing that they are the amino- derivatives of the azines or quinoxalines. At the same time he discovered the first eurhodol. The natural consequence of this discovery was the clearing up of the nature of the safranines, which were recognised in the same year simultaneously and independently by Witt, Nietzki, and Bernthsen as diamino- derivatives of the (then hypothetical) azonium bases. The first representative of this new class of bases was prepared in 1887 by Witt (Ber. 20, 1183).

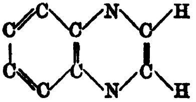
The subject was now taken up and rapidly advanced by many chemists, amongst whom Nietzki and his collaborators, Kehrmann, Ullmann, and their collaborators, may be cited. Otto Fischer and Hepp also did a considerable amount of work in this domain, and especially in the investigation of the indulines and aposafranines.

The typical indulines and safranines have been discovered by purely empirical methods in the early days of the colour industry. The simplest representative of the group, *phenosafranine*, was prepared by Witt in 1877. Its phenylated derivative is *mauveïne*, the first artificial dyestuff prepared by W. H. Perkin in 1856.

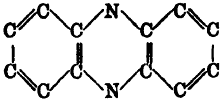
Theory.—It has been already stated that the essential part of the molecule of an azine is the heterocyclic ring consisting of two atoms of nitrogen and four of carbon. Each of these six atoms has three valencies engaged in the formation of the ring; the nitrogen atoms have, therefore, no free valencies left (so long as they remain in the trivalent condition), whilst each of the carbon atoms has one valency free to be saturated by hydrogen or another monovalent element or radicle. The simplest possible compound of the kind would thus have the formula $C_4N_2H_4$. It seems natural to suppose that it would be the prototype of all the azines.

Such a compound exists and is well known. It has received the name *pyrazine*. Many derivatives of it, formed by the substitution of its hydrogen atoms by monovalent organic radicles are also known; they form the large and well-investigated class of the ketine or aldine bases. But neither pyrazine itself (which in its properties resembles pyridine, to which it stands in the same relation as pyridine stands to benzene) nor the ketines show any resemblance to the typical azines. They exhibit no colourations, nor do they form any derivatives which have the nature of dyestuffs. For this reason pyrazine and the ketines are no longer considered as belonging to the azine group.

The characteristic properties of the azines only appear in compounds in which at least one other ring system is linked to the pyrazine ring, in such manner that one of the C_2-groups of the latter becomes part of an aromatic radicle. The process may be repeated. Thus the simplest representatives of the azine group would be compounds of the following type :—



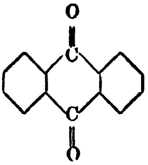
Phenazine.



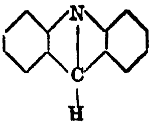
Diphenazine.

The nomenclature of the true azines has been chosen accordingly. The aromatic radicle or radicles linked to the central (or 'meso-') ring are prefixed to the syllables -azine.

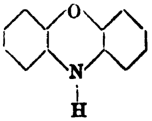
The azines are members of the aromatic series. If we consider them as such, we recognise at once a strong analogy to other substances which contain heterocyclic rings linked to aromatic radicles, such as:



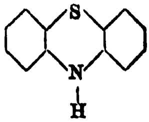
Anthraquinone.



Acridine.



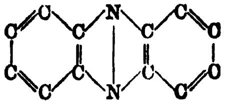
Oxazine.



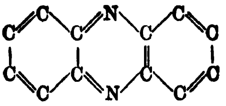
Thiazine.

all of which are chromogens, like the azines.

If we consider the manner in which the six atomicities of the two nitrogen atoms contained in the meso- ring of an azine may be disposed, we recognise two possibilities which are represented in the following structural formulæ of diphenazine :—



I.



II.

Formula I. is the one first proposed by Claus for his 'azophenylene,' and by Merz for his azines; II., the one suggested by Hinsberg for his quinoxalines. Practically, there is no difference between azines and quinoxalines; they form one group; but it has been for a long time a matter of opinion which of the above formulæ was more adapted to the properties of these substances. Formula I. explains by its perfect symmetry the extreme stability of the azines, the fact that they may all be distilled without the slightest decomposition at extremely high temperatures. Formula II., on the other hand, is distinctly (ortho-) quinonoid, and consequently suggestive of chromogenic properties.

The existing difference of opinion as to the constitution of the azines has been finally disposed of by the admission that the azines are undoubtedly tautomeric, capable of assuming either of the constitutions I. and II., according to circumstances. In their free state, in which they are volatile and almost colourless, they possess the symmetrical (azine) constitution I., whereas in their intensely coloured salts they have more probably the asymmetrical, quinonoid (quinoxaline-) constitution II. In the colouring matters derived from the azines, the case is frequently complicated by the fact that the auxochromic groups participate in the formation of the quinonoid constitution, which, by that means, may become *para*- as well as *ortho*-quinoid. Sometimes it is difficult to decide between the existing possibilities.

Synthetical methods for the production of azines, and their derivatives and description of some typical representatives of the group.

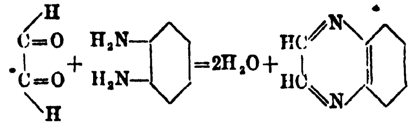
I. **Azines.** (*a*) *Synthetical methods.* (These will be referred to in the description of typical representatives by their number.)

1. By heating α-nitronaphthalene with powdered quicklime, Laurent (Ann. Chim. Phys. 59, 384) obtained dinaphthazine, which he called naphthase. Doer (Ber. 3, 291) and Klobukowski (Ber. 10, 573) modified the method by replacing the quicklime by zinc-dust. Schichuzky (J. R. 6, 2464) used lead oxide.

Wohl and Aue (Ber. 34, 2443) observed (1901) that nitrobenzene gives considerable quantities of diphenazine on being heated with strong caustic soda, a reaction which is practically identical with the one discovered by Laurent.

2. Claus and Rasenack (Annalen, 168, 1) obtained 'azophenylene' (diphenazine) by the dry distillation of orthoazobenzoic acid in the shape of its calcium or potassium salt. Claus proposed the azine formula for his product, but failed to afford convincing proofs for it.

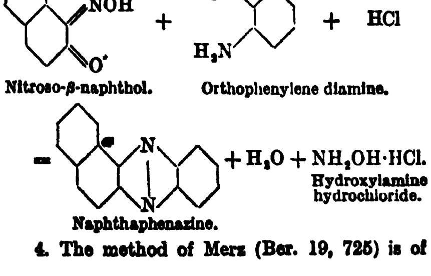
3. A general method of great applicability was indicated by Hinsberg (Ber. 17, 319; 18, 1228), who showed that whenever an *alpha*- or *ortho*-diketone reacts on an aromatic orthodiamine, two molecules of water are given off and an azine is formed. The method was first applied to the production of phenazine:



Glyoxal. *o*-Phenylenediamine. Phenazine (quinoxaline).

It works in most cases so well, that it has been recommended by its author (Annalen, 273, 343, 371) as the best method of identifying either an orthodiamine or an orthodiketone. Very small quantities of the ingredients are necessary, and the azine formed is easily recognised by its melting-point and sulphuric acid reaction.

Hinsberg's reaction may be extended to nitroso-β-naphthol, which is in reality the oxime of ortho-naphthaquinone. Ullmann and Heisler obtained (Ber. 42, 4263) naphthaphenazine by heating ortho-phenylenediamine hydrochloride with nitroso-β-naphthol:

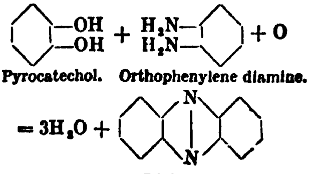


Nitroso-β-naphthol. Orthophenylene diamine.

Hydroxylamine hydrochloride.

Naphthaphenazine.

4. The method of Merz (Ber. 19, 725) is of less general application. It consists in the action of orthodihydroxyl- derivatives upon orthodiamines: the hydro- derivatives of the azines are formed, and these are oxidised by the oxygen of the air into the azines:

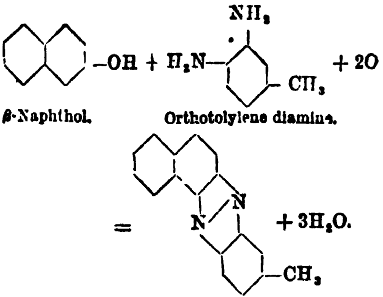


Pyrocatechol. Orthophenylene diamine.

Diphenazine.

5. Early investigators had studied the reaction of ammonia under pressure upon benzoin (Erdmann, Annalen, 135, 181) and phenanthraquinone (Sommaruga, Monatsh. 1, 146). Japp and Burton showed that the free ammonia may be advantageously replaced by ammonium acetate, and proved that the 'ditolane azotide' and 'phenanthrene azotide' obtained were tetraphenylketine and diphenanthrazine. They generalised the method and applied it to β-naphthaquinone, from which they obtained dinaphthazine (Chem. Soc. Trans. 1887, 98).

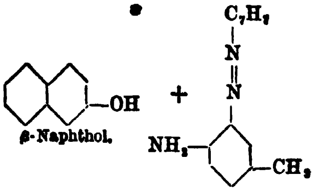
6. Another mode of formation of the azines consists in the joint oxidation of a phenol, in which the *para*- position is no longer open to substitution, and aromatic orthodiamines. This method was discovered by Witt (Ber. 19, 917), who used it for the production of a new isomeride of tolunaphthazine by oxidising a mixture of β-naphthol and orthotolylene diamine:



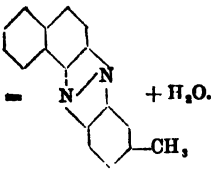
β-Naphthol. Orthotolylene diamine.

Tolunaphthazine.

7. An elegant modification of the above method was devised in 1905 by Ullmann and Ankersmit (Ber. 38, 1811), who heated β-naphthol with orthoaminoazotoluene. The latter takes up the hydrogen liberated in the reaction, yielding at the same time the necessary orthodiamine.

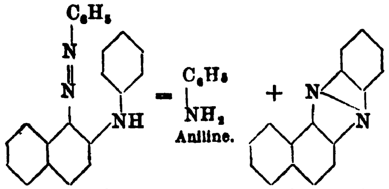


β-Naphthol. Orthoaminoazotoluene.



Tolunaphthazine.

8 A very peculiar mode of formation of these substances was discovered by Witt (Ber. 20, 571), who showed that the orthoazo- derivatives of secondary amines, and more especially of such amines containing the β-naphthyl- group, are decomposed by being heated with acids into the corresponding azine and amino- compound, thus:



Benzene-azo-phenyl-β-naphthylamine. Aniline. Naphthaphenazine.

The reaction is simple and easy, and gives, as a rule, excellent yields. It is in reality a condensation of the secondary amine into the corresponding azine by the dehydrogenating influence of the azo- group temporarily introduced for the purpose.

(*b*) *Generic characters of the azine group.* All azines have certain peculiar properties in common. As a rule, they are solid, well crystallised compounds of white, pale yellow, or even orange colour, possessing a high melting-point, and boiling under atmospheric pressure at very high temperatures (in some cases approaching red heat) practically without decomposition. They sublime at temperatures below their boiling-point, and their vapours condense into voluminous aggregates of crystals.

All the azines are bases which form salts with acids. The mono-acid salts, with the stronger mineral acids, may generally be obtained in a crystallised condition; but they are stable only in the presence of an excess of acid or in the absence of water, which easily decomposes them into their constituents. These salts are intensely coloured, a fact which justifies the inference that they contain the base in the quinonoid (quinoxaline) form. The hydrolytic action of the water is therefore accompanied by the tautomeric change into the symmetrical (azine) form. These salts, some of which have been analysed, invariably contain one equivalent of acid for one molecule of the base. The di-acid salts cannot be isolated, but evidence of their existence is given by the intense red, violet, or blue colourations exhibited by the solutions of azines in a great excess of strong acid, preferably sulphuric acid. If water be added to these solutions, a change takes place; the di-acid salt is decomposed, the yellow or orange mono-acid salt is formed, and, on further addition of a large excess of water, the free azine itself separates out in flakes. These striking colour reactions are highly characteristic, and form the best means of identifying the azines.

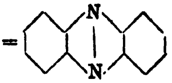
Notwithstanding these intense colourations, the azines are not applicable as dyestuffs. They are only to be considered as chromogens and suitable to produce colouring matters by the introduction of auxochromic groups into their molecules. They are thus strictly analogous to the other heterocyclic chromogens such as anthraquinone, acridine, oxazine, and thiazine.

There is, however, one group of azines to which all the rules and general characteristics given above cannot very well be applied. These are the 'Indanthrenes,' certain azines of the anthracene group, which, owing to their large molecule and very complicated constitution, possess properties quite different from all the other azines. They are intensely coloured and extremely valuable as dyestuffs if applied to the textile fibre by the 'vat process' like indigo. This peculiar mode of application brings them into close relationship with indigo, and they will therefore be treated in this work under INDIGO AND INDIGOID DYESTUFFS (*q.v.*).

(*c*) *Description of some typical representatives of the azine group.*

Diphenazine

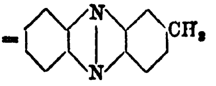
$C_{12}H_8N_2$ =



(Claus, Annalen, 168, 1; Bernthsen, Ber. 10, 3256; Ris, Ber. 19, 2206; Wohl, Ber. 34, 2443) has been obtained by the methods 1, 2, and 4. It forms pale-yellow needles, of the m.p. 170°-171°, soluble in alcohol and most other solvents. It distils without decomposition. It dissolves in strong acids, forming unstable salts of yellow and red colour.

Toluphenazine

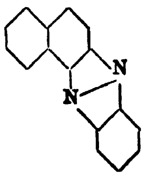
$C_{13}H_{10}N_2$ =



has been prepared by Merz (Ber. 19, 725) by th action of pyrocatechol on orthotolylenediamin (method 4). It is very similar to diphenazin Its m.p. is 117°, its b.p. 350°.

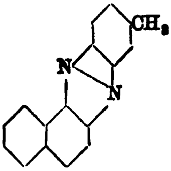
Naphthaphenazine

$C_{16}H_{10}N_2$ =

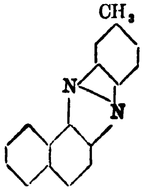


has been prepared by Witt (Ber. 20, 571). Th best mode of obtaining it is by the decomposi tion, by acid, of the azo- compounds derived fror phenyl-β-naphthylamine, but it has also bee prepared by the action of β-naphthaquinone o orthophenylenediamine and by simultaneou oxidation of the latter and β-naphthol. It form yellow needles, melting at 142·5°, distilling at high temperature without decomposition, an dissolving in sulphuric acid with a reddish-brow colouration. On dilution, two sulphates crystal lise from this solution. It is supposed that th formation of two series of monacid salts of thi base is due to either of the two nitrogen atoms becoming pentavalent and saturated with the acid.

Tolunaphthazines $C_{17}H_{12}N_2$. Three substances of this formula are known, the isomerism of which has been discussed by Witt (Ber. 20, 577). One of these, melting at 179·8° has been prepared by the simultaneous oxidation (Ber. 19, 917) of orthotolylenediamine and β-naphthol (methods 6 and 7). Its constitution is expressed by the formula



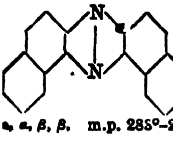
It dissolves in sulphuric acid with a violet colouration. The other is formed by the decomposition by acids of the azo- derivatives of paratolyl-β-naphthylamine (Ber. 20, 577) (method 8). Its constitution is represented by the formula



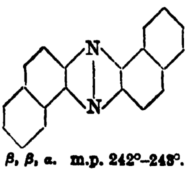
Its melting-point is 169°; its sulphuric acid reaction is similar to that of naphthaphenazine. The third tolunaphthazine, discovered by Hinsberg (Annalen, 237, 343*a*, 371) (method 3), has been proved to consist of a molecular combination of the two preceding ones; its melting-point is 139°–142°.

Several other tolunaphthazines are theoretically possible. They have not, however, hitherto been prepared.

Dinaphthazines $C_{20}H_{12}N_2$. It has already been stated that Laurent's mysterious 'naphthase,' prepared by method 1, finally proved to be dinaphthazine. It is probable that Laurent's product was a molecular combination of two of the four isomeric dinaphthazines foreseen by theory. A similar mixture may be obtained by reacting with αβ-naphthylenediamine upon β-naphthaquinone (method 2). This method was used by Witt in his identification of Laurent's 'naphthase' (Ber. 19, 2791). For preparing the constituents of this mixture in a pure state the synthetical method 8 should be resorted to; it consists in the decomposition of the azo- derivatives of the two isomeric (α, β, and ββ)-dinaphthylamines (Matthes, Ber. 23, 1329 and 1333). The compounds thus obtained have the following constitutions and melting-points:—

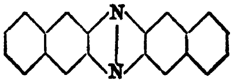


α, α, β, β. m.p. 283°–284°.

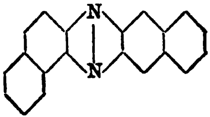


α, β, β, α. m.p. 242°–243°.

The two other possible isomerides:



β, β, β, β.

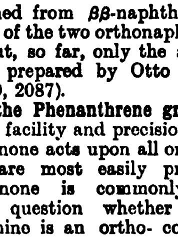


α, β, β, β. m.p. 240°

may be obtained from ββ-naphthylenediamine by the reaction of the two orthonaphthaquinones (method 2), but, so far, only the asymmetrical one has been prepared by Otto Fischer and Albert (Ber. 29, 2087).

Azines of the Phenanthrene group. Owing to the extreme facility and precision with which phenanthraquinone acts upon all orthodiamines, these azines are most easily prepared, and phenanthraquinone is commonly used for deciding the question whether any given aromatic diamine is an ortho- compound. A large number of azines has thus become known, of which only a few may be described as typical representatives of the group.

Phenanthraphenazine $C_{20}H_{12}N_2$ (isomeric with dinaphthazine) may be obtained by acting on orthophenylenediamine with either phenanthraquinone in an acetic acid solution (Hinsberg, Annalen, 237, 340), or with phenanthraquinone sodium bisulphite in an aqueous solution (method 2). It crystallises in pale-yellow needles, melting at 217°, and dissolves in sulphuric acid with a beautiful red colouration. Its constitution is



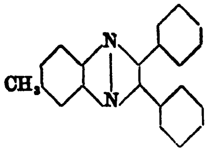
A similar substance may be obtained from orthotolylenediamine. It melts at 212°–213°.

Phenanthranaphthazine $C_{24}H_{14}N_2$ is easily obtained (Lawson, Ber. 18, 2426) from orthonaphthylenediamine and phenanthraquinone (method 2). It gives a violet colouration with sulphuric acid. M.p. 273°. The sulphonic acid derivatives of this substance, $C_{24}H_{13}N_2 \cdot SO_3H$, are obtained (Witt, Ber. 19, 1719; 21, 3485 *seq.*) by acting with an aqueous solution of phenanthraquinone sodium bisulphite upon the solutions of the various naphthylenediamine sulphonic acids in sodium acetate solution, acidulated with acetic acid. These sodium salts are soluble in pure water; very small quantities of alkaline salts are sufficient to precipitate them from these solutions.

Chrysotoluazine $C_{25}H_{16}N_2$ and **Chrysonaphthazine** $C_{28}H_{16}N_2$ have been prepared by Liebermann and Witt (Ber. 20, 2442) from chrysoquinone and the corresponding orthodiamines (method 2). The same authors obtained azine derivatives from the quinone of picene.

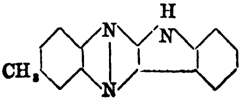
Tolustilbazine $C_{21}H_{18}N_2$ was discovered by Hinsberg, who described it under the somewhat misleading name 'Diphenyltoluquinoxaline' (Annalen, 237, 339). It is typical of the many azines which may be obtained by the action of benzil upon aromatic orthodiamines.

It separates in silvery leaflets from an alcoholic solution of benzil mixed with a solution of orthotolylenediamine (method 2). It melts at 111°, and dissolves with a crimson shade in sulphuric acid. Its constitution is expressed by the formula



The corresponding derivative of orthonaphthylenediamine was prepared by Lawson (Ber. 18, 2426).

Toluindazine $C_{15}H_{11}N_3$, the azine derivative of isatine, has been prepared by Hinsberg (Annalen, 237, 344) from orthotolylenediamine and isatin, by melting together the ingredients (method 2) and crystallising the product obtained from a mixture of alcohol and acetic acid. It forms yellow needles, melting at 290°, and dissolving in acids with a brownish-red colouration. Its constitution is expressed by the formula



A large number of other less important azines have been prepared in experiments made with a view to showing that certain compounds obtained by the authors were either orthodiketones or orthodiamines.

II. Colouring matters derived from azines (eurhodines and eurhodols).

It has already been said that by the introduction of an auxochromic group, NH_2 or OH, into the molecule of an azine, the latter is transformed into a colouring matter. The amino-derivatives of azines containing either one or several amino- groups, are embraced by the generic name of *eurhodines*, whilst the name of *eurhodols* has been given to the phenolic (OH) derivatives of the azines. The following is an enumeration of the various methods by which eurhodines and eurhodols have been obtained:—

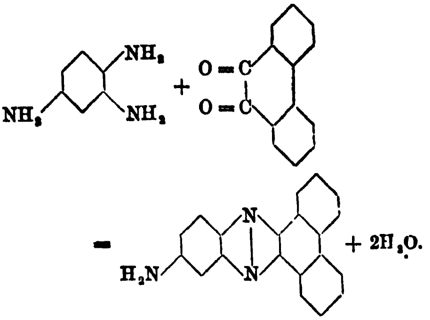
A. EURHODINES.

1. By heating together any orthamino-azo-compound and the hydrochloride of certain aromatic monoamines, such as, for instance, α-naphthylamine or α-aminoquinoline, preferably in a phenol solution, monoamino-azines (the eurhodines proper) are obtained. It was by this process that the first eurhodine was discovered by Witt in 1883 (Ber. 18, 1119; 19, 441) by heating orthaminoazotoluene with naphthylamine hydrochloride. In this reaction an orthodiamine is formed by the reduction of the amino-azo compound, which combines with α-naphthylamine, hydrogen being eliminated and absorbed by the amino-azo- compound still present.

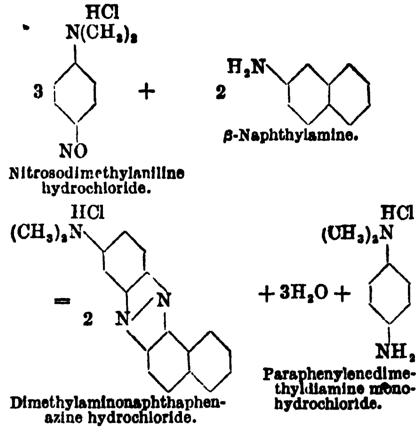
$$C_7H_{10}N_2 + C_{10}H_9N = 6H + C_{17}H_{13}N_3.$$

Orthotolylene-diamine. α-Naphthylamine. Typical eurhodine.

2. Another method of much greater applicability consists in reacting with α-diketones upon aromatic triamines, which contain two amino-groups in the ortho- position. Two molecules of water are eliminated for every molecule of eurhodine formed. Thus, for instance, a eurhodine was obtained from triaminobenzene and phenanthraquinone (Witt, Ber. 19, 445):



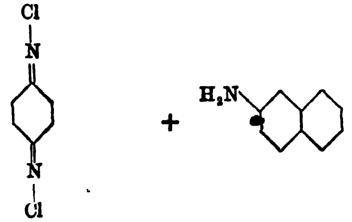
3. Another method of considerable applicability consists in heating together nitroso-amines (Witt, Ber. 21, 719) or quinonedichlorimides (Nietzki a. Otto, Ber. 21, 1598) with aromatic amines in which the para- position to the amino-group is occupied by some radicle. Thus, for instance, a eurhodine is formed by heating together nitrosodimethylaniline hydrochloride and β-naphthylamine, in an acetic acid solution:



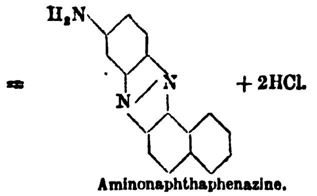
Nitrosodimethylaniline hydrochloride. β-Naphthylamine.

Dimethylaminonaphthaphenazine hydrochloride. Paraphenylenedimethyldiamine monohydrochloride.

and an analogous, though somewhat different reaction takes place if the nitrosodimethylaniline be substituted by dichloroquinonimide.



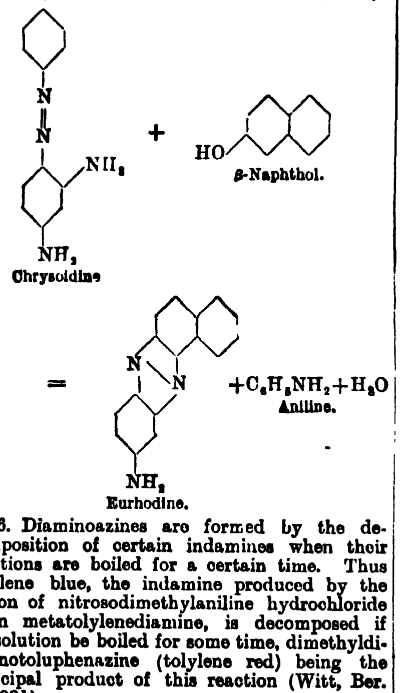
Dichloroquinonimide.



Aminonaphthaphenazine.

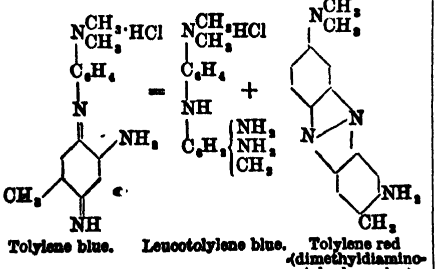
4. Eurhodines proper may also be obtained by the reduction (with ammonium sulphide) of nitro-azines. Thus, for instance, nitrophenophenanthrazine may be reduced into the eurhodine aminophenophenanthrazine (Heim, Ber. 21, 2306).

5. If certain azo- colours, such as chrysoïdine, be heated with β-naphthol, an eurhodine is formed: (Ullmann and Ankersmit, Ber. 38, 1812):



Eurhodine.

6. Diaminoazines are formed by the decomposition of certain indamines when their solutions are boiled for a certain time. Thus tolylene blue, the indamine produced by the action of nitrosodimethylaniline hydrochloride upon metatolylenediamine, is decomposed if its solution be boiled for some time, dimethyldiaminotoluphenazine (tolylene red) being the principal product of this reaction (Witt, Ber. 12, 931):



Tolylene blue. Leucotolylene blue. Tolylene red (dimethyldiaminotoluphenazine).

7. Di- and polyamino- azines may also be prepared by the oxidation of orthodiamines and of polyamines containing two amino- groups in the ortho- position. Thus O. Fischer and E. Hepp proved (Ber. 22, 355) that the red substance which is formed by the oxidation of orthophenylenediamine and which has been observed by many investigators (Griess, Ber. 5, 202; Salkowski, Annalen, 173, 58; Rudolph, Ber. 12, 2211; Wiesinger, Annalen, 224, 353), is nothing else than diaminophenazine. And Nietzki and Müller obtained (Ber. 22, 447) by oxidising tetra-aminobenzene with a current of air tetra-aminophenazine. Aminooxyphenazines may sometimes be found as by-products in this reaction (Ullmann and Mauthner, Ber. 35, 4302 and *ibid.* 36, 4026).

B. Eurhodols.

These may likewise be prepared by various methods.

1. The sulphonic acids of azines, fused with potash, readily yield the corresponding oxyazines or eurhodols (Witt, Ber. 19, 2791). For instance:

$C_{24}H_{13}N_2SO_3Na+2NaOH$
Sodium naphthaphenanthrazinesulphonate.

$=C_{24}H_{13}N_2ONa+Na_2SO_3.$
Phenanthranaphthaeurhodol.

2. Several eurhodines (amino-azines) yield the corresponding eurhodol on being heated under pressure with strong acids, a hydrolysis taking place in the circumstances (Witt, Ber. 19, 444):

$C_{17}H_{11}N_2{\cdot}NH_2+H_2O=NH_3+C_{17}H_{11}N_2{\cdot}OH.$
Typical eurhodine. Eurhodol.

3. Diazo-azines, on being boiled with water, yield the corresponding eurhodols; on being boiled with alcohol they yield the alkyl ethers of these eurhodols (Witt, Ber. 19, 444):

$C_{17}H_{11}N_2{\cdot}N:N{\cdot}Cl+H_2O$
Diazoeurhodine chloride.

$=HCl+N_2+C_{17}H_{11}N_2OH.$
Eurhodol.

$C_{17}H_{11}N_2{\cdot}N:N{\cdot}Cl+C_2H_5OH$
$=HCl+N_2+C_{17}H_{11}N_2OC_2H_5.$
Ethyleurhodol.

The following is an enumeration of those of the eurhodines and eurhodols which have been more closely investigated, the properties of which are typical for the whole class of colouring matters:—

Typical eurhodine $C_{17}H_{13}N_3$ (Witt, Ber. 19, 445). The mode of formation of this substance has already been given (Section A, 1). It is best prepared by heating to 130° equal molecules of orthoaminoazotoluene, of the melting-point 118·5°, and α-naphthylamine hydrochloride, dissolved in phenol until the colour of the mixture, which is at first of an emerald green, has changed into a brilliant scarlet. The mixture is now treated with a large quantity of toluene, when the hydrochloride of the new dyestuff is precipitated in a crystalline state. By recrystallisation from water acidified with hydrochloric acid, it may be obtained in a pure state. From the pure hydrochloride the free eurhodine base is precipitated by alkalis or ammonia in the form of a yellow powder, which may be recrystallised from aniline. Thus prepared, it forms glistening yellow prisms and needles of a dark-brown colour. It dissolves in ether with a yellow colour and a magnificent green fluorescence, which is characteristic of all the members of this group of dyestuffs. Eurhodine forms three series of salts, of which, however, only those with one molecule of acid are fairly stable, whilst those containing more acid are decomposed by the addition of water. It is to the formation of these various salts that the peculiar change of colour is due which is observed on adding water to a solution of eurhodine in concentrated sulphuric acid. This solution is of a cherry-red colour. On adding a small quantity of water the colour changes to a fine emerald green, whilst still more water produces the scarlet shade of the normal sulphate. This change of colour, which is observed with all the eurhodines, links them to their parent-substances, the azines, which exhibit similar curious phenomena, and also to the safranines.

The normal salts of eurhodine are well crystallised and of a bronzed copper colour when solid. In solution they exhibit a bright scarlet tint which they communicate to the fibre. These normal salts are, however, partially decomposed by an excess of water, the free eurhodine base being regenerated. The same takes place if fibres dyed red with eurhodine be washed. The scarlet shade is gradually replaced by the yellow shade of the free eurhodine base. For this reason eurhodine has not found an application in the industry of artificial dyestuffs.

Aminonaphthaphenazine $C_{16}H_{11}N_3$ has been obtained by Nietzki and Otto (Ber. 21, 1598) from β-naphthylamine and dichloroquinonimide (Ullmann and Ankersmit, Ber. 38, 1811). It crystallises in dark-yellow needles. Its salts are of a crimson colour. Its solution in sulphuric acid changes by the addition of water from reddish-brown through green into red. It forms a diazo- compound which, when boiled with alcohol, yields the ordinary naphthaphenazine, of the melting-point 142·5°. The following compound is its dimethyl derivative:—

Dimethylaminonaphthaphenazine $C_{18}H_{15}N_3$ (Witt, Ber. 21, 719). This eurhodine, the formation of which has been described under Section A, 3, may easily be prepared in quantity by heating together 20 parts nitrosodimethylaniline hydrochloride and 10 parts β-naphthylamine with 50 glacial acetic acid; the reaction sets in below 100°, and is apt to become violent. The product changes to a fine violet colour. It is dissolved in water acidified with hydrochloric acid, and the filtered solution is precipitated by the addition of sodium acetate. The crude eurhodine which is thus precipitated may be purified by dissolving it in alcohol acidified with hydrochloric acid. From this solution the normal eurhodine hydrochloride crystallises in bronze-coloured needles. From these ammonia liberates the free eurhodine base in the form of a scarlet crystalline powder. It may be recrystallised from boiling xylene; it is thus obtained in magnificent crystals resembling magnesium-platinocyanide, melting at 205°.

The change of colour of a sulphuric acid solution of this eurhodine is not very marked, going from violet through black and green into violet. The ethereal solution of the free base exhibits the brilliant fluorescence characteristic of all eurhodines.

Aminophenaphenanthrazine $C_{20}H_{13}N_3$. This eurhodine was prepared by Witt (Ber. 19, 445) and by Heim (Ber. 21, 2306) by the methods given under Section A, 2 and 4. It crystallises from toluene in short, thick, yellow prisms, melting at 279°.

Dimethyldiaminotoluphenazine; Tolylene red $C_{15}H_{16}N_4$. The formation of this compound by the spontaneous decomposition of tolylene blue has been described under Section A, 5. This eurhodine forms, in a pure state, orange crystals, which contain 4 mols. of water of crystallisation; at 150° this is given off and the anhydrous base remains as a dark-red powder. The hydrated base is soluble in ether with a pink colour and a beautiful orange fluorescence. The solution in concentrated sulphuric acid is green; on being diluted with water it changes through sky-blue into red. The normal (monacid) salts are perfectly stable and soluble in water with a pink colour. This solution dyes unmordanted or mordanted cotton and other fibres a pink which in darker shades deepens into a coppery red.

The production of this dyestuff has been patented (Otto N. Witt, D. R. P. 15272; Eng. Pat. 4846, 1880). The commercial product, which contains a certain amount of impurities, is sold under the name of 'neutral red.' It is chiefly used in calico-printing, and gives very fast and useful shades.

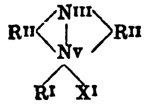
A similar product is prepared from the indamine which is formed by reacting with nitrosodimethylamine hydrochloride upon metaphenylenediamine. It is embraced by the same patent and sold under the name of 'neutral violet.'

Typical eurhodol $C_{17}H_{11}N_2OH$ (Witt, Ber. 19, 444). This substance, the formation of which takes place according to the equation given under Section B, 2, forms small leaflets of a yellow or red colour which dissolve in concentrated sulphuric acid with a red colouration, and are reprecipitated from this solution by the addition of water. Caustic soda solution dissolves it with an orange shade. Thus it is shown that this eurhodol (like all compounds of the same class) exhibits both acid and basic properties, the latter being due to the azine group contained in their molecule.

Eurhodol $C_{24}H_{14}N_2OH$. α-Hydroxynaphthaphenanthrazine has been obtained (Witt, Ber. 19, 2791) by the method described under Section B, 1, by the fusion of naphthaphenanthrazine-α-sulphonic acid with caustic alkalis. Its solution in sulphuric acid is of a fine and intense indigo-blue; it changes very suddenly into red on the addition of water, the sulphate being precipitated. This substance is a yellow colouring matter which may be fixed on cotton with alum-mordant, like alizarin. Owing, however, to its costliness, it has not been brought into commerce. A large number of isomerides may be prepared by starting from the numerous sulpho- derivatives of orthonaphthylenediamine, transforming them into azinesulphonates by condensation with phenanthraquinone and into eurhodols by subsequent fusion with caustic alkalis.

III. **Azonium bases and safranines.** The azonium bases are a class of compounds of which our knowledge is very restricted, very few representatives of the class being at present known, and that rather imperfectly. They are, however, of importance, as it is now established beyond doubt that they are the parent substances of the very important class of dyestuffs known as safranines. Although the first artificial dyestuff, mauveïne, was a true safranine, and although this group of compounds has been frequently under investigation, a correct view of their constitution had not been obtained until quite recently. According to the theory now universally adopted, all safranines are amino- derivatives of azonium bases, to which they stand in the same relation as the eurhodines to the azines. Hydroxy- derivatives of azonium bases have also been prepared and described under the name of safranols. They are, however, of no importance as colouring matters.

The azonium bases themselves, none of which has so far been obtained in a state fit for analysis, stand in the same relation to the azines as the ammonium bases to the amines. They are azines in which one of the nitrogen atoms has become pentavalent by being saturated with three organic radicles and one acid radicle, the connection with the second nitrogen atom being still preserved by the fifth valency of the pentavalent nitrogen atom. Thus the characteristic constitution of the azonium compounds may be expressed by the general formula



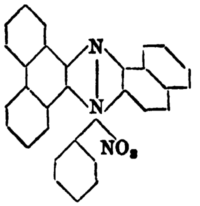
in which R^{I} and R^{II} represent mono- and divalent organic radicles, and X^{I} a monovalent acid radicle. The azonium bases are compounds which possess strong basic properties, and which, by the tenacity with which they retain their acid radicle, strongly resemble the ammonium bases. It is probable that the free azonium bases contain, like the ammonium bases, the hydroxyl group in the position X^{I} of the above general formula. The azonium bases and the dyestuffs derived from them are also capable of tautomeric changes, which lead to their assuming quinonoid structures. The nature of these changes is in many cases doubtful and too complicated to be fully discussed in this article.

The azonium bases are strongly coloured substances, but their dyeing properties are developed and brought to perfection by the introduction of amino- groups into their molecule. As the azonium bases theoretically possible are very numerous, and each of them is capable of producing very numerous isomeric mono- and polyamino- derivatives, the number of possible safranines is exceedingly large, and the number of those which have already been prepared is insignificant in comparison with that foreshadowed by theory.

Of the safranines which have hitherto been prepared, only a few are monoamino- derivatives of azonium bases. A few more are of doubtful or unknown constitution. The majority are asymmetric diamino- derivatives of azonium bases, containing one amino- group in one of the diatomic organic radicles (R^{II}, whilst the other is attached to the monoatomic radicle (R^{I}).

The true constitution of phenosafranine and its congeners has been recognised by Witt, who, after pointing out the analogy between the eurhodines and safranines (Ber. 18, 1119) and clearing up the constitution of the former (Ber. 19, 446), proved the latter to be asymmetric diaminoazonium bases (Ber. 19, 3121). Bernthsen had proposed (Ber. 19, 2690) somewhat earlier a symmetrical formula for the safranines based upon Witt's eurhodine researches. His view was subsequently adopted by some chemists, but the author of this article fails to see the force of the arguments adduced in support of it. *Cf.* supplementary article.

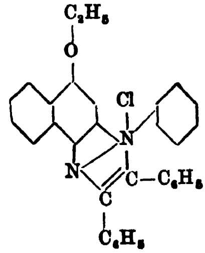
A. Azonium bases. 1. The typical compound was obtained by Witt (Ber. 20, 1183) by the reaction of phenanthraquinone on phenylorthonaphthylenediamine. By heating these ingredients in an acetic acid solution an intermediate product is obtained, which on treatment with a mineral acid is transformed into the salt of the azonium base:



If nitric acid is used, the nitrate is deposited in very fine crystals. It is sparingly soluble in water, readily soluble in spirit with a fine orange-red colouration. The hydrochloride dissolves in sulphuric acid with a violet tint, which changes into red on dilution with water.

2 If in this reaction the phenylorthonaphthylenediamine be replaced by phenylorthophenylenediamine, the resulting compound is a yellow dyestuff of considerable strength. It is manufactured and sold under the name 'Flavinduline' (1893).

3. A very similar compound was obtained by Otto N. Witt and Christoph Schmidt in 1892 (Ber. 25, 1017), by the reaction of benzil upon ethoxyphenylorthonaphthylendiamine. It was called ethoxyphenylnaphthostilbazonium chloride and has the constitution:



It is a beautiful yellow dyestuff, but too expensive to be prepared on a manufacturing scale.

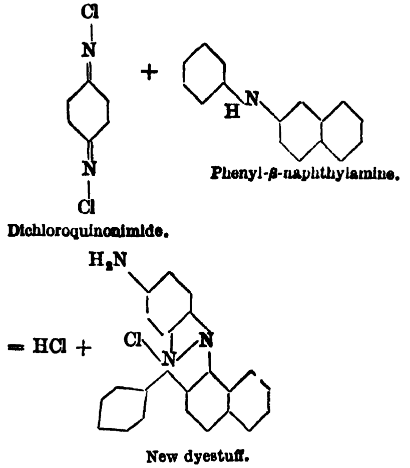
B. Safranines. The various colouring matters belonging to this group have mostly been prepared by different synthetical methods, which may be classed in the following manner:—

1. Reduction of the nitro- derivatives of azonium bases. By reacting with mononitrophenanthraquinone or dinitrophenanthraquinone on phenylorthonaphthylenediamine,

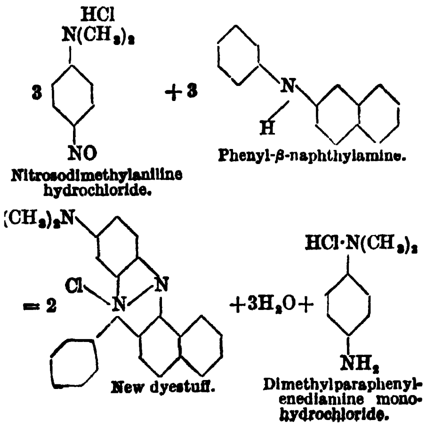
nitro- and dinitro- derivatives of the above azonium base are obtained, which on reduction with ammonium sulphide yield reddish-violet colouring matters belonging to the safranine group (Witt, unpublished observations).

2. If the stilbazonium base obtained by Witt and Schmidt, or any of its congeners prepared from ethylated arylorthonaphthylenediamines be heated with ammonia, the ethoxy group is replaced by the amino- group and the corresponding safranines are formed. This is quite a general reaction (Witt and Schmidt, Ber. 25, 2003; Witt and v. Helmolt, Ber. 27, 2355; Witt and Buntrock, Ber. 27, 2302).

3. By the action of dichloroquinonimides upon secondary aromatic amines, in which the para- position to the amino- group is occupied, monoamino-azonium bases are formed (Nietzki and Otto, Ber. 21, 1598). The reaction, for instance, between dichloroquinonimide and phenyl-β-naphthylamine may be represented by the equation:



4. In a similar manner nitrosodimethylaniline (or any other nitroso-amine) reacts with phenyl-β-naphthylamine (Witt, Ber. 21, 719):

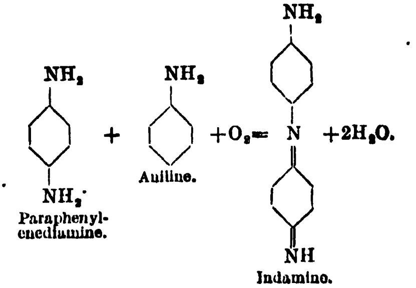


5. The safranines proper (asymmetric diaminoazonium bases) are formed by the joint oxidation of one molecule of diamine and two molecules of an aromatic monoamine. In this reaction fugitive indamines are formed as intermediate products; the process thus becomes strictly analogous to the formation of toluylene red and its congeners.

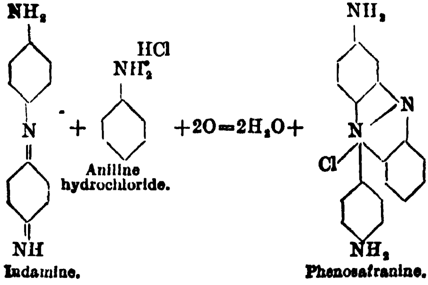
This is the process which is generally used in the manufacture of safranines, and it will therefore be fully explained.

By the joint oxidation of an aromatic paradiamine with one molecule of an aromatic monoamine, an indamine is invariably formed (v. INDAMINES). If these indamines be oxidised in the presence of another molecule of an aromatic monoamine, a safranine is formed:

First Stage.



Second Stage.

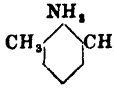


Of course, any other paradiamine may be substituted for paraphenylenediamine, and any other monoamine for aniline. As, however, the formation of an indamine only takes place if the para- position to the amino- group be still free, it results, that at least one of the two molecules of monoamines must fulfil this condition. Thus the formation of a safranine from paraphenylenediamine takes place on oxidation of one molecule of the diamine with

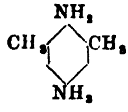
(1) Two molecules of aniline.
(2) Two molecules of orthotoluidine.
(3) One of aniline and one of orthotoluidine.
(4) One of aniline and one of paratoluidine.
(5) One of orthotoluidine and one of paratoluidine; but it does not take place with one molecule of paraphenylenediamine and two of paratoluidine (Witt, J. Soc. Chem. Ind. 1882, 256).

On the other hand, the other of the two

molecules of monoamines must have a free ortho-position in order to be capable of entering the reaction. Thus the indamine of the above formula forms safranines with all the primary aromatic monoamines of the benzene series, with the exception of one xylidine and of mesidine, of the respective formulæ



and

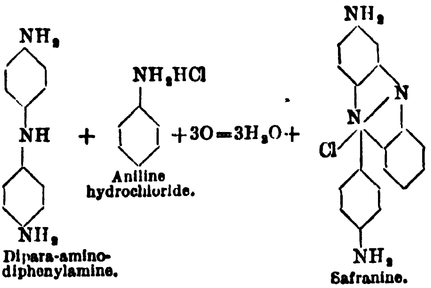


because these two have no free ortho- position to be used for the formation of the azonium group (Nietzki, Ber. 19, 3017 and 3136).

It is also necessary that this second molecule of monoamine be a primary base, whilst the one necessary for the formation of the indamine may be either primary, secondary, or tertiary, provided always that it possesses a free para-position.

6. It is evident that the general process described under 4 may be modified; thus, for instance, the dipara-amino- derivatives of secondary bases (being the leuco- compounds of indamines) may be oxidised together with one molecule of a primary aromatic monoamine, when a safranine is the result (see top of page, second column):

7. Another modification (Witt, Ber. 10, 873) consists in heating aminoazo- compounds with the hydrochlorides of aromatic monoamines.



This is the oldest process for the manufacture of safranines. The mechanism of this reaction is simple. Part of the aminoazo- compound being reduced, a mixture of a paradiamine and a primary monoamine in molecular proportions is formed, which with the monoamine added in the shape of hydrochloride, is transformed into safranine by the dehydrogenating action of the remaining part of the aminoazo- compound. It is evident that the yield must be small in this process of manufacture, and such is actually the case.

8. An asymmetrical safranine has been obtained by the reduction of picryl-orthophenylenediamine (Kehrmann, Ber. 33, 3074).

9. Certain compounds belonging to the safranine group (mauveïne, &c.) are formed in a very complicated reaction by the oxidation of heavy aniline alone; on continued oxidation mauveïne is converted into a safranine (Perkin, Roy. Soc. Proc. 35, 717).

The following is an account of the more important and more thoroughly investigated safranines:—

A. MONAMINO- DERIVATIVES OF AZONIUM BASES.

1. **Aposafranine**, Monoaminophenylphenazonium chloride, has been obtained by Nietzki and Otto (Ber. 21, 1736; *see* also Annalen, 286, 188, and Ber. 30, 2624, and 33, 3078) from phenosafranine (*see* below) by diazotising one of its amino- groups, and eliminating it by means of alcohol. It is a red dyestuff of no practical importance, but very interesting as prototype of the induline group (*see* under INDULINES).

2. **Red dyestuff** $C_{22}H_{16}N_3Cl$. Obtained by the action of dichloroquinonimide on phenyl-β-naphthylamine, was prepared by Nietzki and Otto (Ber. 21, 1598) by heating the ingredients in molecular proportion in alcoholic solution on the water-bath. The nitrate forms green needles or prisms which are soluble in water with a magenta-red colour. The hydrochloride dissolves in sulphuric acid with a red colouration, which on dilution changes through green into red.

3. **Violet colouring matter** $C_{24}H_{20}N_3Cl$. Prepared by Witt (Ber. 21, 719) by acting with 3 molecules of nitrosodimethylaniline hydrochloride in an acetic acid solution on 2 molecules of phenyl-β-naphthylamine. This is the dimethyl- derivative of the preceding substance. The hydrochloride forms large black needles soluble in water, with a fine violet colour. The free base, $C_{24}H_{20}N_3 \cdot OH$, is liberated from the salts by caustic alkalis only. It is insoluble in water, soluble in alcohol, with a red colour and a fine orange fluorescence. It is sold as 'neutral blue.'

4. **Violet colouring matter** $C_{25}H_{22}N_3Cl$. Prepared by Witt (Ber. 21, 719) from paratolyl-β-naphthylamine in exactly the same manner as the preceding substance, of which this is the next homologue. Violet soft needles, resembling in their colour and reactions the phenyl- derivative.

The above substances have been patented (Otto N. Witt, D. R. P. 19224, dated Feb. 18, 1882).

5. **Basle blue** $C_{32}H_{29}N_4Cl$ is a fine blue dyestuff prepared (T. Annaheim, Ber. 20, 1371; Durand and Huguenin, Ger. Pat. 40886) by the reaction of nitrosodimethylaniline hydrochloride on the paratolylnaphthylenediamine which is formed by heating Ebert and Merz's dihydroxynaphthalene with para-toluidine hydrochloride. It forms a brown crystalline powder, soluble in water with a bluish-violet shade. In concentrated sulphuric acid it dissolves with a greenish-brown shade, which changes through green into violet on dilution.

6. **Azine green** $C_{30}H_{25}N_4Cl$ is formed by the reaction of nitrosodimethylaniline hydrochloride upon 2-6-diphenylnaphthylenediamine.

7. **Induline scarlet** $C_{19}H_{18}N_3Cl$, a very beautiful red dyestuff discovered by Schraube (D. R. P. 77266; Eng. Pat. 10138A, 1892), and manufactured by the Badische Aniline und Soda-Fabrik, is really not an induline, but a Safranine. It is prepared by melting together the hydro-

chloride of anilinazoethylparatoluidine and α-naphthylamine. The reaction is strictly analogous to the formation of the typical eurhodine.

(Induline scarlet is used as a catalyst in discharge printing in some cases (*cf.* D. R. P. 184381). Rongalite special (B. A. S. F.) and hydrosulphite conc. special (M. L. B.) both contain induline scarlet.—F. A. M.)

B. DIAMINO- DERIVATIVES OF AZONIUM BASES.

1. **Phenosafranine** $C_{18}H_{15}N_4Cl$. Discovered by Witt (exhibited in Paris in 1878; and mentioned in the catalogue of Messrs. Williams, Thomas & Dower, closely investigated by Nietzki (Ber. 16, 464) and by Bindschedler (Ber. 13, 207; 16, 865).

It was with this compound that the mode of formation of the safranines and their chemical properties were definitely ascertained, chiefly by R. Nietzki, whose brilliant researches on this subject did much to clear up the chemistry of this group.

Phenosafranine is prepared by the joint oxidation of paraphenylenediamine and aniline. The mechanism of this process has already been discussed. A dilute aqueous solution of the normal hydrochlorides of these bases is used, and their oxidation is accomplished by adding potassium or sodium bichromate or manganese dioxide in the necessary proportion to the hot solution. The blue colour of the indamine which appears at first is immediately replaced by the red colour of the safranine formed. A certain quantity of insoluble dark by-products is always formed, but by careful work the yield of pure safranine may be raised to 70 p.c. of the theory. When the oxidation is finished, soda solution or chalk is added in order to precipitate the impurities, and the liquid is filtered. By adding a small amount of nitric acid and some sodium nitrate to the filtered solution, the nitrate of the safranine crystallises out; or the chloride may be prepared by adding common salt to the solution after acidifying it with hydrochloric acid. By repeated recrystallisation from water or alcohol, the phenosafranine is obtained in a state of purity, in the form of magnificent green needles. The *sulphate* forms blue needles. The platinum salt $(C_{18}H_{15}N_4Cl)_2PtCl_4$ forms insoluble shining leaflets. Phenosafranine forms a diacetyl- derivative on boiling with acetic anhydride in the presence of dry sodium acetate It forms two diazo-derivatives, of which the first

$$C_{18}H_{13}N_3Cl\diagdown N:N{\cdot}Cl$$

is rather stable and soluble in water, with blue colouration. The other diazo- compound

$$C_{18}H_{11}N_2Cl\begin{cases}N:N{\cdot}Cl\\N:N{\cdot}Cl\end{cases}$$

is very unstable and of a green colour.

Phenosafranine dyes wool, silk, and cotton a magnificent pink. Its aqueous solutions are red and show no fluorescence, whilst alcoholic solutions show a marked greenish-yellow fluorescence. Phenosafranine dissolves in concentrated sulphuric acid with a green colouration which changes through blue into red on dilution, thus indicating the actual existence of the three series of salts foreshadowed by theory.

If phenosafranine or its homologues be diazotised and then combined with β-naphthol, beautiful basic blue dyestuffs are obtained, which are largely prepared and used for cotton-dyeing and calico-printing under the name of 'Indoine blue.'

The alkyl- derivatives of phenosafranine are interesting colouring matters, some of which have found an industrial application. They have not been prepared by introducing alkyl-groups into ready-formed safranine, but rather by direct synthesis from suitable raw materials. Each of them exists in two isomeric modifications, according to the amino- group into which the alkyl- group has been introduced. The two amino- groups of phenosafranine being asymmetric, and therefore not equivalent to one another, must of necessity produce different products on being alkylated.

α-Dimethylsafranine $C_{20}H_{19}N_4Cl$ is produced by the simultaneous oxidation of one molecule of paraphenylenedimethyldiamine with two molecules of aniline.

It is a dyestuff of a magenta-red shade. Its nitrate crystallises in green needles (Bindschedler, Ber. 16, 869).

β-Dimethylsafranine is obtained by oxidising a mixture of one molecule of paraphenylenediamine with one molecule of aniline and one molecule of dimethylaniline. Its shade is similar to that of the preceding one; its nitrate forms brown leaflets (Nietzki, Ber. 19, 3017 and 3136).

The two **diethylsafranines** are obtained in a similar manner. Their chlorides form green needles which dissolve in water with a violet shade (Nietzki, Ber. 16, 464). These substances, and especially the α- derivatives, are manufactured under the name of *Fuchsia*.

Tetramethylsafranine (Bindschedler, *l.c.*) and **tetraethylsafranine** (Nietzki, *l.c.*) may be prepared by the joint oxidation of one molecule of paraphenylenedimethyl- (or diethyl-) diamine with one molecule of aniline and one molecule of dimethyl- or diethylaniline. These substances have been sold under the name of *Amethyst*. Their shade is a magnificent violet, with a fine crimson fluorescence. Unfortunately, they are very fugitive.

2. **Tolusafranines** (Hofmann and Geyger, Ber. 5, 526, and very numerous other publications) $C_{21}H_{21}N_4Cl$. A mixture of the isomerides of this formula is the safranine of commerce. It is prepared by the oxidation of a mixture of paratolylenediamine with the two toluidines. This mixture is obtained by treating three molecules of the orthotoluidine of commerce (which contains from 6 to 10 p.c. of paratoluidine) with two molecules of hydrochloric acid and one molecule of sodium nitrite dissolved in as little water as possible. A thick heavy oil is the result, which is merely a solution of amino-azotoluene in the excess of toluidine present. By dissolving this oil in hydrochloric acid, and reducing it with either zinc-dust or iron borings, the amino-azo- compound is split up into paratolylenediamine and orthotoluidine; consequently, the aqueous liquid produced contains the bases in the necessary proportions for the production of safranine.

The rest of the treatment is exactly similar to) the one described for pheno-safranine. The safranine is precipitated from the liquid by the addition of salt. By redissolving it in water, boiling with a small quantity of potassium bichromate, treating it afresh with milk of lime or chalk, and reprecipitating the filtered liquid with clean salt, the safranine is purified so as to give the brightest shades on dyeing. Safranine prepared with a toluidine rich in paratoluidine is very insoluble in cold water, and therefore generally disliked by the dyer. The presence of aniline has not the same disagreeable effect: some manufacturers therefore use the first runnings of the magenta process, which consist of aniline and orthotoluidine, and contain no paratoluidine, as a suitable raw product for the manufacture of safranine. The safranine of commerce forms a brown powder which dissolves readily in hot water. It dyes a bluish-pink on textile fibres, and was chiefly used for dyeing cotton. The introduction of the so-called substantive azo- colours, derived from benzidine and its congeners, has much diminished the use of safranine.

3. **Girofle.** A dimethylphenoxylosafranine has been produced by heating nitrosodimethylaniline hydrochloride with xylidine, and sold under the above name as a violet colouring matter of a pleasing shade.

4. **Safranisol** $C_{18}H_{13}(OCH_3)_2N_4 \cdot Cl$ is a substance which has been obtained by Nietzki by the joint oxidation of one molecule of paraphenylenediamine with two molecules of ortho-anisidine. It dyes a very beautiful yellowish-pink with a yellow fluorescence. This product has been patented (Kalle & Co., D. R. P. 24229; Eng. Pats. 218, 1883 and 3095, 1883), but owing to the high price of its production it has been unable to compete with the eosin colours, which are perhaps still more brilliant in shade.

5. **Magdala red** $C_{30}H_{21}N_4Cl$. This old and very beautiful colouring matter is the safranine of the naphthalene series. It was discovered by Schiendl and first investigated by Hofmann (Ber. 2, 374), who, however, owing to the great difficulties of its analysis, assigned to it the erroneous formula $C_{30}H_{21}N_3 \cdot HCl$. After a revision of the analytical data by Julius (Ber. 19, 1365), its true composition was established. This substance cannot be prepared by the usual oxidation process from paranaphthylenediamine and naphthylamine because paranaphthylenediamine is at once transformed into α-naphthaquinone even by the feeblest oxidising agents. Magdala red has therefore to be prepared by the old process of heating α-amino-azonaphthalene with α-naphthylamine acetate. The chief product of this reaction is rhodindine, the induline of the naphthalene series (*v.* INDULINES); but a small proportion (6–8 p.c.) of Magdala red is formed at the same time. This is extracted from the melt by repeated treatment with boiling water, in which it is sparingly soluble. On cooling, this solution deposits the dyestuff in the shape of gelatinous flakes, It is purified by repeated crystallisations from water. When pure, it forms a dark crystalline powder, which dissolves in alcohol with a pink colour and a magnificent orange fluorescence. It is used for dyeing light pinks on silk, but is now rapidly being replaced by rhodamine (*v.* TRIPHENYLMETHANE COLOURING MATTERS) If ready-formed paranaphthylenediamine be added to the magenta-melt, the proportion of Magdala red formed is considerably increased (Otto N. Witt, D. R. P. 40868). It is thus shown that Magdala red is, after all, only a product of the joint oxidation of paranaphthylenediamine and α-naphthylamine.

The pure salts of Magdala red, when recrystallised from spirit, form green needles with a metallic lustre. The chloride, sulphate, picrate, and platinum double chloride have been prepared and analysed. These salts dissolve in concentrated sulphuric acid with a blue-black colour which changes into red on dilution.

Mixed Magdala reds have been prepared either by heating amino-azonaphthalene with aromatic monoamines of the benzene series (M. T. Lecco, Ber. 7, 1290), or by heating aminoazo-compounds of the benzene series with paranaphthylenediamine hydrochloride and aniline, toluidine, or even phenol (Otto N. Witt, D. R. P. 40868). These dyestuffs resemble Magdala red in their properties.

6. **Indazine** is the commercial name of a safranine dye, which is obtained by heating the symmetrical diphenylmetaphenylenediamine (prepared by heating resorcin with aniline hydrochloride in the presence of zinc chloride) with nitrosodimethylaniline hydrochloride. Its constitution may be inferred from its analogy to the violet dyestuff prepared from nitrosodimethylaniline and phenyl-β-naphthylamine. It is a serviceable blue, of considerable intensity, but little brilliancy of shade.

Mauveïne $C_{27}H_{25}N_4Cl$. This subtance, the oldest of all the artificial colouring matters, is still manufactured in a small way, and sold under the name of rosolane. It was discovered and examined by W. H. Perkin (Roy. Soc. Proc 35. 717; Eng. Pat. 1984, 1856). who also described the mode of its production. It is prepared by oxidising heavy aniline with potassium dichromate, and extracting the mauveïne formed with water or spirit from the black insoluble mass which is the chief product of the reaction. A dyestuff resembling mauveïne in all its properties may be prepared by the reaction of nitrosodiphenylamine on aniline (Otto Fischer and Hepp, Ber. 21, 2617) or by the joint oxidation of diphenylmetaphenylenediamine and paraphenylenediamine or meta-aminodiphenylamine and para-aminodiphenylamine. These syntheses are a clue to the constitution of mauveïne, which has been a mystery for nearly half a century—it stands revealed as phenylphenosafranine. The above synthetical methods have been adopted for the industrial preparation of mauveïne, as they give better yields than Perkin's old process of oxidation. Mauveïne is generally sold in the shape of a violet paste. It is insoluble in cold, sparingly soluble in hot water, easily soluble with a fine purple shade in spirit. Concentrated sulphuric acid dissolves it with an olive-green colouration, which on dilution with water changes through green and blue into purple. Mauveïne still holds its own against the cheaper new violets on account of its great fastness to light and other influences. It is used for shading the white in bleached silks, and also for printing on paper. (It was also used for printing the old violet penny postage stamp.)

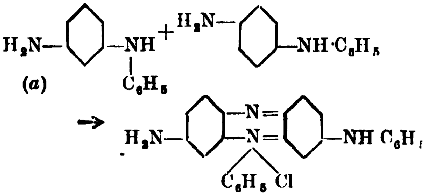
Mauveïne yields on oxidation a pink dyestuff which is supposed to be identical with ordinary phenosafranine. In our opinion this statement requires confirmation. O. N W.

Addendum.

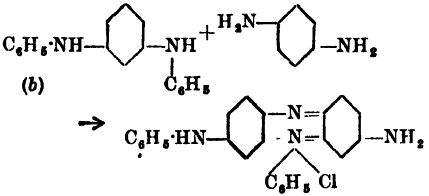
Since the foregoing article was revised by the late Prof. Witt there has been relatively slight activity in the azine group of dyes, such developments as have taken place being chiefly theoretical; on the technical side a few new or improved methods of preparing azine derivatives have been patented, and are noted later, but substantially the situation remains much as it was, no striking advances having been made.

So far as concerns the theory of the structure of the dyes of this class, we may note that the general consensus of opinion amongst chemists is that the ortho-quinoid formulation is, on the whole, in better agreement with the known facts than the older para-quinoid structures ascribed to them by Witt, and, in addition, safranine, one of the most important members of the azine series, is usually given a symmetrical formula rather than the unsymmetrical formula favoured by Witt.

We may therefore note shortly the chief grounds upon which these alterations are based: first as regards the symmetrical formulation, Nietzki showed that the same phenyl-safranine was obtained by condensing (*a*) phenyl-*m*-phenylenediamine and phenyl-*p*-phenylenediamine; (*b*) diphenyl-*m*-phenylenediamine and *p*-phenylenediamine, according to the schemes:



(*a*)



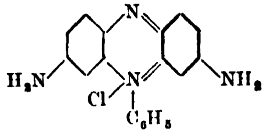
(*b*)

A result that appears hardly explicable if we assume a symmetrical formula for the safranine.

Further, the synthesis of safranine from *m*-aminodiphenylamine and *p*-phenylenediamine also points in the same direction, since a safranine is also produced if methyl-*m*-phenylenediamine be used in place of phenyl-*m*-phenylenediamine, a result clearly incompatible with an unsymmetrical formula, for whilst the methyl group can replace the phenyl group attached to the azonium nitrogen on the symmetrical formula, it cannot possibly replace one of the benzene nuclei of the azine ring system as would be demanded by the unsymmetrical formula.

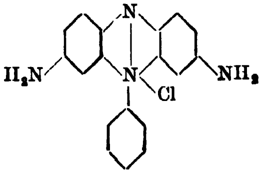
Nietzki claimed to have shown the existence of two isomeric diethyl safranines which he prepared from diethylphenylenediamine + 2 mols. aniline, and from aniline, + *p*-phenylenediamine + diethylaniline respectively, and quoted this as an argument in favour of the unsymmetrical formula. Körner and Schraube, however (Chem. Zeit. 17, 305), destroyed this argument by showing that the two isomers were identical. A further argument in favour of the unsymmetrical formula was brought forward by Barbier and Sisley (Ann. Chim. Phys. 1908, 96), who claimed to have proved the existence of two isomeric safranines, an unsymmetrical and a symmetrical, the technical dye consisting of a mixture of both forms. Hewitt, Newman, and Winmill have, however, contradicted this statement (Chem. Soc. Trans. 1909, 95, 577). Havas and Bernhard (Ber. 46, 2723) also claim to have proved that phenosafranine is homogeneous, and that Barbier and Sisley's two products are either different hydrates or homologues which may be present in the purest commercial safranine.

The balance of evidence appears, therefore, to be strongly in favour of the symmetrical formula for the safranines:

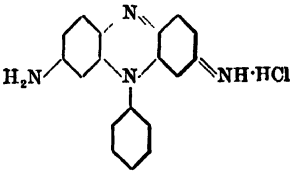


As regards the vexed question of *ortho-* versus *para-* quinoid structure, we cannot say that this is finally settled, as there is little doubt that, in certain cases, at all events, tautomerism occurs between the two forms.

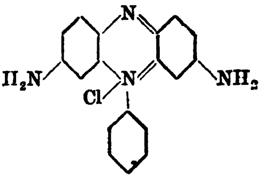
Assuming the correctness of the symmetrical arrangement discussed above, we have three possible methods of writing the structural formula:—



I.



II.

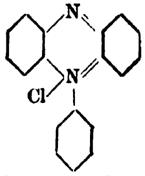


III.

(For a fourth suggested formula, *cf.* Balls, Hewitt, and Winmill, Chem. Soc. Trans. 1912, 101, 1840.)

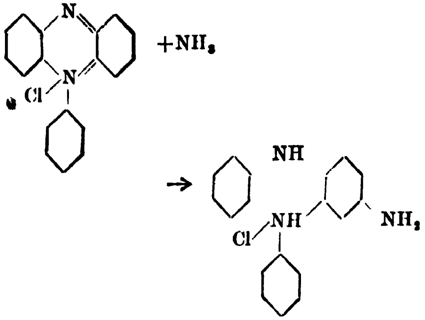
Of these, formula I., originally proposed by Bernthsen (Ber. 19, 2690), is constructed in accordance with the older 'peroxide' formula for quinone, which is not used now, and may therefore be disregarded.

Between II. and III., the *para*-quinoid and the *ortho*-quinoid formulæ, a decision could be arrived at by the behaviour of the substance with nitrous acid, since II. contains only one amino- group, whilst III. possesses two. One amino- group can be readily removed by diazotisation in the ordinary way, yielding aposafranine, whilst the second group is considerably more resistant; but Kehrmann (Ber. 1896, 29, 2316), by diazotising the sulphuric acid solution of aposafranine, succeeded in removing the second amino- group, obtaining by this means phenyl phenazonium chloride :

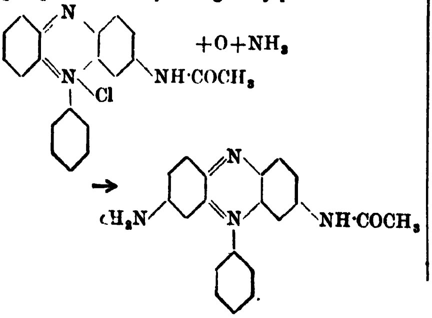


which can only have an *ortho*-quinoid structure (*cf.* also Nietzki, Ber. 29, 2771).

A further proof by Kehrmann (Ber. 30, 1565, 2620; 33, 395) consists in the fact that on treating phenylphenazonium chloride with ammonia an amino- group is added on (just as quinone, for example, adds on hydrochloric acid) yielding leucoaposafranine :



which oxidises at once in air to aposafranine itself; if the latter be then acetylated and again treated with ammonia a further amino- group is added on yielding acetylphenosafranine :



Such a synthesis is readily explicable on the *ortho*-quinoid hypothesis, but it would be difficult to understand how ammonia could add on to the non-quinoid nucleus were the *para*-quinoid structure accepted.

We may therefore take it that the behaviour of the azine group of dyes can be best explained by the assumption of an *ortho*-quinoid structure, but the possibility of tautomeric change into the *p*-quinoid form must not be lost sight of.

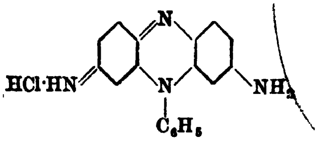
Kehrmann, Havas, and Grandmougin, and their pupils, have carried out a good deal of research in recent years on the structure of the azine dyes. In particular, they have examined the behaviour of some phenazonium compounds with varying concentrations of sulphuric acid. As is well known, by increasing the concentration of the acid striking colour changes are produced, and the results obtained show that, with few exceptions, the number of colour changes produced increases with the number of amino- groups present in the molecule, which they explain by assuming that salt formation takes place step-wise, each transformation of a basic into a salt group causing a colour change.

Frequently the second salt of a diamino compound exhibits colour and spectral relationships identical with those shown by the salt of the monoamino compound, the effect of the acid being to neutralise the chromophoric effects of the particular amino- group, *e.g.* the 'second' colouration of 1 : 3, 3 : 7, or 3 : 11 diaminophenylphenazonium salts is the same as that of the 3-amino- compound 'first' colouration (Ber. 46, 2802).

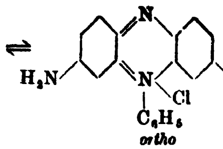
Where this rule does not hold good the assumption is made that a change has occurred from *ortho*- to *para*-quinoid structure, or *vice versa*.

Most of the researches of these investigators are of too theoretical a nature to be considered in the present article, but it is worthy of note that they bring forward evidence which tends to show that the assumption of such a change in the structure of azine dyes from *ortho*- to *para*-quinoid rests to some extent on an experimental basis. Thus Grandmougin and Smirous (Ber. 46, 3425) consider that the green tri-acid safranine salts obtained on solution in sulphuric acid are mixtures of a yellow *o*-quinoid, and a blue *p*-quinoid compound, and it was found that on treating such green solutions with sodium nitrite they at first undergo only partial diazotisation, but on standing for some days the *para*- form is slowly rearranged into the ortho-quinoid form, and is bis-diazotised so that on pouring into alcohol phenylphenazine is formed.

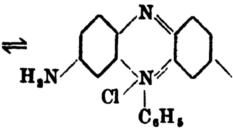
Balls, Hewitt, and Newman (Chem. Soc. Trans. 1912, 101, 1840), from an examination of the absorption curves of various azine dyes, consider these to confirm the tautomeric structure of the safranines, the structure changing from *ortho*- to *para*-quinoid, according to conditions :



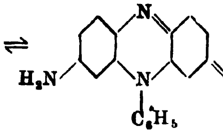
para



ortho



ortho

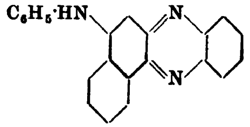


para

Regarding other recent developments we may note that phenazine has been produced by Zerevitinov and Osstromuisslenski (Ber. 44, 2402) by heating nitrobenzene with barium oxide at 200°–280° C., the only other substance produced being aniline.

Another synthesis from *o*-nitraniline and *o*-nitrobrombenzene, using cuprous chloride as a catalyst, is described by Eckert and Steiner (Monatsh. 1914, 35, 1153).

On the purely technical side we may note that Bayer & Co. (D. R. P. 230456) describes the production of green azine dyes of the type:



from 1 : 3-diarylnaphthylene diamines or their sulphonic acids. By oxidising alkylbenzyl-aniline sulphonic acids with derivatives of diphenylamine sulphonic acids of the general formula:

$$(H_2N)\cdot(SO_3H):C_6H_3\cdot NH\cdot C_6H_4\cdot X$$

(X=hydrogen or aralkyl)

to the corresponding indamine, and then the latter with an aromatic amine, safranine sulphonic acids are produced (Akt. ges. f. Aniline Fab.; Fr. Pat. 417669).

In Fr. Pat. 426790 (D. R. P. 243491) the Farbwerke Höchst claim the production of a safranine disulphonic acid by the joint oxidation of *p*-iminodiphenylamine sulphonic acids, sulphanilic acid, and monosulphonic acids of tertiary amines in which the *para*- position is free, such as alkyl-benzyl-aniline sulphonic acids.

J. D. Riedel claims the manufacture of azine dyes by the action of *m*-toluylene diamine and *α*-naphthylamine upon *p*-nitroso phenylglycine (Eng. Pat. 22694, 1913; D. R. P. 268208).

Basic safranine dyes result from the condensation of nitrosomethyl-*o*-toluidine and *m*-aminomethyl-*p*-toluidine, giving yellowish-red prints on cotton. A better method is to produce these safranine dyes by oxidising a mixture of methyl-*p*-toluylenediamine and methyl-*m*-toluylenediamine (Durand, Huguenin & Co., Eng. Pat. 2933, 1915; D. R. P. 282346, 287271).

Bayer & Co. claim the production of compounds of basic dyes of the safranine series by converting the dyes or their salts into the corresponding gallocarboxylic acid salts (D. R. P. 285500).

A somewhat fresh application of safranines is given by the Saccharin Fabrik vorm. Fahlberg List & Co., who claim the treatment of phenosafranine and its homologues with mercury salts, the resultant mercurised safranines possessing therapeutic properties (D. R. P 286097).

Another therapeutic use for safranine derivatives is described by the Akt. Ges. f. Aniline Fab. (Fr. Pat. 463357), who claim the preparation of a substance by combining tolusafranine with tannin in hot 8 p.c. soda lye, and precipitating the product with salt; it forms a red powder slightly soluble in water, soluble in concentrated sulphuric acid to a green solution. It has no purgative action, and may be used as a drug for the treatment of trypanosoma and other protozoic infections.

Finally, it should be noted that recent work by Green and others (Ber. 44, 2570; 45, 1955; 46, 33; Proc. Chem. Soc. 28, 250, 1912; Chem. Soc. Trans. 97, 2388) has proved that aniline black is a complex azine derivative (*see* ANILINE BLACK). The indulines and nigrosines are also complex derivatives containing azine nuclei (*see* INDULINES and NIGROSINES).

F. A. M.

AZOBENZENE $C_{12}H_{10}N_2$. A product of the partial reduction of nitrobenzene, obtained by Mitscherlich (Annalen, 12, 311) by boiling an alcoholic solution of nitrobenzene with potash and distilling the product.

Preparation.—Azobenzene is obtained by acting with sodium amalgam (4–5 p.c. of sodium) on nitrobenzene dissolved in ether containing water (Werigo, Annalen, 135, 176; Alexejeff, J. 1864, 525; Rasenack, Ber. 5, 367); the product, according to Alexejeff (J. 1867, 503) is azobenzene or azoxybenzene, according as the sodium amalgam or nitrobenzene is in excess. On the large scale azobenzene is prepared by the reduction of nitrobenzene in alcoholic solution with zinc-dust and aqueous soda. In this reaction the reduction tends to go further, and some hydrazobenzene is also obtained; this, however, is readily oxidised to azobenzene if nitrous fumes are passed into the alcoholic solution of the product (Alexejeff, J. 1867, 503). Azobenzene can also be prepared by distilling azoxybenzene (1 part) with iron filings (3 parts) (Schmidt and Schultz, Ber. 12, 484); by heating nitrobenzene on a water-bath with the calculated quantity (2 mols.) of stannous chloride dissolved in excess of aqueous caustic soda (Witt, Ber. 18, 2912); by reducing nitrobenzene in alcoholic solution with magnesium amalgam (yield 95 p.c.) (Evans and Fetsch, J. Amer. Chem. Soc. 1904, 1158); by reducing nitrobenzene with alkali sulphide in the presence of alkali (Farb. vorm. Meister, Lucius, and Brüning, D. R. P. 216246, J. Soc. Chem. Ind. 1909, 1310); by heating nitrobenzene with charcoal and alkali (Farb. vorm. Fried. Bayer & Co., D. R. P. 210806; Chem. Zentr. 1909, 2, 163); by treating phenylhydrazine with bleaching powder solution (Brunner and Pelet, Ber. 1897, 284). Azobenzene can be prepared by the electrolytic reduction of nitrobenzene in the presence of alkali (Elbs and Kopp, J. Soc. Chem. Ind. 1898, 1137; Löb, Ber. 1900, 2329; Farb. vorm. Fried. Bayer & Co., D. R. PP. 121899 and 121900; Chem. Zentr. 1901, 2, 153; Farb. vorm. Meister, Lucius and Brüning; D. R. P. 141535; Chem. Zentr. 1903, (i.) 1283; and Farb. vorm. Weiler-ter-Meer, D. R. P. 138496; Chem. Zentr. 1903, (i.) 372).

Properties.—Azobenzene crystallises in large yellowish-red crystals belonging to the monoclinic system (Boeris, R. Accad. Lincei, [5] 8, i. 575), and to the rhombic system (Alexejeff, Chem. Soc. Abstr. 42, 965); melts at 68°, boils at 293°, and is readily soluble in alcohol and ether, insoluble in water. From benzene it crystallises with benzene of crystallisation in rhombic prisms, which lose benzene on exposure to the air. Weak reducing agents, such as ammonium sulphide or zinc-dust in alkaline solution (Alexejeff, Annalen, 207, 327) or phenylhydrazine (Walther, J. pr. Chem. 1896, 54, 433), convert azobenzene into hydrazobenzene, but benzidine is obtained when stronger reducing agents such as sulphurous acid or hydrogen iodide are employed (Bordenstein, D. R. P. 172569; J. Soc. Chem. Ind. 1907, 272), or the alcoholic solution is treated in the cold with stannous chloride and a little sulphuric acid (Schultz, Ber. 17, 464; Mentha and Heumann, Ber. 19, 2970). Azobenzene can also be electrolytically reduced to benzidine (Löb, Ber. 1900, 2329; when heated with ammonium hydrogen sulphite and alcohol under pressure, it is converted into benzidinesulphamic acid (Spiegel, Ber. 18, 1481). When melted with *p*-phenylenediamine in the presence of ammonium chloride, it yields a soluble induline dye (Farb. vorm. Fried. Bayer & Co., D. R. P. 53198; Ber. 1891, Ref. 137). Azobenzene yields a mixture of mono-, di-, and trinitroazobenzenes when treated with fuming nitric acid (Gerhardt and Laurent, Annalen, 75, 73; Janovsky and Erb, Ber. 18, 1133; 19, 2157; Janovsky, Monatsh. 7, 124; Werner and Stiasny, Ber. 1899, 3256): ordinary sulphuric acid dissolves it without alteration, whilst the fuming acid at 130° converts it into azobenzenemonosulphonic acid (Griess, Annalen, 154, 208; Janovsky, Monatsh. 2, 219); chromic acid oxidises it to carbon dioxide and nitrogen (De Coninck, Compt. rend. 1899, 128, 682). The bromine derivatives of azobenzene have been examined by Werigo (Annalen, 165, 189), Janovsky (*l.c.*), and Mills (Chem. Soc. Trans. 1894, 51).

AZOBENZENE RED *v.* Azo- colouring matters.

AZO-BLUE *v.* Azo- colouring matters.

AZO-COCCINE *v.* Azo- colouring matters.

AZO- COLOURING MATTERS.

History.—The colouring matters of this class contain one or more azo-groups —N : N— linking together aromatic radicals. The typical parent substance from which these compounds may be regarded as being derived is azobenzene. $C_6H_5{\cdot}N:N{\cdot}C_6H_5$, which has been known since the year 1834 (Mitscherlich, Annalen, 12, 311). The basic and acid derivatives of azobenzene are all colouring matters, the amino- derivative, aminoazobenzene, having been the first of these compounds which was prepared and introduced into commerce on anything approaching a large scale by the firm of Simpson, Maule, and Nicholson in 1863. This substance was prepared by the action of nitrous gases on aniline dissolved in alcohol, and was known in the market by the name of 'aniline yellow,' the true constitution of the colour being at the time unknown. The introduction of the first azo-colour into commerce is thus due to the firm above mentioned, although the production of the colour itself appears to have been previously observed by Mène (Compt. rend. 1861, 52, 311), Luthringer (Fr. Pat. 50901, Aug. 30, 1861), and Griess (Annalen, 1862, 121, 262, *note*). The first researches on the diazo- compounds (as distinguished from azo- compounds) were published in 1858 by Griess (Annalen, 106, 123), who in 1862 discovered a compound produced by the action of nitrous acid on aniline, to which he gave the name of 'diazoamidobenzol' (Annalen, 131, 257). The latter was, however, a true diazo- compound, and on comparing it with the 'aniline yellow' of commerce it was found that the two substances were isomeric, a discovery which led to the establishment of the true formula of aminoazobenzene by Martius and Griess in 1866 (Zeitsch. Chem. N. F. 2, 132). In this same year a brown dye was sent into the market by the firm of Roberts, Dale, and Co., of Manchester, and this colouring matter (known as Manchester Brown, Vesuvine, Phenylene Brown, or, more generally, Bismarck Brown) was investigated by Caro and Griess, and identified as an azo- compound in 1867 (Zeitsch. Chem. N. F. 3, 278). These chemists regarded it as triaminoazobenzene, but G. Schultz (Chemie des Steinkohlentheers, 2nd ed. 2, 193) showed that it is benzene-1 : 3-disazophenylenediamine. This compound still occupies an important place in the tinctorial industries, whilst the earlier known aminoazobenzene (aniline yellow) has been completely abandoned on account of its fugitive character. It is, however, used in the preparation of other azo-colouring matters and indulines. In 1876 a beautifully crystalline orange colouring matter made its appearance as a commercial product under the name of 'chrysoïdine,' its composition and constitution having been established by Hofmann (Ber. 1877, 10, 213), who showed that it was diaminoazobenzene. This colouring matter was discovered almost simultaneously by Caro and Witt, independently, in 1876, but was first introduced into commerce by the latter, the manufacture having been carried out by the firm of Williams, Thomas, and Dower, o Brentford and Fulham.

The manufacture of chrysoïdine was the first industrial application of Griess's discovery of the diazo- compounds, the colouring matter in question being prepared by the action of a diazo-salt (diazobenzene chloride) on *m*-phenylenediamine, and this manufacture was soon followed by the appearance of acid azo- compounds prepared by the action of diazosulphonic acids on phenols. The typical parent substance of these acid azo- colours may be regarded as hydroxyazobenzene, $C_6H_5{\cdot}N_2{\cdot}C_6H_4{\cdot}OH$, which was first prepared by Griess in 1864 (Phil. Trans. 153, 679). The general method by which the azo-colours are now prepared is an application of the reaction between diazo- salts and phenols in alkaline solution, first made known by Kekulé and Hidegh (Ber. 1870, 3, 233), the first colouring matters of this class having been introduced by Witt under the name of 'Tropæolines' (Chem. Soc. Trans. 1879, 35, 179), and simultaneously by Poirrier, of St. Denis, under the designation of 'Orange' of various brands. Since the first appearance of the acid azo- colours immense numbers of these compounds have been sent into commerce under various designations, the first patent having been taken out by Griess in 1877 (E. P. 3698), and being quickly followed by others, which will be referred to in due order. Of the acid azo- colours described in the earlier specifications, the most successful from an industrial point of view were those manufactured by the Badische Anilin- und Soda-Fabrik (Ber. 1879, 12, 1364), and by Meister, Lucius, and Brüning, of Höchst (*ibid.* 144).

The next step of importance in the industrial history of the azo- colours was the introduction of *disazo- compounds*, containing two azo- groups. The typical compound of this class is benzeneazobenzeneazophenol $C_6H_5{\cdot}N_2{\cdot}C_6H_4{\cdot}N_2{\cdot}C_6H_4{\cdot}OH$, discovered in 1877 by Caro and Schraube (Ber. 10, 2230). In 1879 appeared the 'Biebrich scarlet' of Nietzki (Ber. 1880, 13, 800, 1838), which was introduced by the firm of Kalle & Co. of Biebrich. This dyestuff is prepared by combining diazotised aminoazobenzenedisulphonic acid with β-naphthol, and was the first of the *secondary* disazo- compounds. The first *primary* disazo- colouring matter, 'Resorcin brown,' was discovered in 1881 by Wallach, who combined *two* molecules of a diazo- compound (m-xylidine and sulphanilic acid) with *one* molecule of a phenol (resorcinol). In 1884 a very important discovery in the history of azo-colouring matters was made by P. Böttiger, who found that the disazo- compound obtained by combining the tetrazo- salt prepared from benzidine with naphthionic acid possessed the valuable property of dyeing cotton direct, without the use of a mordant. This colouring matter was put on the market by the Aktiengesellschaft für Anilinfabrikation, under the name of 'Congo red.' This discovery has given rise to the production of a very large number of similarly constituted colouring matters, which appear on the market under the names of benzo-, Congo-, diamine-, and other dyestuffs. In the following year another important development was announced by the introduction of the first satisfactory black azo- colouring matter (naphthol black) for wool. This was discovered by Hoffmann and Weinberg, and placed on the market by L. Cassella & Co. In 1887 A. G. Green found that primuline, which he had discovered, dyed cotton direct, and that the yellow colouring matter when thus dyed on the fibre, could be diazotised and combined (developed) with β-naphthol, m-phenylenediamine, and similar 'developers,' thus giving rise to a series of new azo- dyestuffs (Ingrain colours). This discovery led to the manufacture of many azo-colouring matters which were capable of being similarly diazotised and developed on the fibre (*e.g.* diamine black), as also to the production of azo- colouring matters on the fibre by treating the fibre already dyed with an azo- colour with a diazo- compound (*e.g.* benzonitrol colours). In both cases darker and faster dyeings are obtained.

The first direct cotton black (diamine black, RO) was discovered in 1889 by Gans (Cassella & Co.), and in 1891 Hoffmann and Daimler prepared the first green colouring matter of this kind (diamine green).

A modified method of the process introduced in 1880 by Read Holliday and Sons, of producing insoluble azo- colouring matters directly on the fibre, has been largely developed of late years. The first example of this, viz. the combination of diazotised p-nitroaniline with β-naphthol ('paranitraniline red') still holds the place of greatest importance.

Manufacture.—The general method of preparing the azo- colours on a large scale depends upon the reaction between a diazo- salt, usually the chloride, and a phenol or phenolsulphonic acid in presence of an alkali, as typified by the following example :—

$C_6H_5{\cdot}N_2Cl+C_6H_5{\cdot}ONa$

Diazobenzene chloride. Sodium phenoxide.

$=C_6H_5{\cdot}N_2{\cdot}C_6H_4{\cdot}OH+NaCl.$

Benzeneazophenol.

Aminosulphonic acids or aminocarboxylic acids when diazotised react in a similar manner :

$$C_6H_4\left\langle\begin{matrix}N_2\\SO_3\end{matrix}\right\rangle + C_6H_5{\cdot}ONa$$

Diazosulphanilic acid. Sodium phenoxide.

$=SO_3Na{\cdot}C_6H_4{\cdot}N_2{\cdot}C_6H_4{\cdot}OH.$

Sulphobenzeneazophenol (sodium salt).

Preparation of the diazo- salts.—The amine to be diazotised is usually dissolved in about 10 parts of water and one equivalent of hydrochloric (more rarely sulphuric) acid. For diamines twice this amount of acid is taken. The solution[1] is now cooled by adding ice until the temperature is, in the case of aniline, the toluidines, the xylidines, &c., 0°–2°, or, in the case of the naphthylamines, the nitroanilines and diamines such as benzidine, tolidine, dianisidine, &c., 5°–10°. This is done by adding ice to the solution. More acid (1½–2 equivalents) is now added (or 3–4 in the case of diamines), and a solution of the calculated quantity of sodium nitrite is run in, sufficient being used to give a reaction with starch-iodide paper after the whole has been mixed for two or three minutes. (For velocity of diazotisation, *see* Hantzsch and Schumann, Ber. 1899, 32, 1691 ; Schumann, *ibid.* 1900, 33, 527 ; Tassilly, Compt. rend. 1913, 157, 1148 ; 1914, 158, 335, 489). In certain cases (*e.g.* α-naphthylamine, p-nitroaniline, &c.) it is better to add the nitrite all at once in order to avoid the formation of the diazoamino- compound. In diazotising such compounds as give an insoluble diazo-derivative, as, for example, *p*-sulphobenzeneazo-*a*-naphthylamine or *p*-acetylaminobenzeneazo-*a*-naphthylamine, and which themselves are insoluble in acids (under the above conditions) it is advisable to use an excess of nitrite and to stir the ice-cold mixture for several hours. Special methods have to be employed to diazotise amines containing several negative groups; the operation may often be effected by carrying it out in the presence of excess of 50 p.c. sulphuric acid, and Witt has shown (Ber. 1909, 42, 2953) that diazotisation is easily brought about in these cases by employing strong nitric acid. Other substances which are difficult to diazotise satisfactorily are those which are readily oxidised by the nitrous acid, such as the 1 : 2- and the 2 : 1-aminonaphthols and their sulphonic acids. In this case the diazotisation may be done in the presence of zinc or copper salts (compare E. P. 10235 of 1904; D. R. P. 171024, 172446; F. P. 353786) or by means of zinc nitrite. Another method is to diazotise in presence of an excess of acetic or oxalic acid (compare D. R. P. 155083, 175593, also E. P. 2946 of 1896).

---

[1] Some of the diazosulphonic acids, such as diazonaphthionic acid, are insoluble in water, and are therefore employed in a state of suspension.

Difficulties are often encountered in endeavouring to diazotise certain diamines. *o*-Phenylene- and tolylene-diamines cannot be diazotised, as they yield the azimino- derivatives, and, under the usual conditions, the meta-diamines furnish Bismarck brown; but if the diamine is run into a mixture of nitrite and acid the tetrazo-compound may be obtained (Griess, Ber. 1886, 19, 317; Täuber and Walder, Ber. 1897, 30, 2901; E. P. 1593 of 1888; D. R. P. 103685). In the case of *p*-phenylenediamine and certain diamines of the naphthalene series diazotisation is brought about indirectly, as the direct action of nitrous acid often leads to a mixture of the mono- with the bis-diazo- (or tetrazo-) compound. Either the corresponding nitroamine or the monoacetylated diamine is employed. This is diazotised and combined with a component in the usual way (*see* below), and then the nitro-group is reduced or the acetyl group hydrolysed when the free amino- group can then readily be diazotised. Some diamines, indeed, can only be diazotised as regards one amino-group, the other being quite unattacked. In such cases (*e.g.* *o*-nitro-*p*-phenylenediamine, 1 : 4-naphthylenediamine-2-sulphonic acid—the latter being diazotisable only in acetic or oxalic acid solution) the monodiazo-salt is combined with a component and then the remaining amino- group, which before resisted all attempts at diazotisation, is easily diazotised (compare Bülow, Ber. 1896 29, 2285; E. P. 2946 of 1896). (For further information on this subject, see Cain, The Chemistry and Technology of the Diazo- Compounds, Arnold, 1920.)

Combination (coupling) of the diazo- compound with a component (phenol or amine) to form an azo- dyestuff.[1]—Before the diazo- solution is prepared a solution of a phenol or amine is made ready so that no delay may occur before coupling takes place. As a general rule, phenols are combined in alkaline and amines in acid (acetic) solution. In the case of phenols or naphthols the substance is first dissolved in the calculated amount of sodium hydroxide, the solution diluted with water, and sodium carbonate added in sufficient quantity to ensure an alkaline reaction being obtained at the end of the combination (*i.e.* a little more than one molecule of sodium carbonate to each molecule of hydrochloric acid, so that sodium hydrogen carbonate may be formed). When phenolic sulphonic acids are the components, they may be dissolved in sodium carbonate instead of hydroxide. The phenolic solution, having been cooled to about 10°, is now ready, and the diazo- solution is run in gradually with constant stirring. Combination takes place at once,[1] and when all the diazo- solution has been added, the mixture must be tested to ensure an alkaline reaction, and the presence of a slight excess of the phenol (about 2–5 p.c. excess of the theoretical amount is usually taken). The next day the colouring matter is filtered through filter presses. If it has separated out, no further treatment is necessary, but if it is still partly or wholly in solution, it is 'salted out' (hot or cold) by adding common salt until a spot on filter paper shows only a faintly coloured rim. In rare cases the precipitation is effected by acidifying. The filtration is best effected by the aid of compressed air and the press cake is spread on trays and dried. The dry lumps are then ground in a mill, adjusted to 'type' or 'standard' by means of common salt, sodium sulphate, &c., and the product is then ready for the market. In cases where the possibility of the formation of a disazo- dyestuff is present (dihydroxy- compounds, *a*-naphthol, &c.), the coupling may advantageously be carried out in acetic acid solution.

The procedure adopted in the case of amines is very similar to the above. The amine is first dissolved in the appropriate amount of hydrochloric acid, the solution diluted and sufficient sodium acetate added to ensure that no free mineral acid remains at the end of the combination (in rare cases coupling is effected in mineral acid or alkaline solution). When the combination is complete, the dyestuff is filtered off either as it is or after having been rendered alkaline.

Many disazo- dyestuffs are prepared by combining two molecules of the same or different diazo- compounds with an aminonaphtholsulphonic acid. In this case combination is effected first in acid solution and then the monoazo- dyestuff thus formed is rendered alkaline, and the second molecule of diazo-compound added.

Position assumed by the azo- group in the formation of azo- colouring matters.—(*a*) *Benzene series*: When the para- position with respect to the amino- or hydroxy- group is occupied by a hydrogen atom, and no group, such as NO_2, SO_3H, or NR_3Cl, is in the meta- position, the azo- group enters the para- position in place of the hydrogen atom. (*b*) *Naphthalene series*: In corresponding compounds of the naphthalene series (*a*-naphthylamine, *a*-naphthol) the entering azo- group also takes up the para- position, but when, in *a*-naphthol, a sulphonic group is in the 3- or 5-position with respect to the hydroxy- group, or a nitro- or NR_3Cl- group is in the 3- position the azo- group enters the 2- position.

---

[1] For the mechanism of the reaction, *see* Charrier Gazz. chim. ital. 1914, 44, ii. 503; Auwers and Michaelis, Ber. 1914, 47, 1275; Meyer, Irschick and Schlösser, *ibid.* 1741; and Karrer Ber. 1915, 48, 1398.

[1] For the formation of diazo-oxy- compounds, *see* a paper by Dimroth and Hartmann, Ber. 1908, 41, 4012.

When the para- position is substituted, the azo- group enters the ortho-(2)- position, but if the para- substituent is a carboxy- group, this is usually displaced by the azo- group.

When diazo- compounds act on β-naphthylamine or β-naphthol. the azo- group enters position 1 (in the ortho- position with respect to the amino- or hydroxy- group). If the 1- position in β-naphthol is occupied by a carboxy- group, this is displaced (compare also Scharwin and Kaljanoff, Ber. 1908, 41, 2056 and article on DISAZO- and TETRAZO- COLOURING MATTERS).

Differing capacity for combination.—As will have been gathered from the preceding paragraph, the azo- group never enters the meta- position with respect to an amino- or hydroxy- group. Further, a component in which the para- position is occupied by a substituent group is not so readily attacked (in the ortho- position) as one that is not substituted (when the azo- group enters the para- position). Moreover, the capacity for combination depends also on the kind of diazo- compound employed, thus 2-naphthol-8-sulphonic acid and 2-naphthol-6 : 8-disulphonic acid in dilute solution do not combine at all with diazotised xylidine or naphthylamine, whilst diazotised aniline, aminoazobenzene, aminoazobenzenesulphonic acid and naphthylaminesulphonic acids couple easily with them. The combination with diazotised xylidine and naphthylamine can, however, be made to take place in concentrated solution. The diazo- compound of *p*-nitroaniline, in most cases, combines with extreme ease. Finally, 2-naphthylamine-6 : 8-disulphonic acid does not combine with any diazo- compound. (For measurement of the rate of formation of dyestuffs, *see* Goldschmidt, Ber. 1897, 30, 670, 2075; 1899, 32, 355; 1900, 33, 893; 1902, 35, 3534; Veley, Trans. Chem. Soc. 1909, 95, 1186.)

Considering now the formation of azo- dyestuffs from tetrazotised diamines, it should be noted that diamines of the type of benzidine furnish tetrazo- compounds which can either be combined with two molecules of one component (phenol or amine) or with one molecule each of two components, and the reaction can thus be divided into two stages. This holds good even when one component only is used; thus tetrazotised benzidine combines almost at once with one molecule of naphthionic acid, forming a so-called intermediate product; but the second molecule of naphthionic acid combines with this only slowly. Here also a difference in combining power is to be noted, thus tetrazotised benzidine combines more readily than does the corresponding compound from tolidine.

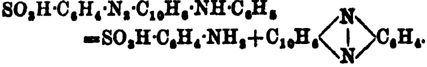
General properties.—(1) *Action of alkalis.* Hydroxyazo- dyes containing a sulphonic or carboxylic group usually form differently coloured salts, and consequently the addition of sodium hydroxide to their solutions produces a modification in the shade (compare Hewitt and Mitchell, Trans. 1907, 91, 1251). The isomeric colouring matters prepared from α- and β-naphthol show a characteristic difference in that only those derived from the former are changed by sodium hydroxide (*e.g.* benzoazurine, &c.).

(2) *Action of cold dilute acids.* Dyestuffs containing amino- or substituted amino- groups generally undergo a change when treated with dilute acid (compare Fox and Hewitt, Trans. 1908, 93, 333 ; Hewitt and Thomas, *ibid.* 1909, 95, 1292 ; Hewitt and Thole, *ibid.* 1909, 95, 1393 ; 1910, 97, 511). In the case of Congo red and methyl orange this change is so profound that these colouring matters can be used as indicators.

(3) *Action of cold concentrated sulphuric acid.* Nearly all azo- colouring matters give characteristic colour changes with this reagent, and it is often used as an aid in the detection of dyes. Mixtures of dyes, when covered with sulphuric acid, often reveal themselves by the various colours produced by the particles as they become dissolved. There are certain relationships between the colour of the solution of azo- dyes in sulphuric acid, and therefore of their absorption spectra and their chemical constitution. Thus the dyestuff from amino-azobenzenesulphonic acid and β-naphthol gives a green colour, those from the same (diazotised) amine and β-naphtholsulphonic acids, a blue, and those from aminoazobenzene and its homologues combined with β-naphtholsulphonic acids a red violet (compare Ber. 1880, 13, 1840 ; Vogel, Sitzungsber. K. Akad. Berlin, 1887, 34, 715 ; Ber. 1889, 22, 634, 2062 ; Schütze, Zeitsch. physikal. Chem. 1892, 9, 2 ; Grebe, Diss. Leipzig, 1892).

(4) *Action of hot hydrochloric acid.* Certain azo- colouring matters, such as, for example, aminoazobenzene, are decomposed when boiled with concentrated hydrochloric acid ; reduction and oxidation take place accompanied by chlorination. In the instance quoted phenylenediamine, aniline, and benzoquinone or its chloro- derivatives are produced (Wallach and Kölliker, Ber. 1884, 17, 395).

(5) *Action of hot sulphuric acid* (Witt, Ber. 1887, 20, 571). Azo- colouring matters which are derived from phenyl- or tolyl-β-naphthylamine by the action of diazo- compounds on these bases, when boiled with moderately dilute sulphuric acid, yield the bases, or their sulphonic acids, from which the diazo- compound was prepared, together with naphthazines. Thus the dyestuff obtained by combining diazotised sulphanilic acid with phenyl-β-naphthylamine, is decomposed into sulphanilic acid and phenonaphthazine :



$$SO_3H{\cdot}C_6H_4{\cdot}N_2{\cdot}C_{10}H_6{\cdot}NH{\cdot}C_6H_5$$
$$=SO_3H{\cdot}C_6H_4{\cdot}NH_2+C_{10}H_6\left\langle\begin{matrix}N\\|\\N\end{matrix}\right\rangle C_6H_4.$$

(6) *Action of nitric acid.* Azo- colouring matters are readily attacked by nitric acid, and the course of the reaction depends largely on the conditions of temperature and concentration. By the moderate action of nitric acid, the dyestuff may simply be nitrated, thus diphenylamine orange yields curcumeine and, by further action, azo- acid yellow, the dyestuffs in both cases, however, being accompanied by some nitrodiphenylamine produced by the fission of the azo- group. Also when flavazol

(diazotised toluidine combined with salicylic acid) is nitrated, it yields Persian yellow (*o*-nitrotolueneazosalicylic acid) (compare Ber. 1906, 40, 4207).

Methyl orange is decomposed even by cold dilute nitric acid; a methyl group is eliminated in the process, and dinitromonomethylaniline is produced. The presence of a diazo- compound can also be detected (Fox, Ber. 1908, 41, 1989).

Cold fuming nitric acid decomposes many azo- colouring matters (particularly those containing an amino- or hydroxy- group in the para- position with respect to the azo- group), with the production of the diazo- compound from which the dye is prepared and the nitro-derivative of the other component; thus, orange II yields diazotised sulphanilic acid and a nitro- derivative of β-naphthol, whilst methyl orange gives *op*-dinitrodimethylaniline, tetranitrodimethylaniline and diazotised sulphanilic acid (O. Schmidt, Ber. 1905, 38, 3201).

Certain hydroxyazo- compounds combine with two molecules of nitric acid forming unstable nitrates (Charrier and Ferreri, Gazz. chim. ital. 1913, 43, ii. 148; 1914, 44, i. 120, 165, 405).

Finally, warm nitric acid usually decomposes azo- dyestuffs, with the production of nitrophenols or bases.

(7) *Action of chlorine and bromine.* All azo-colouring matters are readily attacked by chlorine or bromine. Fission generally takes place at the azo- group with the production of halogenated phenols (compare Schmidt, J. pr. Chem. 1912, (ii.) 85, 235), but some dyestuffs are converted into substitution products (compare Ber. 1884, 17, 272).

(8) *Action of reducing agents.* Reducing agents, such as zinc-dust and water, zinc-dust and ammonia, or sodium hydroxide, zinc-dust and dilute acids, tin and hydrochloric acid, stannous chloride, a solution of sulphur in sodium sulphide (Cobenzl, Chem. Zeit. 1915, 39, 859), or sodium hyposulphite (technically known as 'hydrosulphite') (Grandmougin, Ber. 1906, 39, 2494, 3561, 3929; compare also J. pr. Chem. 1907, (ii.) 76, 124; Franzen and Stieldorf, J. pr. Chem. 1907, (ii.) 76, 467; O. Fischer, Fritzen and Eilles, J. pr. Chem. 1909, (ii.) 79, 562) attack the azo- group and convert it into two amino- groups; thus:

$$NH_2{\cdot}C_6H_4{\cdot}N:N{\cdot}C_6H_5+2H_2$$
$$=NH_2{\cdot}C_6H_4{\cdot}NH_2+C{\cdot}H_5{\cdot}NH_2.$$

The base which was used to provide the diazo-compound is thus regenerated, whilst the other component is converted into its amino-derivative.

By careful reduction with zinc-dust, dyestuffs obtained by the combination of diazotised aminoazobenzenesulphonic acid with phenols yield the aminoazosulphonic acid without the latter undergoing reduction. Further, nitro-azo- dyestuffs can be reduced to the corresponding aminoazo- dyestuffs with sodium sulphide. The reduction of azo- dyestuffs is a useful means of attacking the problem of their constitution, although the operation requires considerable care (compare Witt, Ber. 1886, 19, 1719; 1888, 21, 3468, and especially the references quoted in connection with reduction by hydrosulphite).

Azo- dyestuffs are also readily reduced by titanous chloride, and a process for their estimation by titration with this reagent has been worked out by Knecht (J. Soc. Dyers, 1903, 19, 169; Ber. 1903, 36, 166, 1549; 1907, 40, 3819). A detailed account of the method of carrying out this and other methods of reduction[1] will be found in Knecht and Hibbert's New Reduction Methods in Volumetric Analysis (Longmans).

(9) *Action of sodium bisulphite.* When boiled with aqueous-alcoholic sodium bisulphite solution, hydroxyazo- colouring matters give sulphurous esters, the hydroxyl group being converted into $O{\cdot}SO_2Na$ (Voroshcov, J. Russ. Phys. Chem. Soc. 1911, 43, 771; 1915, 47, 1669; published in French in Ann. Chim. 1916, [ix.] 6, 381; 1917, 7, 50). In aqueous solution fission takes place (Lepetit and Levi, Gazz. chim. ital. 1911, 41, i. 675).

Identification of azo- colouring matters on the fibre. This is carried out by observing the action on the dyed fabric of various reagents, for which various tables have been constructed (compare Cain and Thorpe, The Synthetic Dyestuffs, 4th ed. 1918; Lunge, Chemisch-technische Untersuchungensmethoden, Eng. trans., edited by Keane, 1911; Green, The Analysis of Dyestuffs).

Direct formation of azo- colours in the fibre.—The production of an insoluble azo- dyestuff in the fibre was first achieved by T. and R. Holliday (E. P. 2757 of 1880), who impregnated the fibre with α- or β-naphthol, passed it then through a diazo- solution, and finally developed the colour by treatment with alkali. An improvement on this process was introduced by the Farbwerke vormals Meister, Lucius und Brüning, in 1889, which consisted in 'padding' the fibre (generally cotton) with the sodium salt of a phenol (usually β-naphthol), and passing the cloth through a diazo- solution, the free mineral acid of which has been neutralised by adding sodium acetate. This process is very largely used at the present day, and is applied to the greatest extent to the production of the so-called 'para-red' (the azo- colour obtained by combining diazotised *p*-nitroaniline with β-naphthol). The colouring matters produced in this way will now be described.

Paranitraniline Red. The colouring matter was first prepared in substance by Meldola (Chem. Soc. Trans. 1885, 47, 657) by combining diazotised *p*-nitroaniline with β-naphthol in alkaline solution. As stated above, it is now almost entirely produced on the fibre. The goods are soaked in a bath containing sodium β-naphthoxide and Turkey-red oil, or thickening materials, squeezed out and dried at 65°–80°. They are then passed through the diazo- solution, washed and soaped. In order to avoid preparing the diazo- solution in the dye-house, various preparations may be used. Thus, **Paranitraniline extra N** paste is a mixture of *p*-nitroaniline with the calculated amount of sodium nitrite, and needs only to be stirred slowly into the necessary quantity of hydrochloric or sulphuric acid, ice, and water, to produce the diazo-solution. A similar product is **Benzonitrol**

---

[1] For the estimation with sodium hyposulphite, *see* Grandmougin and Havas, Chem. Zeit. 1912, 36, 1167.

paste. Other preparations contain the diazo- compound in a suitable form for keeping. Thus, **Nitrosamine Red** is the sodium salt of *p*-nitro*anti*diazobenzene (which is very stable) and furnishes the true diazo- solution when mixed with dilute acid. **Azophor Red, Azogen Red** and **Nitrazol C,** are mixtures of the diazo-sulphate with sodium sulphate (whereby sodium hydrogen sulphate is produced); they are dissolved in water, the solution filtered, if necessary, and neutralised before use with sodium acetate or hydroxide. **Paranil** is a stable compound of diazotised *p*-nitroaniline and naphthalene-β-sulphonic acid. Paranitraniline red is used as a substitute for the red Congo dyestuffs and for Turkey red. It is extracted from the fibre when treated with organic solvents, and when the fibre is heated to 180°–200° the dyestuff partly sublimes. (For the formation of paranitraniline red, *see* Pomeranz, Zeitsch. Farben. Ind. 1906, 5, 184; Erban and Mebus, Chem. Zeit. 1907, 31, 663, 678, 687; Lichtenstein, Zeitsch. Elektrochem. 1908, 14, 586; Prud'homme and Colin, Rev. Gen. Mat. Col. 1909, 13, 1, 66; Bull. Soc. chim. 1909, (iv.) 5, 779; Bucherer, and Wolff, Zeitsch. angew. Chem. 1909, 22, 731; Justin-Mueller, Bull. Soc. chim. 1910, (iv.) 7, 60.) When in the form of a lake it is known as **Pigment Red G** (M.[1]); **Autol Red BGL** (B.); **Sitara Red** (T. M.).

Metanitraniline Orange and **Nitro-*o*-toluidine Orange**. Prepared as above from diazotised *m*-nitroaniline or *p*-nitro-*o*-toluidine and β-naphthol. The former gives yellowish and the latter reddish shades of orange. Their use is not very extensive, as they are not fast to rubbing, and the colours sublime on keeping. An orange free from these disadvantages can, however, be obtained by using *m*-nitro-*p*-phenetidine.

Nitro-*o*-toluidine orange, in the form of a lake, is sold as **Pigment Orange R** (M.); **Fast Orange** (By.).

Nitrophenetidine Rose or **Blue-red**. Here *o*-nitro-*p*-phenetidine is used as the diazotised base.

Azophor Rose A (M.) is the stabilised diazo-compound of *o*-anisidine. The compound of diazotised *o*-anisidine and β-naphthol is used as a lake under the names **Pigment Purple A** (M.); **Sudan R** (A.).

Naphthol Rose is the stabilised diazo- compound of *p*-nitro-*o*-anisidine.

Literature.—E. P. 25756 of 1897; D. R. P. 98637; F. P. 271908.

Chloranisidine Scarlet (M.) is produced on the fibre by the aid of diazotised *p*-chloro-*o*-anisidine.

Naphthylamine Bordeaux. Prepared on the fibre from diazotised α-naphthylamine[2] and β-naphthol. The dyestuff is used also as a pigment colour under the names **Carminaph Garnet** (D. H.), **Cerotine Scarlet 2 R** (C. J.), &c.

Azo Turkey Red is produced by treating cloth padded with β-naphthol with diazotised β-naphthylamine. It is a bright scarlet, which, however, is not very fast.

Fast Azo Garnet. Prepared from diazotised *o*-aminoazotoluene and β-naphthol. It is also manufactured in substance and is used for colouring oils and varnishes under the names **Oil Scarlet** (M) (K) (W), **Red B, Oil soluble, extra conc.** (Remy), **Cerotine Ponceau 3 B** (C. J.), and **Fat Ponceau R** (K).

Benzidine and **Tolidine Puce.** Obtained from tetrazotised benzidine or tolidine and β-naphthol. Dark garnet to brown shades are produced which, however, are not fast to light. Rather yellower shades result by using tetrazotised diaminocarbazole instead of these diamines; when treated with copper salts the tints are very fast to light.

Dianisidine Blue. Tetrazotised dianisidine is combined on the fibre with β-naphthol in presence of copper salts. The tetrazo-compound is also put on the market as **Azophor Blue D,** a mixture of the tetrazo- compound and aluminium sulphate which has been dried in a vacuum at 45°. The colour is very fast to light, soap, and rubbing. **Azophor Black S** is a stabilised mixture of the tetrazo- compound of dianisidine with other diazo- compounds (from benzidine, *p*-nitroaniline, and especially *m*-nitroaniline, *cf.* D. R. P. 83963).

The production of black insoluble colours in the fibre was first effected by the Farbwerke vorm. Meister, Lucius und Brüning. The cloth is padded with β-naphthol and tragacanth, and treated with a mixture of the tetrazo-compounds of dianisidine and certain other bases. The mixture of bases sold for this purpose is known as **Azo Black Base O,** and the diazo- compounds are put on the market under the name of **Azophor Black S.** Cassella & Co. have introduced a black obtained by padding the cloth with 1 : 6- or 1 : 7-aminonaphthol, and then passing it through diazotised *p*-nitroaniline so as to form the disazo- colouring matter. The aminonaphthol is put on the market as **Amidonaphthol BD** and **3 B,** and both brands are mixtures of the two aminonaphthols mentioned. Full black colours are obtained which are fast to soap and chlorine, but they are not very easily applied in printing. A black, also introduced by the same firm, is produced from **Azotol C,** which is an asymmetric dialkylated di-*p*-diaminoazobenzene (it is identical with Kinzlberger's **Ice Black**). The base is diazotised and combined with β-naphthol on the fibre in the usual way. The latter firm also has introduced the use of the diazo- compound of aminochrysoïdine, and of the tetrazo- compound of *pp*-diaminodiphenylamine for the production of black colours. Other tetrazo-compounds recommended are these of amino-benzene-azo-α-naphthylamine (By.) and diamino-dimethylcarbazole (M.).

Nigrophor BASF (B.). Diazotised 2 : 5-dichloroaniline is combined with 1-amino-8-naphthol-5-sulphonic acid in acid solution, the monoazo- dye is dissolved in sodium hydroxide solution, mixed with *p*-nitrophenylnitrosamine and cloth padded with the solution. After being dried and exposed to the air a greenish-black is produced on the fibre. α-Naphthylamine may also be used instead of *p*-nitroaniline.

---

[1] See p. 458 for the full names of firms of which these letters are a contraction.

[2] Finely ground α-naphthylamine sulphate is sold as α-Naphthylamine salt S, and a stable compound of diazotised α-naphthylamine with α-naphthalene-disulphonic acid as Naphthol garnet 50 p.c. paste.

Literature.—E. P. 1002 of 1895; D. R. P. 116676; F. P. 24424, 245211.

Another process of producing azo- colouring matters on the fibre is by the use of primuline (*q.v.*). When cotton dyed with this dyestuff is treated with a solution containing hydrochloric acid and sodium nitrite, the dyestuff is diazotised. The cloth is now passed through a bath containing the 'developer,' consisting of a solution of an amine or a phenol. β-Naphthol is mostly used in giving **Ingrain-** or **Primuline Red**. An orange colour is obtained with resorcinol (**Ingrain Orange**), and a brown with *m*-phenylenediamine (**Ingrain Brown**). Many direct-dyeing cotton colours which contain a diazotisable amino- group (for example, diamine black BH) acquire a faster, deeper, and modified shade when similarly diazotised on the fibre and developed with β-naphthol or *m*-phenylenediamine.

In the succeeding portion of this article it is proposed to give an account of the most important azo- colours which are at present in commerce. Each colour will be treated of under its commercial name; its chemical formula given, and the mode of preparation and general properties briefly described.

Unless otherwise stated, it may be assumed that colouring matters containing a sulphonic or carboxylic group are placed on the market in the form of their sodium salts.

The following abbreviations are used for the names of firms [1]:—

(A.) = Aktiengesellschaft für Anilinfabrikation, Berlin.
(B.) = Badische Anilin- und Soda-Fabrik, Ludwigshafen a/Rhein.
(B.K.) = Leipziger Anilinfabrik Beyer & Kegel.
(By.) = Farbenfabriken vorm. Fr. Bayer & Co., Elberfeld.
(C.) = Leopold Cassella & Co., Frankfurt a/Main.
(C. J.) = Carl Jäger, G. m. b. H., Düsseldorf-Derendorf.
(Cl. Co.) = The Clayton Aniline Co., Ltd., Clayton, Manchester.
(Claus & Co.) = Claus & Co., Clayton, Manchester (since 1917 amalgamated with Levinstein, Ltd.).
(D.) = Wülfing, Dahl & Co., Barmen.
(D. H.) = Dye Works, formerly L. Durand, Huguenin, & Co., Basle.
(F.) = A. Fischesser & Co., Lutterbach.
(G.) = Aniline Colour- and Extract-Works, formerly John R. Geigy, Basle.
(H.) = Read Holliday and Sons, Ltd., Huddersfield (now British Dyestuffs Corporation, Ltd., Huddersfield branch).
(I.) = Société pour l'Industrie Chimique, (formerly Bindschedler und Busch), Basle.
(K.) = Kalle & Co., Biebrich a/Rhein.
(K. S.) = Sandoz & Co. (formerly Kern and Sandoz), Basle.
(L.) = Farbwerk Mülheim (formerly A. Leonhardt & Co.), Mülheim, near Frankfurt.
(Lev.) = Levinstein, Ltd., Blackley, Manchester (now British Dyestuffs Corporation, Ltd., Blackley branch).
(M.) = Farbwerke vorm. Meister, Lucius, und Brüning, Höchst a/Main.
(N. I.) = Farbwerk Griesheim, Nötzel, Istel & Co., Griesheim a/Main.
(O.) = Chemische Fabrik Griesheim-Elektron, Werk Oehler (formerly K. Oehler), Griesheim.
(P.) = Société Anonyme des Matières Colorantes & Produits Chimiques de St. Denis, Paris.
(Sch.) = The Schöllkopf Aniline and Chemical Company, Buffalo, U.S.A. (since 1917 is included in The National Aniline and Chemical Co., Inc., New York).
(T. M.) = Chemische Fabriken vorm. Weiler ter Meer, Uerdingen a/Rhein.
(W.) = Williams Bros. & Co., Hounslow, Middlesex.

Also E. P. = English Patent; D. R. P. = German Patent; F. P. = French Patent; A. P. = American Patent.

I. Basic Azo- Compounds.

Aniline Yellow; Aminoazobenzene

$$C_6H_5{\cdot}\underset{[1]}{N_2}{\cdot}C_6H_4{\cdot}\underset{[4]}{NH_2}$$

This compound, discovered by Mène in 1861 (*l.c.*), and introduced into commerce by Simpson, Maule, and Nicholson in 1863, is interesting as being the first azo- colour made on a manufacturing scale. It was formerly prepared by passing nitrous acid gas into an alcoholic solution of aniline. As a colouring matter it is now of no importance, but is largely used as the starting-point in the manufacture of other azo- colours and of indulines. In practice this compound cannot be prepared directly by the action of one molecule of nitrous acid on two molecules of aniline, since diazoaminobenzene is always the first product of this reaction:

$$2C_6H_5{\cdot}NH_2,HCl+NaNO_2$$
$$=C_6H_5{\cdot}N_2{\cdot}NH{\cdot}C_6H_5+NaCl+HCl+2H_2O.$$

The diazo- compound is slowly converted into the isomeric aniline yellow on being kept for some time in contact with aniline and an aniline salt:

$$C_6H_5{\cdot}N_2{\cdot}NH{\cdot}C_6H_5=C_6H_5{\cdot}N_2{\cdot}C_6H_4{\cdot}NH_2.$$

---

[1] Since the last edition of this 'Dictionary' was published a great revival of the Dye Industry has taken place in England, France, Italy, America, Sweden, and Japan. The principal new companies which have been formed are British Dyes, Ltd. (later incorporated with Levinstein Ltd., under the name of British Dyestuffs Corporation, Ltd.), Compagnie Nationale des Matieres Colorantes et Produits Chimiques (France), Italian National Dyestuff Co. (Italy), The National Aniline and Chemical Co., Inc. (America), The A.B. Kemisk Industrie (Sweden), and The Japan Dyestuff Co. (Japan). Other new firms manufacturing azo- colouring matters are indicated under the particular dyes.

The manufacture is carried out as follows: 100 kilos. of aniline are mixed with 36 kilos. of concentrated hydrochloric acid, the mixture cooled (from outside) to about 18°, and a solution of 15·5 kilos. of sodium nitrite in 18 kilos. of water and 18 kilos. of saturated sodium chloride solution added at first fairly rapidly, so that the temperature rises to 25°, and then more slowly, the temperature being kept below 28° by outside cooling. This operation takes about 7–8 hours. After 24 hours the change of diazoaminobenzene into aminoazobenzene is complete. The salt solution is now drawn off, the residue stirred with 96 kilos. of hydrochloric acid and 64 kilos. of water, and the aminoazobenzene hydrochloride is filtered off, washed with 2 p.c. hydrochloric acid, centrifuged and dried at 60°. The yield is 41 kilos. of dry aminoazobenzene hydrochloride. The old aniline yellow was the oxalate of the base. The free base crystallises in yellow rhombic prisms. M.p. 127·4°; b.p. above 300°. The hydrochloride crystallises in steel-blue needles. Base slightly soluble in hot water, readily soluble in alcohol. Yellow solution coloured red by hydrochloric acid.

Literature.—Mène, 1861 (*see* above); Dale and Caro, E. P. 3307 of 1863; Martius und Griess, Zeitsch. f. Chem. 1866, 2, 132; Kekulé, *ibid.* 2, 689; Witt and Thomas, Chem. Soc. Trans. 1883, 43, 112; Friswell and Green, *ibid.* 1885, 47, 917; and 1886, 49, 746; Stadel and Bauer, Ber. 1886, 19, 1953; Paul, Zeitsch. angew. Chem. 1896, 9, 689; Jansen, Zeitsch. Farb. Ind. 1913, 12, 197.

Spirit Yellow R (K.); **Yellow Fat Colour**; *o*-Aminoazotoluene

$$CH_3{\cdot}C_6H_4{\cdot}N_2{\cdot}C_6H_3(CH_3){\cdot}NH_2$$

Prepared similarly to aniline yellow, from *o*-toluidine.

Literature.—Ber. 1877, 10, 662.

Butter Yellow; **Oil Yellow** (W.); Dimethylaminoazobenzene $C_6H_5{\cdot}N_2{\cdot}C_6H_4{\cdot}N(CH_3)_2$. Prepared by the action of diazobenzene chloride on dimethylaniline. Substance forms yellow leaflets of m.p. 115°; soluble in dilute hydrochloric acid with a red colour; precipitated by alkali. Soluble in sulphuric acid[1] with a yellow colour, becoming red on dilution.

Literature.—Griess, Ber. 1877, 10, 528.

Chrysoïdine (most firms); **Chrysoïdine Y** (H). (W.) (Marden, Orth, and Hastings Corp. New York) (Sch.); **Chrysoïdine JEE** (C. J.) (P.); **Chrysoïdine Crystals**[2]; **Chrysoïdine Small Crystals** (T. M.)

Diaminoazobenzene $C_6H_5{\cdot}\underset{[1]}{N_2}{\cdot}C_6H_3\underset{[2:4]}{(NH_2)_2}$.

This colouring matter is prepared by mixing a solution of diazobenzene chloride with a solution of *m*-phenylenediamine. In practice a known weight of aniline is dissolved in dilute hydrochloric acid and diazotised, the solution being diluted so as to contain about 2–3 p.c. of diazo- salt. This and a dilute solution of phenylenediamine hydrochloride are run simultaneously into a sodium chloride solution, and the colouring matter is filtered off through a filter press. The press cake is then dissolved in hot dilute hydrochloric acid, the hot solution filtered, and hydrochloric acid added to the filtrate. The chrysoïdine separates in small needles, which are filtered off, centrifuged, and dried at 50°. The free base forms yellow needles; m.p. 117·5°. Slightly soluble in water, readily in alcohol; solutions orange. The commercial product is the hydrochloride $C_{12}H_{12}N_4,HCl$, which forms beautiful blackish-green prisms with a metallic lustre. The strong solution of the salt solidifies on rapid cooling to a red jelly. Dissolves in sulphuric acid with a brownish-yellow colour.

Literature.—Hofmann, Ber. 1877, 10, 213; Witt, *ibid.* 350 and 654; Griess, *ibid.* 389.

Chrysoïdine R (H.) (W.) (G.) (I.) (Sch.); **Chrysoïdine REE** (P.); **Cerotine Orange** (C. J.); **Gold Orange for Cotton** (T. M.) (D. H.); Benzeneazo-*m*-tolylenediamine

$$C_6H_5{\cdot}N_2{\cdot}C_6H_2(CH_3)(NH_2)_2$$

Prepared from aniline and *m*-tolylenediamine as in the preceding case. The free base melts at 165°–166°. The commercial product is the hydrochloride, which forms yellowish-brown lumps. Dissolves in sulphuric acid with a greenish-yellow colour.

Chrysoïdine R (D. H.) (C.); Tolueneazo-*m*-tolylenediamine $CH_3{\cdot}C_6H_4{\cdot}N_2{\cdot}C_6H_2(CH_3)(NH_2)_2$. Prepared as above from *o*-toluidine and *m*-tolylenediamine. The commercial product is the hydrochloride. It is a crystalline violet powder which gives a brown colour in sulphuric acid.

Meta Chrome Brown B (A.) (Brotherton & Co.); Dinitrophenolazo-*m*-tolylenediamine

$$OH{\cdot}C_6H_2(NO_2)_2{\cdot}N_2{\cdot}C_6H_2(CH_3)(NH_2)_2$$

Prepared from picramic acid and *m*-tolylenediamine. It is a brown paste giving a dark orange-red solution in hot water. It yields a red solution with sulphuric acid.

Literature.—E. P. 13213 of 1899; 10294 of 1910; D. R. P. 112819, 118013; A. P. 657064, 657065.

Chrome Brown P (P.); Dinitrophenolazo-*m*-aminophenol $OH{\cdot}C_6H_2(NO_2)_2{\cdot}N_2{\cdot}C_6H_3(OH){\cdot}NH_2$. Prepared from picramic acid and *m*-aminophenol. Introduced in 1903.

Literature.—D. R. P. 169579; F. P. 336559.

Meta Chrome Bordeaux R, B (A.). Prepared from diazotised picramic acid and a *m*-aminoarylsulphamide. The **R** brand gives an orange-brown solution in hot water, and a reddish-violet solution in sulphuric acid, which yields a brown precipitate on dilution.

Literature.—E. P. 4028 of 1902; D. R. P. 135016; A. P. 704825, 704826.

Diazine Green S (K.); **Janus Green B** (M.); **Union Green B** (M.). Prepared from diazotised safranine and dimethylaniline. The commercial product is a brown or dark-green powder giving an olive-green solution with sulphuric acid. **Janus Green G** is a dyestuff of analogous constitution.

---

[1] In these colour reactions 'sulphuric acid' means the ordinary concentrated acid of 95 96 per cent.

[2] Chrysoïdine Crystals also contain the homologues from *o*- and *p*-toluidine.

Literature.—E. P. 7337 of 1897; F. P. 265438; D. R. P. 95668.

II. Acid Azo- Compounds.

A. Sulphonic Acids of Aminoazo- Compounds.

Acid Yellow (A.); **Fast Yellow** (B.) (By.); **Fast Yellow G**; **New Yellow L** (K.); **Yellow SS** (P.); **Fast Yellow extra** (By.). This colouring matter is a mixture of the sodium salts of mono- and di- sulphonic acids of aminoazobenzene

$$HSO_3\cdot C_6H_4\cdot N_2\cdot C_6H_4\cdot NH_2 \text{ and}$$
$$HSO_3\cdot C_6H_4\cdot N_2\cdot C_6H_3(HSO_3)\cdot NH_2$$

Prepared by the action of fuming sulphuric acid on aniline yellow (3–5 parts acid to one of aminoazobenzene). Solution not precipitated by alkali; colour dissolves in sulphuric acid with a brownish-yellow colour becoming redder on dilution. Solution gives a precipitate with barium chloride, but not with calcium chloride. The corresponding colouring matter from aminoazotoluene is somewhat more orange in shade, and is known as **Fast Yellow Y** (B.); **Fast Yellow R** (K.).

Literature.—Grässler, E. P. 43 of 1879; A. P. 253598; D. R. P. 4186, 7094; Chem. Ind. 1879, 2, 48, 346; Griess, Ber. 1882, 15, 2187; Eger, Ber. 1889, 22, 847.

Methyl Orange (Consolidated Colour and Chemical Co., New Jersey); **Helianthin** (B.); **Orange III.** (P.) (T. M.) (D. H.) (W.); **Gold Orange** (A.); *p*-Sulphobenzeneazodimethylaniline $\underset{[4]}{HSO_3}\cdot C_6H_4\cdot \underset{[1]}{N_2}\cdot C_6H_4\cdot \underset{[4]}{N(CH_3)_2}$. Prepared by the action of diazotised sulphanilic acid [1] on dimethylaniline. Solution of colouring matter orange, and not precipitated by alkali; dilute acids produce a crystalline precipitate, the crystals having a violet reflection (the free sulphonic acid). The substance dissolves in sulphuric acid with a yellow colour becoming red on dilution.

Literature.—Griess, Ber. 1877, 10, 528.

Orange IV. (most firms); **Tropæoline OO** (C.); **Acid Yellow D** (A.); **Orange N** (B.) (I.); **New Yellow** (By.); *p*-Sulphobenzeneazodiphenylamine $\underset{[4]}{HSO_3}\cdot C_6H_4\cdot \underset{[1]}{N_2}\cdot C_6H_4\cdot \underbrace{NH\cdot C_6H_5}_{[4]}$. Produced by the action of diazotised sulphanilic acid on diphenylamine dissolved in alcohol or crude carbolic acid. The product is thrown on an open filter, the paste dissolved in concentrated aqueous potassium carbonate and precipitated by adding sodium hydroxide. The colouring matter is not very readily soluble in water; the solution is yellow, and when strong deposits crystals on cooling. Substance dissolves in sulphuric acid with a violet colour, becoming redder and giving a greyish precipitate of the free sulphonic acid on dilution. The aqueous solution of the substance is coloured red by dilute acids.

When nitrated this colour furnishes a mono-nitro- derivative together with a mixture of mono-, di-, and tri- nitrodiphenylamine; moderate nitration yields a yellow colouring matter which is found in commerce under the names of **Citronine** (D. H.) (I.) (L.) (K. S.) (O.); **Curcumeine** (A.); **Azoflavine 3 R** ex. conc (T. M.); **Citronine NE** (P.); **Indian Yellow R** (By.) (C.) (H.). More energetic nitration of Orange IV. furnishes **Azo Acid Yellow** (A.); **Azo Yellow** (K.) (K. S.) (M.); **Azo Yellow 3 G**, ex. conc. (T. M.); **Citronine 2 AEJ** (P.); **Azoflavine S new** (B.); **Indian Yellow G** (By.). Both dyestuffs are ochre-yellow powders and give with sulphuric acid reddish-violet and magenta-red solutions respectively.

Metanil Yellow (most firms); **Orange MN** (I.); **Tropæoline G** (C.); **Yellow M** (P.); **Metanil Yellow GR extra** (T. M.); *m*-Sulphobenzeneazodiphenylamine $\underset{[3]}{HSO_3}\cdot C_6H_4\cdot \underset{[1]}{N_2}\cdot C_6H_4\cdot \underbrace{NH\cdot C_6H_5}_{[4]}$. Prepared in the same manner as the preceding from *m*-diazobenzenesulphonic acid [1] and diphenylamine. Aqueous solution orange, giving no precipitate with alkalis, becoming red and precipitating with dilute acids. Dissolves in sulphuric acid with a dull violet colour, becoming magenta-red on dilution.

Metanil Yellow S; **Acid Yellow 2 G** (O.); is produced by sulphonating the preceding colouring matter.

Literature.—E. P. 1226 of 1879; 4966 of 1880; Paul, Zeitsch. angew. Chem. 1896, 9, 686.

Metanil Yellow Brominated (P.). Prepared by the action of bromine on metanil yellow; has similar reaction.

Literature.—E. P. 5696 of 1882; D. R. P. 26642; F. P. 140114.

Jaune Solide N (P.); Sulphotolueneazodiphenylamine $HSO_3\cdot C_7H_6\cdot \underset{[1]}{N_2}\cdot C_6H_4\cdot \underbrace{NH\cdot C_6H_5}_{[4]}$. Prepared from diazotised *p*-toluidine-*o*-sulphonic acid and diphenylamine; in its general properties it resembles the two preceding dyes.

Literature.—Roussin and Poirrier, E. P. 4491 of 1878.

Archil Substitute V; *p*-Nitrobenzeneazo-*a*-naphthylamine-4-sulphonic acid

$$NO_2\cdot C_6H_4\cdot N_2\cdot C_{10}H_5(NH_2)\cdot HSO_3$$

Prepared by the action of diazotised *p*-nitroaniline on naphthionic acid [2] in weakly acid solution. Solution precipitated by acids and alkalis. Sulphuric acid gives a magenta-red solution, becoming brownish and precipitating on dilution.

Literature.—Roussin and Poirrier, E. P. 4490 of 1878; D. R. P. 6715; F. P. 127221; Chem. Ind. 1879, 2, 292.

Archil Substitute 3 VN (P.); *p*-Nitrobenzeneazo-*a*-naphthylaminesulphonic acid

$$NO_2\cdot C_6H_4\cdot N_2\cdot C_{10}H_5(NH_2)\cdot SO_3H$$

Prepared by the action of diazotised *p*-nitroaniline on *a*-naphthylamine-5-sulphonic acid.

---

[1] For detailed information on the manufacture of sulphanilic acid and its homologues *see* Mühlhäuser, Dingl. poly. J. 1887, 264, 181 and 238; Paul, Zeitsch. angew. Chem. 1896, 9, 686.

[1] *m*-Aminobenzenesulphonic acid is prepared by sulphonating nitrobenzene and reducing the *m*-nitrobenzenesulphonic acid thus formed.

[2] Naphthionic acid is manufactured on a large scale by heating naphthylamine acid sulphate, mixed with a little oxalic acid, to about 180°.

Forms a brown powder giving a red solution in water or sulphuric acid.

Literature.—E. P. 12692 of 1887; D. R. P. 45787; F. P. 185908.

Azo Cardinal G (A.); *p*-Nitrobenzeneazobenzylethylanilinesulphonic acid

$$NO_2\cdot C_6H_4\cdot N_2\cdot C_6H_4\cdot N(C_2H_5)\cdot CH_2\cdot C_6H_4\cdot SO_3H$$

Prepared by the action of diazotised *p*-nitroaniline on benzylethylanilinesulphonic acid. A brick-red powder giving a reddish-yellow solution in water and a yellow solution in sulphuric acid, becoming red on dilution

Literature.—D. R. P. appl. A 3551.

Palatine Chrome Brown W (B.); **Acid Alizarine Brown B** (M.); **Anthracyl Chrome Brown D** (D.); *p*-Sulpho-*o*-hydroxybenzeneazo-*m*-phenylenediamine

$$SO_3H\cdot C_6H_3(OH)\cdot N_2\cdot C_6H_3(NH_2)_2$$

Prepared from diazotised *o*-aminophenol-*p*-sulphonic acid and *m*-phenylenediamine. A black-brown powder dissolving in hot water with an orange-brown colour, and in sulphuric acid to give a dark orange-brown solution.

Literature.—A. P. 628814; D. R. P. 78409; F. P. 284741.

Omega Chrome Black PV, PB (K. S.); **Omega Chrome Blue B, R** (K. S.) are chrome colours prepared from *o*-diazophenols and aryl-1 : 8-naphthylaminesulphonic acids.

Literature.—E. P. 22738 of 1905; D. R. P. 175625; F. P. 359222; A. P. 841371.

Acid Anthracene Brown R (By.) is prepared from diazotised picramic acid and substituted phenylenediaminesulphonic acids. The aqueous solution is reddish-brown, and that in sulphuric acid is reddish-violet, becoming yellowish-brown on dilution.

Anthracyl Chrome Green (D.); Dinitrophenolazo-*a*-naphthylamine-4-sulphonic acid

$$OH\cdot C_6H_2(NO_2)_2\cdot N_2\cdot C_{10}H_5(SO_3H)\cdot NH_2$$

Prepared by the action of diazotised picramic acid on naphthionic acid. Solution in water is reddish-brown, and in sulphuric acid bluish fiery red.

Literature.—D. R. P. 142153.

Alkali Brown (D.); **Benzo Brown 5 R** (By.); **Alkali Brown R** (L. P.); Primulineazo-*m*-phenylenediamine $P^1\cdot N_2\cdot C_6H_3(NH_2)_2$. Prepared from diazotised primuline or dehydrothio-*p*-toluidinesulphonic acid and *m*-phenylenediamine. Solution brownish-red, precipitated by acids or alkalis. Gives a bluish-violet solution with sulphuric acid.

Pyramine Yellow R (B.) Diazotised primuline is combined with nitro-*m*-phenylenediamine. Aqueous solution is reddish-yellow, and solution in sulphuric acid is brownish-yellow.

Literature.—E. P. 8564 of 1894; D. R. P. 80973; F. P. 238340.

Cotton Orange G (B.); Diazotised primuline is combined with *m*-phenylenediaminedisulphonic acid. It gives an orange-yellow solution in water, and a brownish-orange in sulphuric acid.

Literature.—E. P. 14678 of 1893; D. R. P. 73369; F. P. 231694; A. P. 524262.

Apollo Red (G.); **Archil Substitute extra** (C.); *p*-Nitrobenzeneazo-a-naphthylaminedisulphonic acid, $NO_2\cdot C_6H_4\cdot N_2\cdot C_{10}H_4(NH_2)(SO_3H)_2$. Prepared from diazotised *p*-nitroaniline and *a*-naphthylamine-4 : 6- or 4 : 7-disulphonic acid. Gives a brownish-red solution in water and a magenta-red in sulphuric acid.

Literature.—E. P. 9468 of 1887 A. P. 376392; F. P. 184638.

Brilliant Archil C (C.); Azimide of *p*-nitrobenzeneazo-1 : 8-naphthylenediaminedisulphonic acid

$$NO_2\cdot C_6H_4\cdot N_2{:}C_{10}H_4(SO_3H)_2\langle N_2H \rangle NH$$

Prepared by the action of nitrous acid on the product from diazotised *p*-nitroaniline and 1 : 8-naphthylenediamine-3 : 6-disulphonic acid. A brownish-red powder dissolving in water with a red, and in sulphonic acid with a blue, solution.

Literature.—E. P. 24714 of 1893; D. R. P. 77425; F. P. 234837.

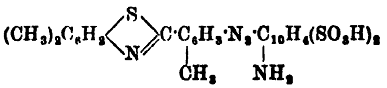
Wool Violet S (B.); Dinitrobenzeneazodiethylmetanilic acid

$$(NO_2)_2C_6H_3\cdot N_2\cdot C_6H_3(SO_3H)\cdot N(C_2H_5)_2$$

Prepared from diazotised 2 : 4-dinitroaniline and diethylmetanilic acid. A black powder giving a reddish-violet solution in water and a scarlet-red in sulphuric acid.

Literature.—E. P. 6197 of 1894; D. R. P. 86071; F. P. 239096; A. P. 525656.

Salmon Red (A.); Methylbenzenylaminothioxylenolazo-*β*-naphthylamine-3 : 6-disulphonic acid



$$(CH_3)_2C_6H_2\langle {}^{S}_{N} \rangle C\cdot C_6H_3(CH_3)\cdot N_2\cdot C_{10}H_4(SO_3H)_2(NH_2)$$

Prepared from diazotised dehydrothio-*m*-xylidine and *β*-naphthylamine-3 : 6-disulphonic acid R. Aqueous solution is orange-red. Gives violet solution in sulphuric acid.

Literature.—Paul, Zeitsch. angew. Chem. 1896, 9, 680.

Brilliant Yellow S (B.) (T. M.) (B K.); **Yellow WR** (I.); **Curcumine** (G.); *p*-Sulphobenzeneazodiphenylaminesulphonic acid. Prepared by sulphonating orange IV. Solution in water is yellow and in sulphuric acid bluish-red.

Literature.—D. R. P. 21903.

Lanacyl Violet B (C.); Disulphohydroxynaphthaleneazoethyl-a-naphthylamine

$$(HSO_3)_2C_{10}H_4(OH)\cdot N_2\cdot C_{10}H_6\cdot NH\cdot C_2H_5$$

Prepared from diazotised 1 : 8-aminonaphthol-3 : 6-disulphonic acid and ethyl-*a*-naphthylamine. Solution in water is reddish violet, and in sulphuric acid is greenish-blue.

Literature.—E. P. 12556 of 1896; D. R. P. 94288; F. P. 257136.

Tolyl Blue SR (M.); **Sulphone Acid Blue R** (By.). Prepared, as the preceding, from diazotised H-acid and 1-phenylnaphthylamine-8-sulphonic acid. Solution in water is reddish-violet, and in sulphuric acid dirty blue. The corresponding colouring matter with the tolyl-substituted acid is **Tolyl Blue SB** (M.); **Sulphone**

---

[1] P = the residue of primuline.

Acid Blue B (By.); **Brilliant Cloth Blue III. F** (K.); it dissolves in water to a reddish-blue, and in sulphuric acid to a dirty violet solution.

Literature.—E. P. 24830 of 1898; D. R. P. 75571, 108546.

B. Carboxylic Acids of Aminoazo- Compounds.

Yellow fast-to-soap (P.); *m*-Carboxybenzeneazodiphenylamine

$$CO_2H{\cdot}C_6H_4{\cdot}N_2{\cdot}C_6H_4{\cdot}NH{\cdot}C_6H_5$$

Prepared by the action of *m*-diazobenzoic acid on diphenylamine. Used in wool-dyeing and especially calico-printing; the shades are very fast to soap. A brown paste, sparingly soluble in water. Solution becomes reddish-violet with acids. Dissolves with a violet colour in sulphuric acid, becoming red on dilution.

Literature.—E. P. 4621 of 1883; D. R. P. 29961; F. P. 157755; A. P. 297852.

C. Hydroxyazo- Compounds.

Sudan Brown (A.) (Sch.); **Brown G** (C. J.); **Pyronal Brown** (D.); **Oil Brown** (Farbwerk Ammersfoort) (Wiescher & Co.); α-Naphthaleneazo-α-naphthol $C_{10}H_7{\cdot}N_2{\cdot}C_{10}H_6{\cdot}OH$. Prepared by the action of diazotised α-naphthylamine on α-naphthol in alkaline solution.

Literature.—E. P. 786 of 1878; D. R. P. 5411; F. P. 123148; A. P. 204799; Frankland, Trans. Chem. Soc. 1880, 37, 752.

Sudan G (A.) (W.); **Carminaph J** (D. H.); **Cerasine Orange G** (C.); **Cerotine Yellow R** (C. J.); **Chrysoïn insoluble** (P.); **Pyronal Yellow** (D.); **Oil Orange** (I.); Benzeneazoresorcinol $C_6H_5{\cdot}N_2{\cdot}C_6H_3(OH)_2$. Prepared by the action of diazobenzene chloride on resorcinol in alkaline solution. Solution of colouring matter in alkali hydroxide is orange-yellow, giving a brown precipitate with acids. Dissolves in sulphuric acid with a yellowish-brown colour.

Literature.—Baeyer and Jager, Ber. 1875, 8, 151; Typke, *ibid.* 1877, 10, 1576; Wallach, *ibid.* 1881, 14, 24; Wallach and Fischer, *ibid.* 1882, 15, 2814; Meyer and Kreis, *ibid.* 1883, 16, 1329; Liebermann and Kostanecki, *ibid.* 1884, 17, 880; Heumann and Oeconomides, *ibid.* 1887, 20, 904; Will and Pukall, *ibid.* 1120; Pukall, *ibid.* 1147; Fischer and Wimmer, *ibid.* 1578; Will, *ibid.* 1888, 21, 604; Kostanecki, *ibid.* 3119.

Sudan I (A.) (K.) (W.); **Carminaph** (D. H.); **Cerotine Orange G** (C. J.); **Oil Orange** (O.) (Farbwerk Ammersfoort) (Wiescher & Co.); **Motl Orange R** (T. M.); **Pyronal Orange** (D.); **Spirit Orange** (L.); **Scarlet B** (B. K.); **Oil Yellow** (Sch.); **Insoluble Aniline Orange** (P.); Benzeneazo-β-naphthol $C_6H_5{\cdot}N_2{\cdot}C_{10}H_6{\cdot}OH$. Prepared from diazobenzene chloride and β-naphthol. A brick-red powder insoluble in water. Used for colouring oils, &c.

Literature.—Liebermann, Ber. 1883, 16, 2860; Denare, Gazz. chim. ital. 1885, 15, 406; Zincke and Bindewald, Ber. 1884, 17, 3031; Zincke and Rathgen, *ibid.* 1886, 19, 2484; Fischer and Wimmer, *ibid.* 1887, 20, 1579; Weinberg, *ibid.* 3172; Jacobson, *ibid.* 1888, 21, 415; Meldola and East, Trans. Chem. Soc. 1888, 53, 460; Meldola and Morgan, *ibid.* 1889, 55, 603; Goldschmidt and Rosell, Ber. 1890, 23, 496; Goldschmidt and Brubacher, *ibid.* 1891, 24, 2306; McPherson, Ber. 1895, 28, 2418; Farmer and Hantzsch, *ibid.* 1899, 32, 3100; Möhlau and Strohbach, *ibid.* 1900, 33, 805; Goldschmidt and Keppeler, *ibid.* 894; Möhlau and Kegel, *ibid.* 2873; Betti, Gazz. chim. ital. 1900, 30, ii. 164.

Pigment Fast Red HL (M.); **Helio Fast Red RL** (By.); **Lithol Fast Scarlet R, RPN** (B.); **Graphitol Fast Red GAERR** (O.); **Sitara Fast Red RL** (T. M.); *m*-Nitrotolueneazo-β-naphthol

$$NO_2{\cdot}C_7H_6{\cdot}N_2{\cdot}C_{10}H_6{\cdot}OH$$

Prepared from diazotised *m*-nitro-*p*-toluidine and β-naphthol. Used only for lakes.

Literature.—E. P. 19100 of 1905; D. R. P. appl. F 20265; F. P. 357858.

Tuscaline Orange G (B.). Prepared from diazotised *m*-nitro-*o*-anisidine and β-naphthol is used in calico-printing and as a lake.

Sudan II (A.) (K.); **Cerotine Scarlet G** (C. J.); **Motl Red G** (T. M.); **Pyronal Red R** (D.); **Orange RR** (B. K.); **Insoluble Xylidine Ponceau** (P.); Xyleneazo-β-naphthol

$$C_6H_3(CH_3)_2{\cdot}N_2{\cdot}C_{10}H_6{\cdot}OH$$

Prepared from diazotised xylidine and β-naphthol.

Carminaph Garnet (D. H.); **Cerotine Scarlet 2 R** (C. J.); **Oil Red Brown** (Farbwerk Ammersfoort); **Pigment Bordeaux N** (M.); **Autol Red** (B.); **Insoluble Naphthylamine Ponceau** (P.); α-Naphthaleneazo-β-naphthol

$$C_{10}H_7{\cdot}N_2{\cdot}C_{10}H_6{\cdot}OH$$

Prepared from diazotised α-naphthylamine and β-naphthol. An insoluble paste used in printing. (*See* also **Naphthylamine Bordeaux.**

Azophosphine GO (M.). Chloride of *m*-trimethylaminobenzeneazoresorcinol

$$ClN(CH_3)_3{\cdot}C_6H_4{\cdot}N_2{\cdot}C_6H_3(OH)_2$$

Prepared from diazotised *m*-aminophenyltrimethylammonium chloride and resorcinol. Solution in water is yellowish-red, and in sulphuric acid brownish-red. A similar dye is **Azophosphine BRO** (M.).

Literature.—E. P. 14494 of 1895; D. R. P. 87257; F. P. 249227; A. P. 626913.

New Phosphine G (C.); ω-Dimethylaminotolueneazoresorcinol

$$N(CH_3)_2{\cdot}CH_2{\cdot}C_6H_4{\cdot}N_2{\cdot}C_6H_3(OH)_2$$

Prepared from diazotised *p*-aminobenzyldimethylamine and resorcinol. Gives a yellowish-brown solution in water and sulphuric acid.

Literature.—E. P. 22572 of 1892; D. R. P. 70678; F. P. 225968; A. P. 515100.

Tannin Orange R (C.); ω-Dimethylaminotolueneazo-β-naphthol

$$N(CH_3)_2{\cdot}CH_2{\cdot}C_6H_4{\cdot}N_2{\cdot}C_{10}H_6{\cdot}OH$$

Prepared from diazotised *p*-aminobenzyldimethylamine and β-naphthol. A brown powder or a 50 p.c. paste. Sparingly soluble in water, with a brown colour. Gives a yellowish-brown solution in sulphuric acid.

Literature.—As for the preceding colour.

Azochromine (G.); Tetrahydroxyazobenzene $OH\cdot C_6H_4\cdot N_2\cdot C_6H_2(OH)_3$. Prepared from diazotised *p*-aminophenol and pyrogallol. Commercial product is a 30 p.c. paste, giving a dark-yellow solution in boiling water. With sulphuric acid it gives a brown solution.

Literature.—E. P. 11902 of 1893; D. R. P. 81109; F. P. 230937; A. P. 548460.

Diazine Black (K.); Safranineazophenol. Prepared from one of the varieties of safranine and phenol. Its solution in water is dark green-blue, and in sulphuric acid green.

Literature.—Mon. Sci. 1886, (iii.) 16, 984.

Indoine Blue R (B.) (G.); **Janus Blue** (M.); **Naphthindone** (C.); **Vac Blue** (H.); **Fast Cotton Blue B** (O.); **Indole Blue** (A.) (L.); **Diazine Blue** (K.); **Madras Blue P** (P.); **Indone Blue** (By.); **Fast Blue B** (T. M.); **Indogenin** (Delft Colour Works); Safranineazo-β-naphthol. Prepared from various safranines and β-naphthol. It gives a violet solution in water, and a greenish-brown in sulphuric acid.

Literature.—E. P. 4543 of 1891, 18769 of 1893, 3488 of 1895, 23985 of 1898; D. R. P. 61692, 85690, 85932, 91721, 92015, 105433, 108497; F. P. 212276, 246239, 250239, 283013, 285360; A. P. 524251, 524254; Walter, Aus der Praxis der Anilinfarbenfabrikation, 1903, 306 (where the preparation is described in detail).

Methyl Indone B, R (C.) is prepared from diazotised safranine and an aminonaphthol. The aqueous solution is blue, and that in sulphuric acid greenish-blue.

Literature.—D. R. P. appl. L 3377.

Azarine S (M.)

$$OH\cdot C_6H_2Cl_2\cdot NH\cdot N(SO_3\cdot NH_4)\cdot C_{10}H_6\cdot OH$$

4 : 6-Dichloro-2-aminophenol is diazotised and combined with β-naphthol, and the product is treated with ammonium bisulphite. It forms a yellow paste, giving a yellow solution in water and a magenta-red solution in sulphuric acid, giving a reddish-brown precipitate on dilution.

Literature.—E. P. 5767 of 1883; D. R. P. 29067; F. P. 159604; A. P. 302790, 306546.

Sulphamine Brown A (D.); **α-Naphthine Brown** (P.) is prepared by the action of diazotised α-naphthylamine on the sodium bisulphite compound of nitroso-β-naphthol. It dissolves in water to a brown, and in sulphuric acid to a green, solution. **Sulphamine Brown B** (D.) is made from β-naphthylamine; the aqueous solution is red, and that in sulphuric acid is violet.

Literature.—E. P. 11556 of 1893; D. R. P. 79583; F. P. 239100.

D. Sulphonic Acids of Hydroxyazo- Compounds.

1. MONOSULPHONIC ACIDS.

Chrysoïn (most firms); **Tropæoline O** (C.); **Resorcin Yellow** (A.) (B. K.) (K.) (T. M.) (H.) (Sch.); **Gold Yellow** (By.); **Acme Yellow** (L.); *p*-Sulphobenzeneazoresorcinol

$$HSO_3\cdot C_6H_4\cdot N_2\cdot C_6H_3(OH)_2$$

Produced by the action of diazotised sulphanilic acid on resorcinol in alkaline solution. Solution of colouring matter orange; substance dissolves in sulphuric acid with a yellow colour.

Literature.—Griess, Ber. 1878, 11, 2195; Witt, Trans. Chem. Soc. 1879, 35, 183.

Acid Alizarine Garnet R (M.); *p*-Sulphophenolazoresorcinol

$$HSO_3\cdot C_6H_3(OH)\cdot N_2\cdot C_6H_3(OH)_2$$

Similarly prepared from *o*-aminophenol-*p*-sulphonic acid and resorcinol. Solution in water or sulphuric acid is orange-brown.

Orange II (Most firms); **Mandarin G** (A.) (B. K.) (By.); **Gold Orange** (By.) (B. K.) (D.) (T. M.); **Orange Extra** (C.); **Orange A** (L.) (Sch.); **Orange P** (O.); **Orange G** (B. K.) (H.); **Acid Orange** (G.); *p*-Sulphobenzeneazo-β-naphthol $HSO_3\cdot C_6H_4\cdot N_2\cdot C_{10}H_6\cdot OH$. Prepared from diazotised sulphanilic acid and β-naphthol. Solution orange, becoming red on addition of sodium hydroxide. Solution in sulphuric acid red, becoming orange on dilution.

Literature.—Hofmann, Ber. 1877, 10, 1378; Griess, *ibid.* 1878, 11, 2198; Witt, *ibid.* 1879, 12. 259; Miller, *ibid.* 1880, 13, 268; Witt, Chem. Zeit. 1880, 4, 437; Mühlhäuser, Dingl. poly. J. 1887, 264, 181, 238; Paul, Zeitsch. angew, Chem. 1896, 9, 686 (the last two papers give details of the manufacture).

Orange R (I.) (C.) (D. H.) (B.) (Sch.); **Orange T** (K.) (T. M.); **Kermesin Orange** (L.) Sulpho-*o*-tolueneazo-β-naphthol

$$HSO_3\cdot C_7H_6\cdot N_2\cdot C_{10}H_6\cdot OH(\beta)$$

Homologous with the preceding, the diazotised sulphonic acid of *o*-toluidine being used instead of sulphanilic acid.

Literature.—The manufacture is described in the paper by Mühlhauser already referred to.

Lithol Rubine B (B.); **Permanent Red 4 B** (A.); **Pigment Rubine R** (A.); Sulpho-*p*-tolueneazo-β-hydroxy-3-naphthoic acid

$$HSO_3\cdot C_7H_6\cdot N_2\cdot C_{10}H_5(OH)\cdot CO_2H$$

Prepared by the action of diazotised *p*-toluidinesulphonic acid $(CH_3 : NH_2 : SO_3H = 1 : 4 : 3)$ on β-hydroxynaphthoic acid. A fiery red powder or paste used for making lakes.

Literature.—E. P. 11004 of 1903; D. R. P. 151205; F. P. 332145; A. P. 741029.

Azofuchsine B (By.); Tolueneazo-1 : 8-dihydroxynaphthalenesulphonic acid

$$CH_3\cdot C_6H_4\cdot N_2\cdot C_{10}H_4(OH)_2\cdot SO_3H$$

Prepared by the action of diazotised commercial toluidine on 1 : 8-dihydroxynaphthalene-4-sulphonic acid. Solution in water is bluish-red, and in sulphuric acid violet.

Literature.—E. P. 18517 of 1889; D. R. P. 54116; F. P. 203744; A. P. 466841, 468142.

Ponceau 4 GB (A.) (Lev.) (B K.); **Croceïne Orange** (By.) (B. K.) (K.) (P.); **Croceïne Orange Y** (Sch.); **Croceïne Orange GR** (T. M.); **Brilliant Orange G** (M.) (C. J.); **Orange GRX** (B.); **Pyrotine Orange** (D.); Benzeneazo-β-naphtholsulphonic acid $C_6H_5\cdot N_2\cdot C_{10}H_5(SO_3H)\cdot OH(\beta)$. Prepared by the action of diazobenzene chloride on β-naphthol-6-sulphonic acid (Schäffer's acid) in alkaline solution. Solutions in water or sulphuric acid are orange-yellow.

Literature.—Griess, Ber. 1878, 11, 2197.

Orange GT (By.); **Orange RN** (C.); **Brilliant Orange O** (M.); **Brilliant Orange RO** (C. J.); **Croceïne Orange R** (By.) (T. M.); Tolueneazo-β-naphtholsulphonic acid

$$C_7H_7\cdot N_2\cdot C_{10}H_5(SO_3H)\cdot OH(\beta)$$

Prepared by diazotising commercial toluidien and combining with Schäffer's β-naphtholmonosulphonic acid in alkaline solution. Orange aqueous solution gives an oily precipitate with acids. Dissolves in sulphuric acid with a magenta-red colour, giving an oily deposit on dilution.

Literature.—E. P. 623 of 1879; Ber. 1880, 13, 586.

Scarlet GR (A.); **Scarlet R** (By.); **Brilliant Orange R** (M.) (C. J.) (B. K.); **Orange L** (Lev.) (P.) (O.); **Xylidine Orange 2 R** (T. M.); **Orange N** (K.) (B.); **Ponceau 2 G** (B.). Homologous with the last; prepared from diazotised xylidine and Schäffer's acid. Dissolves in sulphuric acid with a red colour, becoming brown and precipitating on dilution.

Literature.—Levinstein, Ber. 1880, 13, 586.

Azococcine 2 R (A.); **Double Scarlet R** (Lev.); **Jute Scarlet** (D.); **Ponceau R for Jute** (B.); Xyleneazo-α-naphtholsulphonic acid

$$(CH_3)_2C_6H_3{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}OH(\alpha)$$

Prepared by the action of diazoxylene chloride (commercial xylidine diazotised) on α-naphthol-4-sulphonic acid in alkaline solution. Aqueous solution not precipitated by alkalis; when hot and concentrated deposits bronzy crystals on cooling. Dissolves in sulphuric acid with a reddish-violet colour, becoming brown and precipitating free acid on dilution.

Literature.—E. P. 2237 of 1883; D. R. P. 26012.

Cochineal Scarlet 4 R (Sch.). Isomeric with the preceding, α-naphthol-5-sulphonic acid being used instead of the 4-sulphonic acid. Dissolves in sulphuric acid with a magenta-red colour, giving a precipitate on dilution.

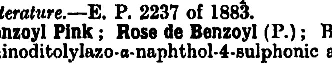
Azoeosine G (K.) (By.) (Lev.); **Cochineal Scarlet R** (D.); **Buffalo Flamine G** (Sch.); Anisoleazo-α-naphthol-4-sulphonic acid

$$CH_3{\cdot}O{\cdot}C_6H_3{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}OH$$

Prepared from diazotised *o*-anisidine and α-naphthol-4-sulphonic acid. Gives a red solution in water and a carmine-red in sulphuric acid.

Literature.—E. P. 2237 of 1883.

Benzoyl Pink; **Rose de Benzoyl** (P.); Benzoylaminoditolylazo-α-naphthol-4-sulphonic acid



$$C_6H_5{\cdot}CO{\cdot}NH{\cdot}\underset{CH_3}{\underset{|}{C_6H_4}}{\cdot}\underset{CH_3}{\underset{|}{C_6H_4}}{\cdot}N_2{\cdot}\underset{SO_3H}{\underset{|}{C_{10}H_6}}{\cdot}OH$$

Prepared from diazotised monobenzoyl-*o*-tolidine and α-naphthol-4-sulphonic acid. A brick-red paste, giving a cherry-red solution in water, and a bluish-red solution in sulphuric acid.

Literature.—D. R. P. 60332.

Double Ponceau R, 2 R, 3 R, 4 R (By.); α-Naphthaleneazo-α-naphthol-5-sulphonic acid $C_{10}H_7{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}OH$. Prepared from diazotised α-naphthylamine and α-naphthol-5-sulphonic acid. Gives an orange-red solution in water, and a red in sulphuric acid.

Fast Red BT (By.) (Lev.) (D. H.) (B. K.); α-Naphthaleneazo-β-naphthol-6-sulphonic acid. Isomeric with the preceding. Prepared from diazotised α-naphthylamine and β-naphthol-6-sulphonic acid (Schäffer). Gives a red solution in water and a violet in sulphuric acid.

Literature.—E. P. 786 of 1878; D. R. P. 5411; F. P. 123148; A. P. 204799.

Pigment Scarlet G (M.); **Carboxybenzeneazo-β-naphthol-6-sulphonic acid**

$$CO_2H{\cdot}C_6H_4{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}OH$$

Prepared from diazotised anthranilic acid and Schäffer salt. A bronzy-red powder giving a yellowish-red aqueous solution and used for the preparation of lakes.

Literature.—D. R. P. 175828; F. P. 366110.

Fast Brown N (By.); **Chrome Brown RO** (M.); **Naphthylamine Brown** (B.); *p*-Sulphonaphthaleneazo-α-naphthol $HSO_3{\cdot}C_{10}H_6{\cdot}N_2{\cdot}C_{10}H_6{\cdot}OH$. Prepared by the action of diazotised α-naphthylamine-4-sulphonic acid (naphthionic acid) on α-naphthol in alkaline solution. Colouring matter gives a reddish-brown solution, not changed by acids or alkalis. Dissolves in sulphuric acid with a reddish-violet colour.

Literature.—E. P. 786 of 1878; D. R. P. 5411, 87003; F. P. 123148; A. P. 204799.

Fast Brown 3 B (A.); Sulphonaphthalene-2-azo-α-naphthol $HSO_3{\cdot}C_{10}H_6{\cdot}N_2{\cdot}C_{10}H_6{\cdot}OH$. Prepared by the action of diazotised β-naphthylamine-6-sulphonic acid on α-naphthol in alkaline solution.

Aqueous solution brownish-red, becoming violet with dilute acids and red with alkalis. Solution in sulphuric acid blue, giving reddish-violet precipitate on dilution.

Literature.—E. P. 3724 of 1882; D. R. P. 22547; F. P. 150503; A. P. 332829.

Permanent Orange R (A.); Chlorosulphobenzeneazo-β-naphthol

$$HSO_3{\cdot}C_6H_3Cl{\cdot}N_2{\cdot}C_{10}H_6{\cdot}OH$$

Prepared from diazotised *m*-chloroaniline-*o*-sulphonic acid and β-naphthol. It is an orange paste used for making lakes.

Fast Orange O (M.); Nitrosulphobenzeneazo-β-naphthol

$$HSO_3{\cdot}C_6H_3(NO_2){\cdot}N_2{\cdot}C_{10}H_6{\cdot}OH$$

Prepared from diazotised *o*-nitroaniline-*p*-sulphonic acid and β-naphthol. An orange powder used for making lakes.

Literature.—E. P. 16409 of 1901; D. R. P. 129539; F. P. 313598; A. P. 714883.

Lake Red P (M.); Isomeric with the preceding. Prepared from diazotised *p*-nitroaniline-*o*-sulphonic acid and β-naphthol. It is a yellowish-red paste used for making calcium and barium lakes.

Literature.—E. P. 16409 of 1901; D. R. P. 128456; F. P. 313598; A. P. 714882.

Lake Red C (M.); Chlorosulphotolueneazo-β-naphthol $HSO_3{\cdot}C_7H_5Cl{\cdot}N_2{\cdot}C_{10}H_6{\cdot}OH$. Prepared from diazotised 6-chloro-3-toluidine-4-sulphonic acid ($CH_3=1$) and β-naphthol. An orange paste used for making the red barium lake.

Literature.—E. P. 23831 of 1902; D. R. P. 145908; F. P. 328131; A. P. 733280.

Chrome Fast Cyanine G (I.), introduced into commerce in 1907, is prepared by the action of diazotised 1-amino-2-naphtholsulphonic acid on α-naphthol.

Eriochrome Blue Black B (G.); Sulphonaphtholazo-α-naphthol

$$HSO_3{\cdot}C_{10}H_5(OH){\cdot}N_2{\cdot}C_{10}H_6{\cdot}OH$$

Prepared by the action of diazotised 1-amino-β-naphthol-4-sulphonic acid on α-naphthol.[1] The blackish-violet aqueous solution on addition of hydrochloric acid becomes first reddish-brown, and then gives a brownish-black precipitate. With sodium hydroxide the solution becomes first blue and, on adding excess, finally red. The solution in sulphuric acid is blue, giving a violet-black precipitate on dilution.

Literature.—E. P. 15025 of 1904; D. R. P. 181326; F. P. 350055; Ital. P. 73530; Aust. P. 30630.

Eriochrome Black T (G.); Nitrosulphonaphtholazo-α-naphthol

$$NO_2\cdot C_{10}H_4(SO_3H)\cdot N_2\cdot C_{10}H_6\cdot OH$$

Prepared by the action of diazotised 8-nitro-1-amino-β-naphthol-4-sulphonic acid on α-naphthol. The reddish-brown aqueous solution gives a violet-brown precipitate with hydrochloric acid, and, with sodium hydroxide, becomes first deep-blue and then red. The solution in sulphuric acid is blackish-blue, giving a brown precipitate on dilution.

Literature.—E. P. 15982 of 1904; D. R. P. 169683; F. P. 350071; Ital. P. 73531; Aust. P. 127191.

Double Brilliant Scarlet G (A.) (Lev.) (K.) (T. M.) (A.); **Scarlet for silk** (M.); **Double Scarlet** (D.). Prepared from β-naphthylamine-6-sulphonic acid and β-naphthol. Aqueous solution gives brown precipitate with dilute acids. Dissolves in sulphuric acid with a red colour, giving a brown precipitate on dilution.

Literature.—E. P. 3724 of 1882; D. R. P. 22547; F. P. 150503; A. P. 332829.

Fast Red conc. (Sch.); **Fast Red A** (B.) (C. J.) (Lev.) (B. K.) (By.) (Claus & Co.) (L.) (K.) (D.) (T. M.) (O.); **Roccelline** (D. H.) (B. K.) (C.) (I.) (G.) (P.) (K. S.) (T. M.) (Central Dyestuff and Chemical Co.); **Fast Red AV** (B.); **Fast Red O** (M.); **Cardinal Red** (H.); **Rubidine** (B. K.); Sulphonaphthaleneazo-β-naphthol

$$HSO_3\cdot C_{10}H_6\cdot N_2\cdot C_{10}H_6\cdot OH$$

Prepared by the action of diazotised naphthionic acid on β-naphthol in alkaline solution. Substance dissolves in hot water with a reddish-brown colour; concentrated solution when rapidly cooled solidifying to a brown gelatinous mass. Soluble in sulphuric acid with a violet colour, becoming brown and giving a precipitate of the free acid on dilution. The corresponding colouring matter from α-naphthylamine-5-sulphonic acid is called **Brilliant Fast Red G** (B.).

Literature.—E. P. 786 of 1878; D. R. P. 5411; F. P. 123148; A. P. 204799; Griess, Ber. 1878, 11, 2199; 1879, 12, 1364.

Acid Ponceau (D. H.) (K. S.); **Ponceau for Silk** (P.); **Ponceau S for silk** (I.); **Ponceau G for Silk** (K.); **Scarlet for Silk** (B.); Sulpho-β-naphthaleneazo-β-naphthol

$$HSO_3\cdot C_{10}H_6\cdot N_2\cdot C_{10}H_6\cdot OH$$

Prepared by sulphonating β-naphthylamine, diazotising the mixed isomeric sulphonic acids, and combining with β-naphthol in alkaline solution. Aqueous solution gives a brown precipitate with dilute acids. Dissolves in sulphuric acid with a red colour, becoming brown and precipitating on dilution.

Lithol Red R (B.); Sulphonaphthaleneazo-β-naphthol $HSO_3\cdot C_{10}H_6\cdot N_2\cdot C_{10}H_6\cdot OH$. Prepared by the action of diazotised β-naphthylamine-1-sulphonic acid on β-naphthol. The commercial product is a paste which is only very sparingly soluble even in hot water. It is used exclusively in the manufacture of lakes.

Literature.—E. P. 25511 of 1899; 4859 of 1909; 7922 of 1910; D. R. P. 112833; F. P. 297330; A. P. 650757.

Lake Bordeaux B (M.). Prepared from the same diazo- compound as the preceding and β-hydroxynaphthoic acid. It is a bordeaux-red paste used for making lakes.

Literature.—E. P. 7351 of 1907; D. R. P. 205080; F. P. 385570; A. P. 858065.

Clayton Cloth Red (Cl. Co.); **Stanley Red** (Cl. Co.); **Titan Scarlet** (H.); Sulphobenzenylaminothiocresolazo-β-naphthol

$$CH_3\cdot C_6H_3\overset{N}{\underset{S}{\langle\rangle}}C\cdot C_6H_4(SO_3H)\cdot N_2\cdot C_{10}H_6\cdot OH$$

Prepared by the action of diazotised dehydrothio-*p*-toluidinesulphonic acid on β-naphthol. The commercial product is the ammonium salt. Forms a reddish-brown solution in water, and a violet-red with sulphuric acid.

Literature.—E. P. 18901 of 1889; D. R. P. 51331.

Acid Alizarine Violet N (M.); **Palatine Chrome Violet** (B.); **Anthracene Chrome Violet B** (C.); **Ortho Cerise B** (A.); **Copper Red N** (M.); Sulphophenolazo-β-naphthol

$$OH\cdot C_6H_3(SO_3H)\cdot N_2\cdot C_{10}H_6\cdot OH$$

Prepared from diazotised 2-aminophenol-4-sulphonic acid and β-naphthol. Aqueous solution is dark bordeaux-red, and solution in sulphuric acid is magenta-red.

Literature.—D. R. P. 78409; D. R. P. appl. A 7938; F. P. 310508.

Acid Alizarine Black R (M.); Nitrosulphophenolazo-β-naphthol

$$OH\cdot C_6H_2(NO_2)(SO_3H)\cdot N_2\cdot C_{10}H_6\cdot OH$$

Prepared from diazotised 6-nitro-2-aminophenol-4-sulphonic acid and β-naphthol. Aqueous solution is brownish-violet, and solution in sulphuric acid is reddish-violet.

Literature.—E. P. 2772 of 1900; D. R. P. 143892; F. P. 300011; A. P. 667935.

Anthracene Chrome Black (C.); Sulphonaphtholazo-β-naphthol

$$HSO_3\cdot C_{10}H_5(OH)\cdot N_2\cdot C_{10}H_6\cdot OH$$

Prepared by the action of diazotised 3-amino-β-naphthol-7-sulphonic acid (R.) on β-naphthol. Aqueous solution is red; hydrochloric acid gives a reddish-violet precipitate, and sodium hydroxide turns it bluish-violet. Solution in sulphuric acid is bluish-green, giving a reddish-violet precipitate on dilution.

Literature.—E. P. 28107 of 1897; D. R. P. 109932; F. P. 272620, 272621.

---

[1] In the constitutional formula of this colouring matter, kindly communicated along with other information to the writer by the manufacturers, the azo- group is shown attached to the 2- position of the α-naphthol, although the 4- position is unoccupied. The combination is probably effected in presence of very concentrated alkali hydroxide. Other examples of this ortho- combination are known, both in the benzene and naphthalene series. (Compare Michel and Grandmougin, Ber. 1893, 26, 2353; Bamberger, *ibid.* 1900, 33, 3188; Bamberger and Meimberg, *ibid.* 1895. 28, 1889; Bamberger, *ibid.* 848: D. R. P. 14443.)

Palatine Chrome Black 6 B (B.); **Eriochrome Blue Black R** (G.); **Salicin Black** (K.); **Acid Alizarin Blue Black A** (M.); **Diamond Blue Black EB** (By.); **Anthracene Blue Black BE** (C.); **Chrome Fast Black PW** (I.); **Chrome Blue N** (P.). Isomeric with the preceding. Prepared from diazotised 1-amino-β-naphthol-4-sulphonic acid and β-naphthol. Blue aqueous solution gives yellowish-brown precipitate with hydrochloric acid, and turns first blue and then red with sodium hydroxide. Solution in sulphuric acid is dark-blue, giving a blackish-brown precipitate on dilution.

Literature.—E. P. 27372 of 1903; 4997 and 15025 of 1904; D. R. P. 156440, 160536, 181326, 171024, 188645, 190693, 181714, 189175; D. R. P. appl. G 21484; F. P. 338819, 350055; A. P. 770177.

Salicin Black UL (K.) is the zinc sodium salt of the above, and is prepared by diazotising 1-amino-β-naphthol-4-sulphonic acid with zinc nitrite and combining the diazo-compound with β-naphthol in concentrated alkaline solution.

Literature.—E. P. 23034 of 1905; 22200 of 1909; D. R. P. 175593, 195228; F. P. 353786; A. P. 807422; Tomioka, J. Soc. Chem. Ind. 1917, 36, 1043.

Eriochrome Black A (G.); Nitrosulphonaphtholazo-β-naphthol

$$NO_2\cdot C_{10}H_4(SO_3H)(OH)\cdot N_2\cdot C_{10}H_6\cdot OH.$$

Prepared from diazotised 8-nitro-1-amino-β-naphthol-4-sulphonic acid and β-naphthol. Dark-blue aqueous solution gives a reddish-brown precipitate with hydrochloric acid, and becomes cherry-red with sodium hydroxide. Solution in sulphuric acid is dark-violet blue, giving a brown precipitate on dilution.

Literature.—E. P. 15982 of 1904; D. R. P. 169683; F. P. 350071; A. P. 790363; Ital. P. 73531; Aust. P. 27191.

Diamond Black PV (By.); Sulphophenolazo-1 : 5-dihydroxynaphthalene

$$OH\cdot C_6H_3(SO_3H)\cdot N_2\cdot C_{10}H_5(OH)_2$$

Prepared from diazotised *o*-aminophenol-*p*-sulphonic acid and 1 : 5-dihydroxynaphthalene. The azo- group enters the 2-position in the latter component. Bluish-red aqueous solution gives a dark-red precipitate with hydrochloric acid. Solution in sulphuric acid is blackish-green, giving a reddish precipitate on dilution.

Literature.—E. P. 18139 and 18569 of 1902; Fischer, J. pr. Chem. 1917, [ii.] 95, 261.

Azo Acid Blue (M.) (By.); **Ethyl Acid Blue RR** (B.). Is prepared by the action of diazotised *p*-nitroaniline on 1 : 8-dihydroxynaphthalene-4-sulphonic acid, reducing the nitro- group and alkylating the product, or by the action of diazotised dialkyl-*p*-phenylenediamine on the sulphonic acid. It gives a blue-violet solution in water and a reddish-violet in sulphuric acid.

Literature.—E. P. 8270 of 1892; D. R. P. 70885, 77169; F. P. 221363; A. P. 567615.

Milling Yellow (Lev.) (D.) (L.); **Chrome Yellow D** (By.); **Anthracene Yellow BN** (C.); **Mordant Yellow** (B.) (M.); **Chrome Fast Yellow R** (A.); **Salicin Yellow D** (K.); **Alizarol Yellow** (Sch.); Sulphonaphthaleneazosalicylic acid

$$HSO_3\cdot C_{10}H_6\cdot N_2\cdot C_6H_3(CO_2H)\cdot OH$$

Prepared by the action of diazotised β-naphthylamine-6-(or 5-)-sulphonic acid on salicylic acid. Solution in water is yellow, and in sulphuric acid yellowish-red.

Literature.—F. P. 206755.

Oriol Yellow (G.); **Cotton Yellow R** (B.); **Alkali Yellow** (D.). Prepared by the action of diazotised dehydrothio-*p*-toluidinesulphonic acid or primuline on salicylic acid. Gives an orange-yellow solution in water, and a scarlet-red with sulphuric acid.

Literature.—D. R. P. 48465; F. P. 192628; A. P. 398990.

Eriochrome Phosphine R (G.); Nitrosulphobenzeneazosalicylic acid

$$NO_2\cdot C_6H_3(SO_3H)\cdot N_2\cdot C_6H_3(CO_2H)\cdot OH$$

Prepared by the action of diazotised *p*-nitroaniline-*o*-sulphonic acid on salicylic acid. Yellowish-orange aqueous solution becomes pale orange with hydrochloric acid, and blue-red with sodium hydroxide. Solution in sulphuric acid is yellowish-orange giving a pale-yellow precipitate on dilution.

Literature.—D. R. P. 226242.

2. Disulphonic Acids.

Chrome Brown RR (G.); Disulphophenolazopyrogallol

$$OH\cdot C_6H_2(SO_3H)_2\cdot N_2\cdot C_6H_2(OH)_3$$

Prepared by the action of diazotised *p*-aminophenol-2 : 6-disulphonic acid on pyrogallol. Solution in water is yellow, and in sulphuric acid brown.

Literature.—E. P. 11902 of 1893; D. R. P. 81109; F. P. 230937; A. P. 548460.

Orange G (A.) (M.) (B.) (P.) (C. J.) (T. M.) (Sch.) (K.) (O.) (Central Dyestuff and Chemical Co.); **Orange GG** (C.) (B. K.) (D.); **Orange GG in Crystals** (Sch.); **Fast Light Orange G** (By.); Benzeneazo-β-naphtholdisulphonic acid

$$C_6H_5\cdot N_2\cdot C_{10}H_4(SO_3H)_2\cdot OH(\beta)$$

Produced by the action of diazobenzene chloride on β-naphthol-6 : 8-disulphonic acid (G-salt) in alkaline solution. Solution not precipitated by alkali; dissolves in sulphuric acid with an orange colour, undergoing no change on dilution.

Literature.—E. P. 1715 of 1878; D. R. P. 3229; F. P. 124811; A. P. 251162.

Crystal Scarlet 6 R (C.) (M.) (By.) (B. K.); **Crystal Ponceau** (A.) (K.) (B.) (D.) (L.) (P.); **Ponceau 6 R** (T.M.); α-Naphthaleneazo-β-naphthol-6 : 8-disulphonic acid (G-acid). Produced by the action of diazotised α-naphthylamine upon β-naphthol-6 : 8-disulphonic acid in alkaline solution.

Literature.—E. P. 816 of 1884; D. R. P. 36491; A. P. 332528.

Ponceau 2 G (B.) (M.) (B. K.); **Brilliant Ponceau GG** (C.); **Orange R** (H.). Isomeric with Orange G. Prepared by the action of diazobenzene chloride upon β-naphthol-3 : 6-disulphonic acid (R-salt). Properties similar to those of the preceding compound; colour slightly redder in shade.

Literature as for Orange G.

Azocoralline L (D.); **Azogrenadine L** (By.); *p*-Acetylaminobenzeneazo-β-naphthol-3 : 6-disulphonic acid

$$CH_3\cdot CO\cdot NH\cdot C_6H_4\cdot N_2\cdot C_{10}H_4(SO_3H)_2\cdot OH$$

Prepared by the action of diazotised acetyl-*p*-phenylenediamine on β-naphthol-3 : 6-disulphonic acid (R-salt). Solution in water is orange-red, and in sulphuric acid yellowish-red.

Literature.—Nietzki, Ber. 1884, 17, 344.

Acid Alizarine Red B (M.); **Palatine Chrome Red B** (B.); Carboxybenzeneazo-β-naphthol-3 : 6-disulphonic acid

$$CO_2H{\cdot}C_6H_4{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)_2{\cdot}OH$$

Prepared from diazotised anthranilic acid and R-salt. It gives a yellowish-red aqueous solution, and a red solution in sulphuric acid. In the form of a lake it is known as **Pigment Scarlet 3 B** (M.).

Literature.—E. P. 23830 of 1902; D. R. P. 141257; F. P. 328128; A. P. 757109.

Ponceau R, 2 R, G and **GR** [1] (A.) (B.) (M.) (By.) (B. K.) (O.) (P.) (L.) (K. S.) (T. M.) (Lev.) (C.) (C. J.); **Brilliant Ponceau R** (T. M.); **Scarlet 2 R** (H.) (Calco Chemical Co.); Xyleneazo-β-naphthol-3 : 6-disulphonic acid

$$C_8H_9{\cdot}N_2{\cdot}C_{10}H_4(SO_3)H_2{\cdot}OH(\beta)$$

Produced by the action of diazotised xylidine (chiefly meta-) on β-naphthol-3 : 6-disulphonic acid (R-salt). Properties similar to those of Orange G. Colour a distinct scarlet; aqueous solution not precipitated by alkali; an amorphous precipitate by calcium or barium chloride. Soluble with a red colour in sulphuric acid, becoming brown and precipitating on dilution.

Literature.—E. P. 1715 of 1878; D. R. P. 3229; F. P. 124811; A. P. 210233.

Ponceau 3 R (A.) (B.) (M.) (C. J.) (K.) (By.) (L.) (O.); **Ponceau 4 R** [2] (A.); **Ponceau 3 R 56** (Sch.); Cumeneazo-β-naphthol-3 : 6-disulphonic acid

$$C_9H_{11}{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)_2{\cdot}OH(\beta)$$

Produced by the action of diazocumene chloride (from ψ-cumidine) on R-salt. Properties as above; colour of a redder shade than the last.

Literature.—*See* above, and A. P. 251163.

Bordeaux B (H.) (A.) (M.) (B. K.) (Calco Chemical Co.); **Fast Red B** (B.) (B. K.) (L.); **Fast Red P extra** (By.); **Bordeaux BL** (C.); **Bordeaux R extra** (M.); **Bordeaux G** (D.); **Bordeaux R** (T. M.); **Cerasine** (P.); **Cerasine R** (D. H.); **Archelline 2 B** (Lev.); **Azo Bordeaux** (Sch.); α-Naphthaleneazo-β-naphthol-3 : 6-disulphonic acid

$$C_{10}H_7{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)_2{\cdot}OH$$

Prepared from diazotised α-naphthylamine and R-salt. Solution in water is magenta-red, and in sulphuric acid blue, becoming magenta-red on dilution.

Literature.—E. P. 1715 of 1878; D. R. P. 3229; F. P. 124811; A. P. 251164.

Coccinine B, C (M.)

$$CH_3{\cdot}O{\cdot}C_6H_3(CH_3){\cdot}N_2{\cdot}C_{10}H_4(SO_3H)_2{\cdot}OH$$

Prepared from diazotised 3-amino-4-cresol methyl ether and R-salt. Gives a cherry-red solution in water or sulphuric acid.

Literature.—E. P. 4914 of 1878; D. R. P. 7217; F. P. 124811.

Sorbine Red (B.); **Azogrenadine S** (By.); **Lanafuchsine** (various marks) (C.); **Azo Acid Red B** (M.); **Wool Red 8B** (O.); *p*-Acetylaminobenzeneazo-α-naphthol-3 : 6-disulphonic acid

$$CH_3{\cdot}CO{\cdot}NH{\cdot}C_4H_4{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)_2{\cdot}OH$$

Prepared by the action of diazotised acetyl-*p*-phenylenediamine on α-naphthol-3 : 6-disulphonic acid. Aqueous solution is currant-red, and in sulphuric acid fiery red.

Literature.—Chem. Zeit. 1900, 24, 493; Zeitsch. Farben. Ind. 1902, 26, 223.

Palatine Scarlet A (B.); **Cochineal Scarlet PS** (By.); **Nassoira Scarlet O** (M.); **Brilliant Wool Scarlet** (K.); **Brilliant Cochineal 2 R, 4 R** (C.); *m*-Xyleneazo-α-naphthol-3 : 6-disulphonic acid $C_8H_9{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)_2{\cdot}OH$. Prepared from diazotised *m*-xylidine and α-naphthol-3 : 6-disulphonic acid. Solution in water is scarlet-red, and in sulphuric acid bluish-red.

Literature.—D. R. P. appl. G 3636.

XL Carmoïsine 6 B (H.); *m*-Xyleneazodihydroxynaphthalene-3 : 6-disulphonic acid $C_8H_9{\cdot}N_2{\cdot}C_{10}H_3(SO_3H)_2(OH)_2$. Prepared by the action of diazotised *m*-xylidine on 1 : 8-dihydroxynaphthalene-3 : 6-disulphonic acid (chromatrope acid).

Eosamine B, G (A.); Methoxytolueneazo-α-naphthol-3 : 8-disulphonic acid

$$CH_3{\cdot}O{\cdot}C_7H_6{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)_2{\cdot}OH$$

Prepared from diazotised *m*-amino-*p*-cresol methyl ether and α-naphthol 3 : 8-disulphonic acid. Solution in water is bluish-red, and in sulphuric acid violet-blue.

Literature.—Chem. Ind. 1896, 19, 8.

Palatine Red A (B.); **Naphthorubin O** (M.); α-Naphthaleneazo-α-naphthol-3 : 6-disulphonic acid $C_{10}H_7{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)_2{\cdot}OH$. Prepared from diazotised α-naphthylamine and α-naphthol-3 : 6-disulphonic acid. Bluish-red solution in water, and blue in sulphuric acid.

Literature.—E. P. 15716 of 1885; D. R. P. 38281.

Direct Rose G (K. S.); **Erika 2 GN** (A.):

Prepared from diazotised dehydrothio-*p*-toluidine and α-naphthol-3 : 8-disulphonic acid (ε-acid). Cherry-red aqueous solution gives a scarlet-red precipitate with hydrochloric acid, and a bluish-red one with sodium hydroxide. Solution in sulphuric acid is dark-bluish red, giving a scarlet-red precipitate on dilution.

Geranine 2 B, G (By.); **Brilliant Geranine B, 2 BN, 3 B** (By.). These dyes are prepared from the same diazo- compound as the preceding, combined with α-naphthol-4 : 8-disulphonic acid (2 B), α-naphthol-3-sulphonic acid (G), or 1 : 8-dihydroxynaphthalene-4-sulphonic acid (Brilliant Geranine). The aqueous solution is red, and that in sulphuric acid is violet-red (2 B and G) or blue (Brilliant Geranine).

Literature.—D. R. P. 73251, 73340.

Erika B extra, BN (Lev.) (L.) (A.); Methylbenzenylaminothioxylenolazo-α-naphthol-3 : 8-disulphonic acid

Prepared from diazotised dehydrothio-*m*-xylidine and α-naphthol-3 : 8-disulphonic acid Solution in water or sulphuric acid is red.

---

[1] **G GR** and **Brilliant Ponceau G** (C) are made from crude xylidine and crude R-salt, **R** from crude xylidine and **2 R** from *m*-xylidine and pure R-salt.

[2] **3 R** is made from crude cumidine and **4 R** from pure ψ-cumidine.

Literature.—E. P. 17333 of 1888; D. R. P. 63951; F. P. 194406; A. P. 418657; Anschütz and Schultz, Ber. 1889, 22, 583.

Erika G extra, GN (A.) (Lev.); **Erika 4 GN** (A.). Is isomeric with the preceding, being prepared from β-naphthol-6 : 8-disulphonic acid (G-acid), and has similar reactions.

Literature.—Ber. 1889, 22, 585.

Azocochineal (By.); Anisoleazo-α-naphthol-4 : 8-disulphonic acid

$$CH_3{\cdot}O{\cdot}C_6H_4{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)_2{\cdot}OH$$

Prepared from diazotised *o*-anisidine and α-naphthol-4 : 8-disulphonic acid. Solution in water and sulphuric acid is red.

Literature.—E. P. 15775 and 15781 of 1885; D. R. P. 40571; F. P. 173083, 173084.

Chromotrope 2 R (M.); **XL Carmoisine R** (H.); Benzeneazo 1 : 8-dihydroxynaphthalene-3 : 6-disulphonic acid

$$C_6H_5{\cdot}N_2{\cdot}C_{10}H_3(SO_3H)_2(OH)_2$$

Produced from diazotised aniline and 1 : 8-dihydroxynaphthalene - 3 : 6 - disulphonic acid. Gives in water a magenta-red, and in sulphuric acid a ruby-red solution.

Literature.—E. P. 9258 of 1890; D. R. P. 69095; F. P. 206439, 212607; A. P. 458283.

Chromotrope 2 B (M.); *p*-Nitrobenzeneazo-1 : 8 - dihydroxynaphthalene - 3 : 6 - disulphonic acid $NO_2{\cdot}C_6H_4{\cdot}N_2{\cdot}C_{10}H_3(SO_3H)_2(OH)_2$. Prepared by the action of diazotised *p*-nitroaniline on 1 : 8-dihydroxynaphthalene-3 : 6-disulphonic acid. Solution in water is yellowish-red, and in sulphuric acid dark-violet.

Literature.—As under Chromotrope 2R.

Victoria Violet 4 BS (M.) (By.); **Domingo Violet A** (L.); **Ethyl Acid Violet S 4 B** (B.); **Azo Wool Blue** (C.); *p*-Aminobenzeneazo-1 : 8-dihydroxynaphthalene - 3 : 6 - disulphonic acid $NH_2{\cdot}C_6H_4{\cdot}N_2{\cdot}C_{10}H_3(SO_3H)_2(OH)_2$. Prepared by the alkaline reduction of chromotrope 2 B or by eliminating the acetyl- group from chromotrope 6 B (*see* below). It gives a dark-violet solution in water, and a bluish-red in sulphuric acid. Similar colouring matters are **Victoria Violet 8 BS** (M.), **Victoria Violet 5 B** (By.), and **Victoria Violet L** (I.).

Literature.—E. P. 8270 of 1892; D. R. P. 70885, 73321; F. P. 221363, 226690.

Chromotrope 6 B (M.); **XL Fuchsine 6 B** (H.); **Fast Acid Red EBB** (L.); *p*-Acetylaminobenzeneazo-1 : 8-dihydroxynaphthalene-3 : 6-disulphonic acid

$$CH_3{\cdot}CO{\cdot}NH{\cdot}C_6H_4{\cdot}N_2{\cdot}C_{10}H_3(SO_3H)_2(OH)_2$$

Prepared by the action of diazotised acetyl-*p*-phenylenediamine on 1 : 8-dihydroxynaphthalene-3 : 6-disulphonic acid. Solution in water is violet-red, and in sulphuric acid ruby-red.

Literature.—D. R. P. 75738.

Chromotrope 10 B (M.); Naphthaleneazo 1 : 8-dihydroxynaphthalene-3 : 6 disulphonic acid

$$C_{10}H_7{\cdot}N_2{\cdot}C_{10}H_3(SO_3H)_2(OH)_2$$

Prepared from diazotised α-naphthylamine and the above acid. Violet solution in water, and greenish-blue in sulphuric acid.

Literature.—As under Chromotrope 2 R.

Chromazone Red A (G.); Benzaldehydeazo-1 : 8-dihydroxynaphthalene-3 : 6-disulphonic acid $CHO{\cdot}C_6H_4{\cdot}N_2{\cdot}C_{10}H_3(SO_3H)_2(OH)_2$. Produced from diazotised *p*-aminobenzaldehyde and 1 : 8-dihydroxynaphthalene-3 : 6-disulphonic acid. Solution in water is red, and in sulphuric acid blue.

Literature.—E. P. 13744 of 1896; D. R. P. 85233; F. P. 248517.

Chromazone Blue R (G.); Phenylethylhydrazone of the preceding colouring matter

$$C_6H_5(C_2H_5)N\,N:CH{\cdot}C_6H_4{\cdot}N_2\,C_{10}H_3(SO_3H)_2(OH)_2$$

Prepared either by condensing chromazone red with *as*-phenylethylhydrazine or by the action of diazotised *p*-aminobenzylidenephenylethylhydrazone on 1 : 8-dihydroxy-3 : 6-disulphonic acid. Solution in water is blue-violet, and in sulphuric acid blue-red.

Literature as above.

Diamine Rose (various marks); **Dianil Rose BD** (M.); Benzenylaminothiophenolazochloronaphtholdisulphonic acid

$$CH_3{\cdot}C_6H_3{<}\overset{S}{\underset{N}{}}{>}C{\cdot}C_6H_4{\cdot}N_2{\cdot}C_{10}H_4Cl(SO_3H)_2{\cdot}OH$$

Prepared from diazotised dehydrothio-*p*-toluidine and 8-chloro-α-naphthol-3 : 6-disulphonic acid. Magenta-red solution in water, and reddish-violet in sulphuric acid.

Literature.—E. P. 1920 and 9441 of 1894; D. R. P. 79055, 82285, 96768, 99227; F. P. 235271; A. P. 535037.

Fast Acid Fuchsine B (By.); **Fast Acid Fuchsine G** (B.K.); Benzeneazo-1 8: -aminonaphthol 3 : 6-disulphonic acid

$$C_6H_5{\cdot}N_2{\cdot}C_{10}H_3(SO_3H)_2(OH){\cdot}NH_2$$

Prepared from diazotised aniline and 1 : 8-aminonaphthol-3 : 6-disulphonic acid (H-acid) in alkaline solution. Solution in water or sulphuric acid is magenta-red.

Literature.—E. P. 13343 of 1890; D. R. P. 62368, 70031; F. P. 210033.

Tolane Red B (K.); Benzeneazo-1 : 8-aminonaphthol-4 · 6-disulphonic acid. Isomeric with the preceding. Prepared from diazotised aniline and 1 : 8-aminonaphthol-4 : 6-disulphonic acid (K-acid). Solution in water or sulphuric acid is magenta-red.

Literature.—E. P. 515 of 1894; D. R. P. 99164; A. P. 563383.

Amidonaphthol Red G (M.); **Brilliant Acid Carmine 2 G** (O.); **Azo Phloxine 2 G** (By.); Benzeneazo-1 : 8-acetylaminonaphthol-3 : 6-disulphonic acid

$$C_6H_5{\cdot}N_2{\cdot}C_{10}H_3(SO_3H)_2(OH){\cdot}NH{\cdot}CO{\cdot}CH_3$$

Prepared from diazotised aniline and acetyl H-acid in alkaline solution. Scarlet-red solution in water, and red solution in sulphuric acid.

Literature.—E. P. 26457 of 1905; D. R. P. 180089; F. P. 348426.

Amido Naphthol Red 6 B (M.); **Brilliant Acid Carmine 6 B** (O.). Prepared as the preceding, but *p*-aminoacetanilide is used instead of aniline. The solution in water or sulphuric acid is red.

Palatine Chrome Green G (B.); **Chrome Fast Green G** (I.); 4-Nitro-2-aminophenol is diazotised and combined with H-acid. It gives a dark reddish-violet solution in water, and a reddish-violet in sulphuric acid.

Fast Sulphone Violet 5 BS (K. S.) is prepared by combining a diazo- compound with 1 : 8-

aminonaphthol-3 : 6- or -4 : 6-disulphonic acid in alkaline solution, and treating the product with *p*-toluenesulphonyl chloride, whereby the amino- group is transformed into the *p*-toluenesulphonylamino- group. Other dyestuffs of the same kind are **Brilliant Sulphone Red B** (K. S.) and **Fast Sulphone Violet 4 R** (K. S.).

Literature.—E. P. 22886 of 1899; D. R. P. 120081; F. P. 294325; A. P. 640989.

Azo Archil R. (A.); Benzeneazo-2-amino-8-naphthol-3 : 6-disulphonic acid (2 R- acid). Isomeric with fast acid fuchsine B (By.). Prepared from diazotised aniline and 2 R-acid. Solution in water or sulphuric acid is yellowish-red.

Literature.—D. R. P. appl. A 3710.

Azorubine (Wiescher & Co.) (O.) (Lev.) (Central Dyestuff and Chemical Co.); **Azorubine S** (A.) (Sch.); **Azorubine G** (T. M); **Azorubine A** (C.); **Azo Acid Rubine** (C. J.) (D.); **Azo Acid Rubine R** (K.); **Nacarat** (P.); **Fast Red C** (B.) (B. K.); **Carmoisine** (K. S.); **Carmoisine B** (By.); **Carmoïsine S** (H.); **Mars Red G** (B.); **Brilliant Crimson** (Cl. Co.); **Brilliant Carmoisine O** (M.); Sulpho-α-naphthaleneazo-α-naphthol-sulphonic acid

$$HSO_3{\cdot}C_{10}H_6{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}OH$$

Prepared by the action of diazotised naphthionic acid on α-naphthol-4-sulphonic acid in presence of alkali. Solution gives a red crystalline precipitate with calcium chloride; substance dissolves in sulphuric acid with a bluish-violet colour, becoming red on dilution. When used for after-chroming on wool the dyestuff is known as **Azochrome Blue R** (K.); **Chrome Blue R** (B.); **Chromotrope FB** (M.); **Omega Chrome Blue A** (K. S.).

Literature.—E. P. 2237 and 4237 of 1883; D. R. P. 26012, 66838, 67240.

Fast Red VR (By); isomeric with the preceding. Prepared from diazotised naphthionic acid and α-naphthol-5-sulphonic acid. Aqueous solution is bluish-red and gives a reddish-brown precipitate with hydrochloric acid. Substance dissolves in sulphuric acid with reddish-blue colour. When used for after-chroming on wool the dyestuff is known as **Azochrome Blue B** (K.); **Chromotrope F 4 B** (M.). **Diamond Blue 3 B** (By.) also belongs to this class.

Fast Red (B.) (K.) (By.) (B. K.) (T. M.) (D.) (O.); **Fast Red S** (M.) (D. H.); **Naphthol Red EB** (C.); **Naphthol Red GR** (B.); **Acid Carmoïsine B** (B. K.); **Fast Red** (Lev.) (A.) (C. J.) (P.); Sulpho-α-naphthaleneazo-β-naphtholsulphonic acid $HSO_3{\cdot}C_{10}H_6{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}OH$. Isomeric with the preceding; prepared from diazotised naphthionic acid and β-naphthol-6-sulphonic acid. Aqueous solution claret-red; not precipitated by acids, dissolves in sulphuric acid with a violet colour, becoming red on dilution.

Literature.—E. P. 786 of 1878; D. R. P. 5411; F. P. 123148; A. P. 204799.

Croceïne Scarlet 3 BX (By.) (K.); **Coccine 2 B** (A.); **Scarlet OOO** (H.); **Acidol Coccine 2 B** (T. M.). Isomeric with the last; prepared from diazotised naphthionic acid and β-naphthol-8-sulphonic acid. Hot solution (concentrated) gives a crystalline magnesium salt on adding magnesium sulphate and allowing to cool; solution in sulphuric acid reddish-violet becoming yellowish-red on dilution.

Literature.—E. P. 2031 of 1881; D. R. P. 20402; A. P. 256376.

Double Scarlet Extra S (A.) (Lev.); **Double Brilliant Scarlet 3 R** (By.); **Double Brilliant Scarlet S** (K.); **Brilliant Ponceau 4 R** (By.); **Scarlet PR** (P.); **Scarlet 2 R extra conc.** (T. M.). Isomeric with the last; prepared from diazotised β-naphthylamine-6-sulphonic acid and α-naphthol-4-sulphonic acid

$$HSO_3{\cdot}C_{10}H_6{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}OH$$

Aqueous solution gives yellowish-brown precipitate with dilute acids. Dissolves in sulphuric acid with a red colour, becoming yellower on dilution.

Literature.—E. P. 3724 of 1882; D. R. P. 22547; F. P. 150503; A. P. 332829.

Azofuchsine G (By.); **Fast Fuchsine G** (Sch.); *p*-Sulphobenzeneazodihydroxynaphthalene-4-sulphonic acid

$$HSO_3{\cdot}C_6H_4{\cdot}N_2{\cdot}C_{10}H_4(OH)_2{\cdot}SO_3H$$

Prepared from diazotised sulphanilic acid and 1 : 8-dihydroxynaphthalene-4-sulphonic acid. Solution in water is bluish-red, and in sulphuric acid violet. Analogous colours are **Azofuchsine S, 6 B,** and **GN extra** (By.).

Literature.—E. P. 18517 of 1889; D. R. P. 54116; F. P. 203744; A. P. 466841, 468142.

Crumpsall Yellow (Lev.); Disulphonaphthaleneazosalicylic acid

$$C_{10}H_{.}(SO_3H)_2{\cdot}N_2{\cdot}C_6H_3(OH){\cdot}CO_2H$$

Produced by the action of diazotised β-naphthylamine-6 : 8-disulphonic acid on salicylic acid. Solution in water is yellow, and in sulphuric acid, orange-red.

Literature.—E. P. 12145 of 1894; D. R. P. 87483.

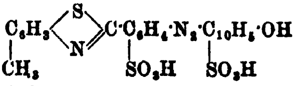
Lanacyl Blue BB (C.); Disulphohydroxynaphthaleneazoaminonaphthol

$$C_{10}H_4(SO_3H)_2(OH){\cdot}N_2{\cdot}C_{10}H_5(OH){\cdot}NH_2$$

Prepared from diazotised 1 : 8-aminonaphthol-3 : 6-disulphonic acid (H-acid) and 1 : 5-aminonaphthol in acetic acid solution (the azo- group attacks the ortho- position relative to the hydroxy- group). Solution in water is reddish or bluish-violet, and in sulphuric acid blue. To this group belong also **Lanacyl Blue R** and **Lanacyl Navy Blue B, 2 B,** and **3 B** (C.).

Literature.—E. P. 24134 of 1896; D. R. P. 95190; F. P. 260848.

Rosophenine 10 B (Cl. Co.); **Rosophenine Pink** (Cl. Co.); **Direct Scarlet B** (K.); **Thiazine Red R** (B.); **Benzoin Fast Red AE** (B. K.); Sulphobenzenylaminothiocresolazo-α-naphthol-4-sulphonic acid



$$\underset{\displaystyle CH_3}{\overset{|}{C_6H_3}}\left<\begin{matrix}S\\N\end{matrix}\right>C{\cdot}\underset{\displaystyle SO_3H}{\overset{|}{C_6H_4}}{\cdot}N_2{\cdot}\underset{\displaystyle SO_3H}{\overset{|}{C_{10}H_5}}{\cdot}OH$$

Prepared from diazotised dehydrothio-*p*-toluidinesulphonic acid and α-naphthol-4-sulphonic acid. Solution in water is crimson-red, and in sulphuric acid violet-red.

The corresponding colour from diazotised primuline is called **Rosophenine SG** (Cl. Co.); (D. R. P. 48465; F. P. 192628, 196988; A. P. 398990).

Thiazine Red G (B.). Prepared from diazotised primuline (sulphonic acid) and β-naphthol-6-sulphonic acid. Orange-red aqueous solution gives an orange-red precipitate with hydrochloric acid, and becomes dark with sodium hydroxide. Solution in sulphuric acid is blood-red, giving an orange precipitate on dilution.

The corresponding colour from diazotised dehydrothio-*p*-toluidinesulphonic acid is **Clayton Cloth Scarlet** (Cl. Co.); **Titan Pink 3 B** (H.); **Thiazine Red GN** (B.).

References as for rosophenine SG.

3. Trisulphonic Acids.

Azo Red A (C.); Sulpho-α-naphthaleneazo-α-naphthol-3 : 6-disulphonic acid

$$HSO_3\cdot C_{10}H_6\cdot N_2\cdot C_{10}H_4(SO_3H)_2\cdot OH$$

Prepared by the action of diazotised naphthionic acid on α-naphthol-3 : 6-disulphonic acid. Aqueous solution red. Solution in sulphuric acid is blue, becoming violet and then red on dilution.

New Coccine (A.) (M.); **Brilliant Scarlet** (Lev.) (C.); **Croceine Scarlet 4 BX** (K.); **Victoria Scarlet 4 R** (T. M.); **Special Ponceau** (P.); **Cochineal Red A** (B.); **Brilliant Ponceau 4 R** (By.) (C.); **Brilliant Ponceau 5 R** (By.) (D.); **Ponceau 4 R** (B. S.); **Amaranth 107** (Sch.); **Acid Crimson** (H.); **Wool Red** (Sch.); **Wool Red extra** (K.); **Azo Red N extra** (L.). Isomeric with the preceding. Prepared from diazotised naphthionic acid and R-salt.

Literature.—D. R. P. 3229.

Chromotrope 8 B (M.); *p*-Sulphonaphthaleneazodihydroxynaphthalene-3 : 6-disulphonic acid

$$HSO_3\cdot C_{10}H_6\cdot N_2\cdot C_{10}H_3(SO_3H)_2(OH)_2$$

Prepared by the action of diazotised naphthionic acid on 1 : 8-dihydroxynaphthalene-3 : 6-disulphonic acid. Solution in water is violet-red, and in sulphuric acid indigo-blue. In addition to this and the other 'chromotrope' colours mentioned above, the marks S and 7 B also appear on the market, but their constitution has not yet been published.

Literature.—E. P. 9258 of 1890; D. R. P. 69095; F. P. 212607; A. P. 458283.

4. Tetrasulphonic Acids.

Ponceau 6 R (M.) (B.); *p*-Sulphonaphthaleneazo-β-naphtholtrisulphonic acid

$$HSO_3\cdot C_{10}H_6\cdot N_2\cdot C_{10}H_3(SO_3H)_3\cdot OH$$

Prepared by the action of diazotised naphthionic acid on β-naphthol-3 : 6 : 8-trisulphonic acid. Solution in water is magenta-red, and in sulphuric acid violet.

Literature.—E. P. 2544 of 1882; D. R. P. 22038; F. P. 149249; A. P. 268506.

Heliopurpurine 4 BL (By.); Disulphonaphthaleneazo-α-naphthol-3 : 6-disulphonic acid

$$C_{10}H_5(SO_3H)_2\cdot N_2\cdot C_{10}H_4(SO_3H)_2\cdot OH$$

Prepared from diazotised β-naphthylamine-3 : 6-disulphonic acid and α-naphthol-3 : 6-disulphonic acid. Used exclusively in the manufacture of lakes.

Literature.—Farber-Zeit. 1904, 15, 95.

Heliopurpurine 7 BL (By.). Isomeric with the preceding. Prepared by the action of diazotised β-naphthylamine-1 : 6-disulphonic acid on β-naphthol-3 : 6-disulphonic acid (R-salt). Used only for lakes.

Literature as above.

5. Pentasulphonic Acids.

Heliopurpurine GL (By.); Disulphonaphthaleneazo-β-naphthol-3 : 6 : 8-trisulphonic acid

$$C_{10}H_5(SO_3H)_2\cdot N_2\cdot C_{10}H_3(SO_3H)_3\cdot OH$$

Prepared from diazotised β-naphthylamine-3 : 6-disulphonic acid and β-naphthol-3 : 6 : 8-trisulphonic acid.

Use and literature as above.

E. Carboxylic Acids of Hydroxyazo- Compounds.[1]

Alizarine Yellow GG (M.) (I.); **Chrome Yellow R** (P.); **Alizarine Yellow G, 3 G** (Lev.); **Alizarine Yellow 3 G** (By.); **Mordant Yellow 2 G T** (B.); **Anthracene Yellow GG** (C.); **Alizarine Yellow G** (K. S.); *m*-Nitrobenzeneazosalicylic acid

$$NO_2\cdot C_6H_4\cdot N_2\cdot C_6H_3(CO_2H)\cdot OH$$

Prepared from diazotised *m*-nitroaniline and salicylic acid. The commercial product (the free acid) is usually a yellow paste, insoluble in water, and giving an orange solution with sulphuric acid. The sodium salt is put on the market in the dry state as **Alizarine Yellow GGW** (M.) (Ault and Wiborg Co.).

Literature.—E. P. 17583 of 1887; D. R. P. 44170; F. P. 187821; A. P. 424019.

Alizarine Yellow R (M.) (C. R.) (By.); **Alizarine Orange R, 2 R** (Lev.); **Mordant Yellow 3 R** (B.); **Mordant Yellow PN** (Farbwerk Ammersfoort); **Orange R** (K. S.); **Milling Orange R** (L.); **Anthracene Yellow RN** (C.); **Metachrome Orange R** (A.) (Brotherton & Co.); **Chromoxanthine** (K. S.); **Terracotta R** (G.); **Chrome Orange** (P.). Isomeric with the last. Prepared from diazotised *p*-nitroaniline and salicylic acid. Comes on the market as a brown paste insoluble in water and giving an orange-yellow solution with sulphuric acid. This consists of the free acid; the sodium salt (soluble in water with an orange colour) is called **Alizarine Yellow RW** (M.) (Marden, Orth, and Hastings Corporation).

Literature.—Meldola, Chem. Soc. Trans. 1885, 47, 666; Bull. Mulhouse, 1892, 198; J. Soc.

---

[1] Carboxylic acids containing also sulphonic acid groups are described under the corresponding sulphonic or disulphonic acids.

Chem. Ind. 1890, 9, 53; 1892, 11, 599; J. Soc. Dyers, 1889, 5, 106; E. P. 13920 of 1888; F. P. 193190; A. P. 431297.

Chrome Fast Yellow GG (A.); *o*-Anisoleazosalicylic acid $CH_3{\cdot}O{\cdot}C_6H_4{\cdot}N_2{\cdot}C_6H_3(CO_2H){\cdot}OH$. Prepared from diazotised *o*-anisidine and salicylic acid. In commerce as a bright-yellow paste or a yellow powder. Solution in hot water is greenish-yellow, and in sulphuric acid yellowish-brown.

Literature.—E. P. 12221 of 1895; D. R. P. 84772.

Azoalizarine Yellow 6 G (D. H.); **Alizarine Yellow 5 G** (M.); **Tartrachromine GG** (I.); *p*-phenetoleazosalicylic acid

$$C_2H_5{\cdot}O{\cdot}C_6H_4{\cdot}N_2{\cdot}C_6H_3(CO_2H){\cdot}OH$$

Prepared from diazotised *p*-phenetidine and salicylic acid. Solution in water is yellowish-brown, and in sulphuric acid brown-red.

Diamond Flavine G (By.); *p*-Hydroxydiphenylazosalicylic acid

$$OH{\cdot}C_{12}H_8{\cdot}N_2{\cdot}C_6H_3(CO_2H){\cdot}OH$$

Prepared by boiling the intermediate product from tetrazotised benzidine and one molecule of salicylic acid. In commerce as a yellowish-brown paste or powder which dissolves in water only after the addition of sodium acetate. Solution in sulphuric acid is blood-red. If the intermediate product is treated with sodium bisulphite, the product is known as **Dutch Yellow** (Farbwerk Ammersfoort); **Mordant Yellow GRO** (B.), which gives a yellow solution in water, and a bordeaux-red one in sulphuric acid (D. R. P. 68953).

Literature.—E. P. 11603 of 1891; D. R. P. 60373; F. P. 214756.

Diamond Yellow G (By.); *m*-Carboxybenzeneazosalicylic acid

$$CO_2H{\cdot}C_6H_4{\cdot}N_2{\cdot}C_6H_3(CO_2H){\cdot}OH$$

Prepared from diazotised *m*-aminobenzoic acid and salicylic acid. A greyish-yellow paste soluble in water (with addition of sodium acetate or carbonate) with a yellow colour. Gives a reddish-yellow solution with sulphuric acid.

Literature.—E. P. 8299 of 1889; D. R. P. 58271; F. P. 198521 (addition); A. P. 502368, 502369.

Lake Red D (M.); Carboxybenzeneazo-β-naphthol $CO_2H{\cdot}C_6H_4{\cdot}N_2{\cdot}C_{10}H_6{\cdot}OH$. Prepared from diazotised anthranilic acid and β-naphthol. Orange-red paste used for lakes.

Literature.—E. P. 22781 of 1906; D. R. P. 189023; F. P. 373115; A. P. 878964.

Brilliant Lake Red R (M.); Benzeneazo-2-hydroxy-3-naphthoic acid

$$C_6H_5{\cdot}N_2{\cdot}C_{10}H_5(OH){\cdot}CO_2H$$

Prepared from diazotised aniline and β-hydroxynaphthoic acid. Used for making lakes

Literature.—Ber. 1893, 26, 2897.

F. Unclassified Monoazo- Colouring Matters.

Peri Wool Blue B, BG, G (C.). These colouring matters are produced by the action of diazotised nitroaminophenols on *peri*- derivatives of naphthalene.

III. DISAZO- COMPOUNDS.[1]

A. Primary Disazo- Colouring Matters.[2]

Leather Brown (O.):

$$NH_2{\cdot}C_6H_4{\cdot}N_2{\cdot}C_6H_2(NH_2)_2{\cdot}N_2{\cdot}C_6H_4{\cdot}NH_2$$

Prepared by combining 2 mols. of *p*-diazoacetanilide with 1 mol. of *m*-phenylenediamine, and heating the product with strong hydrochloric acid. Commercial product is the monohydrochloride or the zinc chloride double salt. The brown aqueous solution becomes yellower on adding hydrochloric acid, and gives a brown precipitate with sodium hydroxide. The substance gives a brown solution in sulphuric acid, which becomes yellowish-brown on dilution.

Literature.—E. P. 11218 of 1891; D. R. P. 57429; A. P. 462414.

Terra Cotta F (G.); **Clayton Cotton Brown** (Cl. Co.):

$$P^{3}{\cdot}N_2{\cdot}C_6H_2(NH_2)_2{\cdot}N_2{\cdot}C_{10}H_6{\cdot}SO_3H$$

Prepared by combining first diazotised naphthionic acid and secondly diazotised primuline with *m*-phenylenediamine. Solution in water is brown, giving a brown precipitate with hydrochloric acid. Sulphuric acid dissolves colour to a reddish-violet solution, giving a brown precipitate on dilution.

Literature.—E. P. 1688 and 8215 of 1890; D. R. P. appl. G. 5870; F. P. 203439; A. P. 440288.

Cotton Orange R (B.):

$$P^{3}{\cdot}N_2{\cdot}C_6(NH_2)_2(SO_3H)_2{\cdot}N_2{\cdot}C_6H_4{\cdot}SO_3H^{4}$$

Prepared by combining first diazotised primuline and secondly diazotised metanilic acid with *m*-phenylenediaminedisulphonic acid. The orange-red aqueous solution gives a reddish precipitate with hydrochloric acid. Solution in sulphuric acid is bright red, precipitating on dilution.

Literature.—E. P. 21753 of 1893; D. R. P. 76118; F. P. 231694; A. P. 524261.

Anthracene Acid Brown G (C.) (Marden, Orth, and Hastings Corporation):

$$HSO_3{\cdot}C_6H_4{\cdot}N_2{\cdot}C_6H_2(CO_2H)(OH){\cdot}N_2{\cdot}C_6H_4{\cdot}NO_2$$

Prepared by combining diazotised sulphanilic acid (1 mol.) and diazotised *p*-nitroaniline (1 mol.) with salicylic acid (1 mol.). Aqueous solution is reddish-brown, and that in sulphuric acid is bluish-green.

Literature.—E. P. 17590 of 1896; D. R. P. 95066; F. P. 258783.

Resorcin Brown (A.) (K.) (H.) (I.) (B. K.) (Sch.):

$$HSO_3{\cdot}C_6H_4{\cdot}N_2{\cdot}C_6H_2(OH)_2{\cdot}N_2{\cdot}C_8H_9$$

Diazoxylene chloride is combined with resorcin yellow. Aqueous solution gives a brown precipitate with acids. Dissolves in sulphuric acid with a brown colour.

Literature.—D. R. P. 18861; A. P. 269359.

---

[1] *See* also DISAZO- AND TETRAZO- COLOURING MATTERS.

[2] It will be sufficient to give the chemical formulæ of these disazo-compounds without giving their names in full.

[3] P=residue of primuline or dehydrothiotoluidine refers to sulphonic acid.

[4] According to Heumann (Die Anilinfarben und ihre Fabrikation) the formula is—

$$P{\cdot}N_2{\cdot}C_6H(NH_2)(SO_3H)_2{\cdot}NH{\cdot}N_2{\cdot}C_6H_4{\cdot}SO_3H$$

Fast Brown G (A.); **Acid Brown** (D.) (P.); **Acid Brown G** (T. M.) (B. K.)

$$(HSO_3 \cdot C_6H_4 \cdot N_2)_2C_{10}H_5 \cdot OH(\alpha)$$

Prepared by the action of diazotised sulphanilic acid (2 mols.) on α-naphthol (1 mol.). Aqueous solution red-brown; violet precipitate with dilute acid. Sulphuric acid solution violet, becoming yellowish-brown on dilution.

Literature.—Krohn, Ber. 1888, 21, 3241.

Fast Brown (By.); **Resorcin Dark Brown** (B. K.): $(HSO_3 \cdot C_{10}H_6 \cdot N_2)_2C_6H_2(OH)_2$. Prepared by the action of diazotised naphthionic acid (2 mols.) on resorcinol (1 mol.). Brown aqueous solution gives a readily soluble precipitate with hydrochloric acid, and becomes cherry-red with sodium hydroxide. Solution in sulphuric acid is currant-red.

Literature.—D. R. P. 18861.

Palatine Black A (B.); **Wool Black 4 B** and **6 B** (A.); **Buffalo Black PY** (Sch.)

$$HSO_3 \cdot C_6H_4 \cdot N_2 \cdot C_{10}H_3(SO_3H)(OH)(NH_2) \cdot N_2 \cdot C_{10}H_7$$

Prepared by the action of diazotised sulphanilic acid (1 mol.) on 1 : 8-aminonaphthol-4-sulphonic acid in acid solution, and treating the product in alkaline solution with diazotised α-naphthylamine (1 mol.) in alkaline solution. Dark-blue aqueous solution becomes bluish-green with hydrochloric acid and pure blue with sodium hydroxide. The solution in sulphuric acid is blue, giving a dark-blue precipitate on dilution.

Literature.—E. P. 7713 of 1891 and 9894 of 1893; D. R. P. 71199, 91855; F. P. 213232; A. P. 590088, 593790.

Naphthol Blue Black S; **Naphthol Black 12 B** (C.); **Naphthol Blue Black B**; **Acid Black 16622** (L.); **Wool Black 6 G extra conc.** (T. M.); **Naphthalene Black 10 B** (P.); **Blue Black NB** (K.); **Coomassie Blue Black** (Lev.); **Amido Black 10 BO** (M.); **Amido Acid Black 10 B** (A.); **Naphthylamine Black 10 B** (By.); **Buffalo Black NB** (Sch.); **Agalma Black 10 B** (B.):

$$NO_2 \cdot C_6H_4 \cdot N_2 \cdot C_{10}H_2(SO_3H)_2(OH)(NH_2) \cdot N_2 \cdot C_6H_5$$

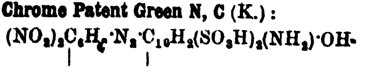
Prepared by the action of diazotised *p*-nitroaniline (1 mol.) on 1 : 8-aminonaphthol-3 : 6-disulphonic acid (H-acid) in acid solution, and treating the product in alkaline solution with diazotised aniline. The dark-blue aqueous solution gives a blue precipitate with hydrochloric acid. The solution in sulphuric acid is green, giving a blue precipitate on dilution.

Literature.—E. P. 1742 and 6972 of 1891; D. R. P. 65651; F. P. fourth addition to 201770; A. P. 480326.

Domingo Blue Black (various marks) (L.). Isomeric with the preceding, 1 : 8-aminonaphthol-3 : 5-disulphonic acid being used instead of H-acid. Mark B gives a violet aqueous solution, and a green solution in sulphuric acid.

Literature.—E. P. 19253 of 1895; D. R. P. appl. F 8626; A. P. 606438.

Chrome Patent Green N, C (K.):

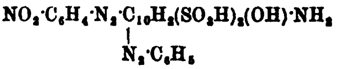


$$\begin{array}{l}(NO_2)_2C_6H_2 \cdot N_2 \cdot C_{10}H_2(SO_3H)_2(NH_2) \cdot OH\\ \qquad\;\; | \qquad\quad\;\; |\\ \qquad OH \qquad N_2 \cdot C_6H_5\end{array}$$

Prepared by the action of diazotised aniline (1 mol.) and diazotised picramic acid (1 mol.) on 1 : 8-aminonaphthol-4 : 6-disulphonic acid.

Literature.—E. P. 15074 of 1899; D. R. P. 110711; F. P. 291316.

Blue Black N (K.):



$$\begin{array}{l}NO_2 \cdot C_6H_4 \cdot N_2 \cdot C_{10}H_2(SO_3H)_2(OH) \cdot NH_2\\ \qquad\qquad\qquad\;\; |\\ \qquad\qquad\qquad N_2 \cdot C_6H_5\end{array}$$

Prepared by the action of diazotised *p*-nitroaniline (1 mol.) on 1 : 8-aminonaphthol-4 : 6-disulphonic acid in acid solution, and treating the product in alkaline solution with diazotised aniline.

Literature.—D. R. P. 108266; F. P. 271070; A. P. 563384, 613639.

Supramine Black BR (By.). The special base used in the preparation of this colouring matter is *p*-aminophenyl ether. Two mols. (or one of this and one of another base) are diazotised and combined with 1 : 8-aminonaphthol-4 : 6- or 3 : 6-disulphonic acid.

Literature.—F. P. 402546; A. P. 958830.

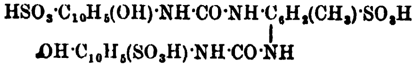
Janus Yellow R (M.).

$$N(CH_3)_3Cl \cdot C_6H_4 \cdot N_2 \cdot C_6H_2(OH)_2 \cdot N_2 \cdot C_6H_4 \cdot NO_2$$

Prepared by combining diazotised *m*-aminophenyltrimethylammonium chloride with *m*-nitrobenzeneazoresorcinol. Yellowish-brown aqueous solution gives a yellowish-brown precipitate. Solution in sulphuric acid is magenta-red, becoming yellow on dilution.

Literature.—E. P. 5119 of 1897; D. R. P. 93499, 95530, 99127, 100420; F. P. 264579; A. P. 623697.

Azidine Fast Scarlet GGS, 4 BS, 7 BS (C. J.). These dyes are prepared by the action of 2 mols. of a diazo- compound on the substance



$$\begin{array}{l}HSO_3 \cdot C_{10}H_5(OH) \cdot NH \cdot CO \cdot NH \cdot C_6H_2(CH_3) \cdot SO_3H\\ \qquad\qquad\qquad\qquad\qquad\qquad\qquad\;\; |\\ \quad OH \cdot C_{10}H_5(SO_3H) \cdot NH \cdot CO \cdot NH\end{array}$$

The brand **GGS** is made from diazotised *o*-toluidine (2 mols.), **4 BS** from diazotised *o*-toluidine (1 mol.), and diazotised β-naphthylamine (1 mol.), and **7 BS** from diazotised β-naphthylamine (2 mols.).

Literature.—E. P. 1781 of 1910; D. R. P. appl. J. 11718; F. P. 412138; A. P. (appl.) 541843.

Benzo Fast Scarlet GS, 4 BS, 8 BS, &c. (By.). These dyes are obtained by the action of 2 mols. of a diazo- compound on the urea produced by the action of carbonyl chloride on 2 mols. of 5-amino-α-naphthol-3-sulphonic acid (J-acid): *i.e.* $HSO_3 \cdot C_{10}H_5(OH) \cdot NH \cdot CO \cdot NH \cdot C_{10}H_5(OH) \cdot SO_3H$, or by treating azo- colouring matters from diazo- compounds and J-acid with carbonyl chloride or with carbon disulphide.

Literature.—E. P. 3615 of 1900; D. R. P. 122904, 126133, 126801, 128195, 132511, 133466; F. P. 297367; A. P. 653498, 662122, 675629, 675632.

B. Secondary Disazo- Colouring Matters.

Sudan III (A.); **Cerasine Red** (C.) (Barking Chemicals Co., Ltd.); **Fat Ponceau G** (K.); **Scarlet R** (C. J.); **Scarlet B Oil Soluble** (B. K.); **Moti Red 2 R** (T. M.); **Pyronal Red B** (D.); **Oil Red O** (Sch.):

$$C_6H_5 \cdot N_2 \cdot C_6H_4 \cdot N_2 \cdot C_{10}H_6 \cdot OH(\beta)$$

Prepared by the action of diazotised aminoazobenzene on β-naphthol. Insoluble in water; dissolves in sulphuric acid with a green colour.

becoming blue, and finally red and precipitating on dilution.

Literature.—Nietzki, Ber. 1880, 13, 1838; E. P. 5003 of 1879; D. R. P. 16483, 55779; F. P. 134802.

Ponceau 5 R (M.) (K.); **Erythrine P** (B.):

$$C_6H_5{\cdot}N_2{\cdot}C_6H_4{\cdot}N_2{\cdot}C_{10}H_3(SO_3H)_3{\cdot}OH$$

Prepared by the action of diazotised aminoazobenzene on β-naphthol-3 : 6 : 8-trisulphonic acid in alkaline solution. Cherry-red aqueous solution gives a brown precipitate with hydrochloric acid, and becomes violet with sulphuric acid.

Literature.—E. P. 2544 of 1882; D. R. P. 22038; F. P. 149249; A. P. 268507.

Cloth Red G (By.); **Cloth Red R** (D.); **Silk Red R** (B.); **Fast Silk Red** (O.):

$$C_6H_5{\cdot}N_2{\cdot}C_6H_4{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}OH$$

Prepared by the action of diazotised aminoazobenzene on α-naphthol-4-sulphonic acid in alkaline solution. Dissolves in sulphuric acid with a violet colour, giving a brownish-red precipitate on dilution.

Literature.—E. P. 2237 of 1883; D. R. P. 26012.

Croceine B (Sch.). The disulphonic acid corresponding with the preceding; produced by the action of diazotised aminoazobenzene on α-naphthol-4 : 8-disulphonic acid.

Literature.—E. P. 15775 and 15781 of 1885; D. R. P. 40571; F. P. 173083, 173084; A. P. 333037.

Croceine AZ (C.). Isomeric with the preceding. Prepared from α-naphthol-3 : 6-disulphonic acid. The solution in water is red, and in sulphuric acid reddish-violet.

Brilliant Croceine M (C.) (B K.) (O.); **Brilliant Croceïne 3 B** (By.); **Brilliant Croceine bluish** (M.); **Brilliant Croceine O** (K.); **Brilliant Croceïne, extra conc.** (T. M.); **Cotton Scarlet** (B.); **Ponceau BO extra** (A.); **Croceine 3 B** (P.); **Croceïne AZ** (K. S.); **Paper Scarlet** (M.):

$$C_6H_5{\cdot}N_2{\cdot}C_6H_4{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)_2{\cdot}OH$$

Prepared by the action of diazotised aminoazobenzene on β-naphthol-6 : 8-disulphonic acid. Dissolves in sulphuric acid with a reddish-violet, becoming first bluer and then red on dilution.

Literature.—E. P. 816 of 1884; D. R. P. 36491; F. P. 159998; A. P. 314939.

Azo Acid Violets (various marks) (By.) are prepared from diazotised aminoazobenzene (and similar compounds) and 1 : 8-dihydroxynaphthalene-4-sulphonic acid (or disulphonic acid).

Literature.—E. P. 3397 of 1890; 5984 of 1891; D. R. P. 57021, 64017.

Sudan IV (A.) (D.); **Oil Ponceau** (M.) (W.); **Cerotine Ponceau 3 B** (C. J.); **Fat Ponceau R** (K.); **Scarlet BBB Oil Soluble** (B. K.); **Red P 1566** (P.). (*See* also **Fast Azo Garnet**, p. 457.) $C_7H_7{\cdot}N_2{\cdot}C_7H_6{\cdot}N_2{\cdot}C_{10}H_6{\cdot}OH$. Prepared from diazotised *o*-aminoazotoluene and β-naphthol. Insoluble in water, but soluble in alcohol or benzene with a bluish-red colour. Sulphuric acid gives a blue solution, which yields a red precipitate on dilution.

Cloth Red B (By.) (D.):

$$C_7H_7{\cdot}N_2{\cdot}C_7H_6{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}OH$$

Prepared by the action of diazotised *o*-aminoazotoluene on α-naphthol-4-sulphonic acid. The red aqueous solution gives a red precipitate with hydrochloric acid, and on adding sodium hydroxide to the solution it becomes violet. The solution in sulphuric acid is blackish-blue.

Literature.—E. P. 5003 of 1879; D. R. P. 16482.

Cloth Red G (O.); **Cloth Red G extra** (By.); **Cloth Red GA** (A.); **Acidol Cloth Red G** (T. M.):

$$C_7H_7{\cdot}N_2{\cdot}C_7H_6{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}OH(\beta)$$

Produced by the action of diazotised aminoazotoluene on β-naphthol-6-sulphonic acid. Dissolves in water with a red-brown colour giving a similarly coloured precipitate on addition of acid. Dissolves with a blue colour in sulphuric acid, giving a brownish-red precipitate on dilution.

Literature.—E. P. 5003 of 1879; D. R. P. 16482.

Cloth Red B (O.) (K.); **Cloth Red O** (M.); **Cloth Red BA** (A.); **Cloth Red BB** (D.); **Fast Bordeaux O** (M.); **Fast Milling Red B** (Lev.); **Wool Red B** (C.):

$$C_7H_7{\cdot}N_2{\cdot}C_7H_6{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)_2{\cdot}OH(\beta)$$

Prepared by the action of diazotised aminoazotoluene on β-naphthol-3 : 6-disulphonic acid (R-salt). Aqueous solution red, becoming brownish on addition of hydrochloric acid. Dissolves in sulphuric acid with a blue colour, giving a brownish-red precipitate on dilution.

Literature as under preceding colour and E. P. 536 of 1880.

Cloth Red 3 G extra (By.); **Cloth Red 3 GA** (A.); **Cloth Red 3 G** (O.):

$$C_7H_7{\cdot}N_2{\cdot}C_7H_6{\cdot}N_2{\cdot}C_{10}H_6(SO_3H){\cdot}NH_2$$

Prepared by the action of diazotised aminoazotoluene on β-naphthylamine-6-sulphonic acid. The red aqueous solution gives with hydrochloric acid a dark reddish-brown precipitate. The solution in sulphuric acid is dark greenish-blue, and gives a brownish-red precipitate on dilution.

Bordeaux BX (By.):

$$C_8H_9{\cdot}N_2{\cdot}C_8H_8{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}OH$$

Prepared by the action of diazotised aminoazoxylene on β-naphthol-6-sulphonic acid. Solution in water is brownish-red, and gives a brownish-red precipitate with hydrochloric acid or sodium hydroxide. Sulphuric acid dissolves colour to a green solution, which gives a reddish-brown precipitate on dilution.

Literature.—E. P. 5003 of 1879; D. R. P. 16482.

Union Fast Claret (Lev.):

$$C_8H_9{\cdot}N_2{\cdot}C_8H_8{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)_2{\cdot}OH(\beta)$$

Prepared by the action of diazotised aminoazoxylene on β-naphthol-3 : 6-disulphonic acid. Soluble in water with a Bordeaux-red colour; reddish-brown flocculent precipitate on adding dilute acid. Solution in sulphuric acid dark blue, giving reddish-brown precipitate on dilution.

Literature.—E. P. 5003 and 5021 of 1879, 536 of 1880; D. R. P. 22010; A. P. 210233, 246221.

Croceïne Scarlet 3 B (By.) (K.) (T. M.); **Erythrine 2 R** (B.); **Ponceau 4 RB** (A.):

$$HSO_3{\cdot}C_6H_4{\cdot}N_2{\cdot}C_6H_4{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}OH$$

Produced by the action of diazotised aminoazobenzenesulphonic acid on β-naphthol-8-sulphonic acid (Bayer's). Solution not precipitated by alkali; a red precipitate produced by barium chloride, becoming dark-violet and crystalline on boiling. Dissolves in sulphuric acid with a deep-blue colour, becoming violet and then red on dilution.

Literature.—E. P. 1225 and 2030 of 1881, 2411 of 1883, 8390 of 1884; D. R. P. 18027; F. P. 142024; A. P. 256380.

Fast Scarlet B (K.):

$HSO_3{\cdot}C_6H_4{\cdot}N_2{\cdot}C_6H_4{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}OH$

Prepared by the action of diazotised aminoazobenzenemonosulphonic acid on β-naphthol-6-sulphonic acid (Schaffer's). Red solution in water, giving brown precipitate with hydrochloric acid and a red-violet colouration with sodium hydroxide. Solution in sulphuric acid is blue, and becomes red on dilution.

Literature.—D. R. P. 16482.

Cloth Scarlet G (K.):

$HSO_3{\cdot}C_6H_4{\cdot}N_2{\cdot}C_6H_4{\cdot}N_2{\cdot}C_{10}H_6{\cdot}OH$

Prepared by the action of diazotised aminoazobenzenemonosulphonic acid on β-naphthol. The scarlet solution in water gives a brown precipitate with sodium hydroxide, and becomes yellower on addition of hydrochloric acid when dilute, but in concentrated solutions a light-red precipitate is produced. The solution in sulphuric acid is green, becoming red on dilution.

Literature.—E. P. 5003 and 5021 of 1879, 536 of 1880; D. R. P. 16482.

Milling Orange (D.):

$HSO_3{\cdot}C_6H_4{\cdot}N_2{\cdot}C_6H_4{\cdot}N_2{\cdot}C_6H_3(CO_2H){\cdot}OH$

Prepared by the action of diazotised aminoazobenzenemonosulphonic acid on salicylic acid. Orange-red solution in water, giving greyish-yellow precipitate with hydrochloric acid, and a dark-red solution and precipitate with sodium hydroxide. The solution in sulphuric acid is violet, giving a greyish-yellow precipitate on dilution.

Ponceau 3 RB (A.) (B K.); **New Red L** (K.); **Ponceau B extra** (M.); **Fast Ponceau B** (B.); **Double Scarlet** (K.); **Scarlet EC** (C.); **Blackley Scarlet** (Lev.); **Scarlet B** (P.):

$HSO_3{\cdot}C_6H_4{\cdot}N_6{\cdot}C_6H_3(SO_3H){\cdot}N_2{\cdot}C_{10}H_6{\cdot}OH$

Prepared from diazotised aminoazobenzenedisulphonic acid and β-naphthol. Solution not precipitated by alkali; a brown flocculent precipitate by dilute acids. Dissolves in sulphuric acid with a green colour, becoming first blue and finally brown and precipitating on dilution.

Literature.—E. P. 5003 of 1879, 529 of 1880; D. R. P. 16482; A. P. 224927, 224928; Nietzki, Ber. 1880, 13, 800, 1838; Miller, *ibid.* 542, 803, 980.

Croceïne Scarlet O extra (K.):

$HSO_3{\cdot}C_6H_4{\cdot}N_2{\cdot}C_6H_3(SO_3H){\cdot}N_2{\cdot}C_{10}H_4(SO_3H){\cdot}OH$

Prepared by the action of diazotised aminoazobenzenedisulphonic acid on β-naphthol-8-sulphonic acid. The yellowish-red aqueous solution gives a violet colouration with hydrochloric acid or sodium hydroxide. The solution in sulphuric acid is blue, becoming yellowish-red on dilution.

Croceïne Scarlet 7 B (Ruch & Fils); **Ponceau 6 RB** (A.); **Croceine Scarlet 8 B** (K.) (By.); **Erythrine 7 B** (B.); **Cocceïne 7 B** (P.):

$HSO_3{\cdot}C_7H_6{\cdot}N_2{\cdot}C_7H_6{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}OH(\beta)$

Prepared by the action of diazotised aminoaz toluenesulphonic acid on β-naphthol-8-sulphoni acid (Bayer's) in presence of alkali. Resemble croceïne scarlet 3 B in general properties; give a crystalline magnesium salt on adding magnesium sulphate to hot concentrated solution an allowing to cool. Dissolves with a blue colou in sulphuric acid, becoming red on dilution.

Literature as for croceïne scarlet 3 B; an A. P. 256375.

Orseilline 2 B (By.). Prepared by the actio of diazotised aminoazotoluenesulphonic aci on α-naphthol-4-sulphonic acid. Dissolves wit a blue colour in sulphuric acid, becoming re on dilution.

Literature.—E. P. 2237 and 4237 of 1883 D. R. P. 26012.

Bordeaux G (By.) (M.). Prepared by th action of diazotised aminoazotoluenemon sulphonic acid on β-naphthol-6-sulphonic aci

Literature.—E. P. 5003 of 1879; D. R. 16482, 16483.

Eriochrome Verdone A (G.):

$HSO_3{\cdot}C_6H_4{\cdot}N_2{\cdot}C_7H_5(OH){\cdot}N_2{\cdot}C_{10}H_6{\cdot}OH$

Sulphanilic acid is diazotised and combined wit *m*-amino-*p*-cresol and the product is diazotise and combined with β-naphthol. The viole aqueous solution becomes claret-red wit hydrochloric acid, and blue-green with sodiu hydroxide. The solution in sulphuric acid i green, giving a brown-red precipitate on dilution. Wool is dyed in claret-red shades fro an acid-bath and on chroming becomes blue green.

Literature.—E. P. 13903 and 13904 of 1909 D. R. P. 201377, 224024, 227197; F. P. 40453

Ponceau 10 RB (A.):

$HSO_3{\cdot}C_6H_4{\cdot}N_2{\cdot}C_6H_3(O{\cdot}CH_3){\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}OH$

Sulphanilic acid is diazotised and combine with *o*-anisidine, and the product diazotise and combined with β-naphthol-8-sulphonic acid The aqueous solution is red, and that in sulphuric acid blue.

Janus Red B (M.):

$N(CH_3)_3Cl{\cdot}C_6H_4{\cdot}N_2{\cdot}C_6H_3(CH_3){\cdot}N_2{\cdot}C_{10}H_6{\cdot}OH$

Prepared by diazotising *m*-aminophenyltrimethylammonium chloride, combining wit *m*-toluidine, diazotising the product and combining with β-naphthol. The red aqueou solution gives a brownish-red precipitate wit hydrochloric acid and a bluish-violet precipitat with sodium hydroxide. The solution in sulphuric acid is green, and gives a red precipitat on dilution.

Literature.—E. P. 5119 of 1897, 10596 o 1898; D. R. P. 93499, 95718, 98585, 100919 F. P. 264579; A. P. 623697.

Neutral Grey G (A.):

$C_6H_5{\cdot}N_2{\cdot}C_{10}H_6{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)(NH_2){\cdot}OH$

Diazotised benzeneazo-α-naphthylamine is combined with 7-amino-α-naphthol-3-sulphonic aci (γ-acid). It gives a blackish-violet solution i water, and a bluish-green in sulphuric acid.

Literature.—D. R. P. appl. A. 3743.

Nyanza Black B (A.):

$NH_2{\cdot}C_6H_4{\cdot}N_2{\cdot}C_{10}H_6{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)(NH_2){\cdot}OH$

Prepared by the action of diazotised *p*-amino benzeneazo-α-naphthylamine (only one amino-group is diazotised)[1] on 7-amino-α-naphthol-3-sulphonic acid (γ-acid). Solution is dark-violet and gives violet precipitates with hydrochloric acid and sodium hydroxide. The solution in sulphuric acid is blue, and gives a violet precipitate on dilution. The colouring matter itself produces only indifferent shades, but when diazotised and developed on the fibre fast shades are obtained. When developed with *m*-tolylenediamine, a brown-black is obtained, and with β-naphthol a navy-blue.

Literature.—E. P. 277 and 6630 of 1892; D. R. P. 72393, 72394, 80421; F. P. 221378; A. P. 491410, 511688, 512167.

Coomassie Wool Black R (Lev.):

$$NH_2{\cdot}C_6H_4{\cdot}N_2{\cdot}C_{10}H_6{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}OH$$

Prepared by the action of diazotised *p*-acetylaminobenzeneazo-α-naphthylamine on β-naphthol-6-sulphonic acid (Schaffer's), and hydrolysing the product. The dark-violet solution gives a precipitate with hydrochloric acid. The solution in sulphuric acid is green, becoming red on dilution.

Literature.—E. P. 24980 of 1899; D. R. P. 122457; A. P. 654167, 654168.

Coomassie Wool Black S (Lev.):

$$NH_2{\cdot}C_6H_4{\cdot}N_2{\cdot}C_{10}H_6{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)_2{\cdot}OH$$

Prepared as the preceding dyestuff, the final component being β-naphthol-3 : 6-disulphonic acid (R-salt). The blue-black aqueous solution becomes redder with hydrochloric acid. The solution in sulphuric acid is green, becoming red on dilution.

Literature.—as above.

Diaminogen BB extra (C.):

$$NH_2{\cdot}C_{10}H_5(SO_3H){\cdot}N_2\,C_{10}H_6\,N_2\,C_{10}H_5(SO_3H){\cdot}OH$$

Monoacetyl-1 : 4-naphthylenediamine-7-sulphonic acid is diazotised and combined with α-naphthylamine, the intermediate product diazotised and combined with 7-amino-α-naphthol-3-sulphonic acid (γ-acid), and the product hydrolysed. When diazotised and developed on the fibre a fast black is produced.

Literature.—E. P. 15444 of 1893; D. R. P. 78831, 79910; F. P. 232209; A. P. 533463, 560796.

Diaminogen Blue BB (C.); **Diazanil Blue BB** (M.). Prepared as the preceding, but the end component is β-naphthol-6-sulphonic acid (Schaffer's).

Literature as above.

Diaminogen Blue G (C.). Prepared as above, the end-component being β-naphthol-3 : 6-disulphonic acid (R-salt).

Literature as above.

Diazo Indigo Blue is an analogous product.

Zambesi Sky Blue 4 B (A.). Prepared from diazotised monoacetyl-3 : 6-diaminocresyl methyl ether combined with α-naphthylamine,[2] the intermediate product being diazotised and combined with β-naphthol-6-sulphonic acid and the end-product saponified. The reddish-violet aqueous solution becomes redder with hydrochloric acid and bluer with sodium hydroxide. The solution in sulphuric acid is blue, and becomes violet-red on dilution.

Literature.—E. P. 2188 of 1901; D. R. P. 126172.

Victoria Black B (By.):

$$HSO_3{\cdot}C_6H_4{\cdot}N_2{\cdot}C_{10}H_6{\cdot}N_2{\cdot}C_{10}H_4(OH)_2{\cdot}SO_3H$$

Prepared by the action of diazotised *p*-sulphobenzeneazo-α-naphthylamine on 1 : 8-dihydroxynaphthalene-4-sulphonic acid. The dark reddish-violet aqueous solution gives with hydrochloric acid a Bordeaux-red precipitate, and with sodium hydroxide becomes dark-blue violet. The solution in sulphuric acid is moss-green, changing on dilution to sea-green, and then to bluish-red.

Literature.—E. P. 13665 of 1889; D. R. P. 61707, 62945; F. P. 200520; A. P. 466202.

Buffalo Black 10 B (Sch.); **Acid Black N** (P.):

$$HSO_3{\cdot}C_6H_4{\cdot}N_2{\cdot}C_{10}H_6{\cdot}N_2{\cdot}C_{10}H_3(SO_3H)_2(OH){\cdot}NH_2$$

Prepared as the preceding, except that 1 : 8-aminonaphthol-3 : 6-disulphonic acid (H-acid) is used as the end-component. The solutions in water or sulphuric acid are blue.

Literature.—A. P. 618963.

Jet Black R (By.):

$$(HSO_3)_2C_6H_3{\cdot}N_2{\cdot}C_{10}H_6{\cdot}N_2{\cdot}C_{10}H_6{\cdot}NH{\cdot}C_6H_5$$

Prepared by the action of diazotised disulphobenzeneazo-α-naphthylamine on phenyl-α-naphthylamine. The bluish-violet aqueous solution gives a bluish-black precipitate with hydrochloric acid, and a soluble violet precipitate with sodium hydroxide. Sulphuric acid dissolves the colouring matter to a blue solution, which gives a greenish-blue precipitate on dilution.

Literature.—E. P. 14442 of 1888; D. R. P. 48924; F. P. 193430; A. P. 425885.

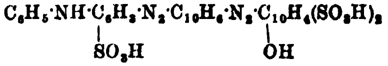
Diamond Black F (By.) (B.) (L.); **Chrome Fast Black FRW** (I.); **Chrome Deep Black** (T. M.); **Salicin Black D** (K.); **Era Black F** (Lev.); **Fast Chrome Black B** (Sch.); **Fast Mordant Black B, T** (M.); **Chrome Black J** (H.):

$$CO_2H{\cdot}C_6H_3(OH){\cdot}N_2{\cdot}C_{10}H_6{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}OH$$

Aminosalicylic acid is diazotised and combined with α-naphthylamine, and the product diazotised and combined with α-naphthol-4- (or 5-) sulphonic acid. Bluish-violet solution gives violet precipitate with hydrochloric acid, and becomes blue with sodium hydroxide. Solution in sulphuric acid is greenish, giving a violet precipitate on dilution. Similar dyestuffs are **Era Blacks J** and **NG** (Lev.).

Literature.—E. P. 8209 of 1889; D. R. P. 51504; F. P. 198521; A. P. 438438.

Nerol B (A.):



$$\underset{\textstyle SO_3H}{C_6H_5{\cdot}NH{\cdot}C_6H_3}{\cdot}N_2{\cdot}C_{10}H_6{\cdot}N_2{\cdot}\underset{\textstyle OH}{C_{10}H_4}(SO_3H)_2$$

p-Aminodiphenylamine-*o*-sulphonic acid is diazotised and combined with α-naphthylamine, and the intermediate product is diazotised and combined with β-naphthol-3 : 6-disulphonic acid (R-salt). Dark violet-blue solution in water gives a blue precipitate with hydrochloric acid. The solution in sulphuric acid is dark blue-violet, giving a blue-violet precipitate on dilution.

---

[1] All the authorities give the above constitution for this colouring matter, but it is generally understood that a benzenoid amino- group is diazotised preferably to a naphthalenoid amino- group.

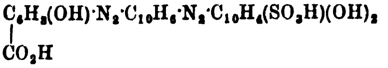
[2] According to Buntrock (Zeitsch. Farben-Ind. 1902, 1, 224). The patents quoted give the 6- or 7-sulphonic acid as intermediate component.

Literature.—E. P. 24527 of 1897; D. R. P. 101274; F. P. 271609.

Nerol 2 B (A.). Prepared as the preceding, except that the last component is α-naphthol-4-sulphonic acid.

Properties and literature as above.

Diamond Green (By.):



$$\underset{\displaystyle CO_2H}{\underset{|}{C_6H_3}}(OH)\cdot N_2\cdot C_{10}H_6\cdot N_2\cdot C_{10}H_4(SO_3H)(OH)_2$$

Prepared by diazotising aminosalicylic acid and combining with α-naphthylamine, the intermediate product being diazotised and combined with 1 : 8-dihydroxynaphthalene-4-sulphonic acid. The blackish-violet aqueous solution gives a dark reddish-violet precipitate with hydrochloric acid, and becomes dark blue with sodium hydroxide. The solution in sulphuric acid is bluish-green, becoming greenish-blue, and finally giving a blackish-violet precipitate on dilution.

Literature.—E. P. 8299 of 1889 1828 of 1890; D. R. P. 51504, 62003; F. P. 198521; A. P. 438438.

Naphthylamine Black D (C.) (K.); **Deep Black D, conc.** (T. M.); **Coomassie Wool Black D** (Lev.); **Buffalo Black AD** (Sch.); **Acid Black NN** (I.); **Naphthalene Black R** (H.):

$$(HSO_3)_2C_{10}H_5\cdot N_2\cdot C_{10}H_6\cdot N_2\cdot C_{10}H_6\cdot NH_2$$

α-Naphthylamine-3 : 6-disulphonic acid is diazotised and combined with α-naphthylamine, and the intermediate product diazotised and combined with α-naphthylamine. The violet-black aqueous solution gives a black precipitate with hydrochloric acid. The solution in sulphuric acid is bluish-black, and on dilution becomes green, and finally gives a black precipitate.

Literature.—E. P. 18425 of 1888; D. R. P. 50907; F. P. 170342; A. P. 412440.

Naphthylamine Black 4 B (C.); **Naphthalene Black D** (H.) is a mixture of Naphthol blue-black and the preceding colouring matter.

Naphthyl Blue Black N (C.); **Alphyl Blue Black O** (M.). 4 : 7-Disulphonaphthaleneazo-α-naphthylamine is diazotised and combined with aminonaphthol ethyl ether. The dark-violet aqueous solution turns blue and gives a blackish-blue precipitate with hydrochloric acid, and becomes blue and precipitates with sodium hydroxide. The solution in sulphuric acid is dark blue, which on dilution becomes blue, and finally bluish-violet.

Literature.—Chem. Ind. 1896, 19, 548.

Anthracite Black B (C.); **Phenylene Black** (P.):

$$(HSO_3)_2C_{10}H_5\cdot N_2\cdot C_{10}H_6\cdot N_2\cdot C_6H_3(NH\cdot C_6H_5)_2$$

α-Naphthylamine-3 : 6-(4 : 7-in the case of the latter dye) -disulphonic acid is diazotised and combined with α-naphthylamine, and the product diazotised and combined with diphenyl-*m*-phenylenediamine. The dull-violet aqueous solution gives a violet precipitate with hydrochloric acid. The solution in sulphuric acid is black, giving a greenish-black precipitate on dilution.

Literature.—E. P. 4825 and 7977 of 1889; D. R. P. 52616, 61202; F. P. 196793, 197963; A. P. 502912.

$$(HSO_3)_2C_{10}H_5\cdot N_2\cdot C_{10}H_6\cdot N_2\cdot C_{10}H_4(SO_3H)_2.OH$$

β-Naphthylamine-6 : 8-disulphonic acid is diazotised and combined with α-naphthylamine, and the product diazotised and combined with β-naphthol-3 : 6-disulphonic acid (R-salt). The violet aqueous solution gives with hydrochloric acid a reddish-violet and with sodium hydroxide a blue precipitate. The solution in sulphuric acid is green, becoming bluer on dilution, and then giving a reddish-violet precipitate.

Literature.—E. P. 9214 of 1885; D. R. P. 39029; F. P. 170342; A. P. 345901.

Naphthol Black 2 B (Lev.) is prepared as the preceding, but starting with α-naphthylamine-3 : 6-disulphonic acid.

Naphthol Black 6 B (C.) (K.); **Acid Black 6 B** (H.); **Brilliant Black BD** (B.); **Naphthalene Black 5 B** (P.); **Naphthol Black** (D.); **Acid Black 5 B, BR** (T. M.); **Wool Black** (B. K.); **Acidol Black** (T. M.) is prepared by the action of diazotised 4 : 7-disulphonaphthaleneazo-α-naphthylamine on β-naphtholdisulphonic acid (R-salt). Aqueous solution dark violet, becoming dark blue with acid or alkali; dissolves in sulphuric acid with a dark-green colour, becoming blue on dilution.

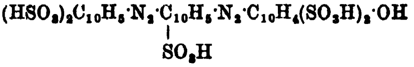
Literature.—E. P. 9214 of 1885; D. R. P. 39029; F. P. 170342; A. P. 345901.

Sulphone Black G, R (By.):

$$C_6H_5\cdot N_2\cdot C_{10}H_5(SO_3H)\ N_2\cdot C_{10}H_4(OH)_2\cdot SO_3H$$

Diazotised aniline is combined with α-naphthylamine-6-(or 7)-sulphonic acid, the product diazotised and combined with 1 : 8-dihydroxynaphthalene-4-sulphonic acid. The aqueous solution is reddish-violet, and that in sulphuric acid is greenish-blue.

Biebrich Patent Black BO (K.):



$$(HSO_3)_2C_{10}H_5\cdot N_2\cdot \underset{\displaystyle SO_3H}{\underset{|}{C_{10}H_5}}\cdot N_2\cdot C_{10}H_4(SO_3H)_2\cdot OH$$

α-Naphthylaminedisulphonic acid is diazotised and combined with α-naphthylamine-6-(or 7)-sulphonic acid, the product diazotised and combined with β-naphthol-3 : 6-disulphonic acid (R-salt). The dark reddish-violet aqueous solution is turned slightly blue with hydrochloric acid and pure blue with sodium hydroxide. Solution in sulphuric acid is dark greenish-blue, becoming dark violet on dilution.

Literature.—E. P. 2718 of 1892; D. R. P. 73901, 83572, 84460; F. P. 219424; A. P. 476070, 546068, 546069.

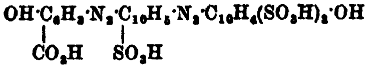
Biebrich Patent Black 4 AN (K.):

$$HSO_3\cdot C_{10}H_6\cdot N_2\cdot C_{10}H_5(SO_3H)\cdot N_2\cdot C_{10}H_6\cdot NH_2$$

Prepared from diazotised naphthionic acid and α-naphthylamine-6-(or 7)-sulphonic acid, the product being diazotised and combined with α-naphthylamine. The violet aqueous solution gives a bluish-black precipitate with hydrochloric acid, and becomes blue with sodium hydroxide. Solution in sulphuric acid is bluish-green, giving a bluish-black precipitate on dilution. Similar dyestuffs bear the brands 6 AN, 4 BN, and 6 BN.

References as above.

Anthracene Acid Black (various marks) (C.):



$$\mathrm{OH{\cdot}}\underset{\substack{|\\ CO_2H}}{C_6H_3}{\cdot}N_2{\cdot}\underset{\substack{|\\ SO_3H}}{C_{10}H_5}{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)_2{\cdot}OH$$

Aminosalicylic acid is diazotised and combined with *a*-naphthylamine-6-(or 7)-sulphonic acid, and the product diazotised and combined with *β*-naphthol-3 : 6-disulphonic acid (R-salt). The violet aqueous solution gives a violet precipitate with hydrochloric acid, and becomes bluish-violet with sodium hydroxide. Solution in sulphuric acid is green, giving a violet precipitate on dilution.

Naphthalene Acid Black 4 B (By.):

$$HSO_3{\cdot}C_6H_4{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}N_2{\cdot}C_{10}H_6{\cdot}NH_2$$

Metanilic acid is diazotised and combined with the same acid as in the preceding, and the product diazotised and combined with *a*-naphthylamine. Aqueous solution is violet, becoming blue with hydrochloric acid, and redder with sodium hydroxide. Solution in sulphuric acid is blue, becoming violet on dilution.

Sulphocyanines (various marks) (By.); **Tolyl Blue GR extra, 5 R extra** (M.); **Coomassie Navy Blue** (various marks) (Lev.) are prepared from diazotised metanilic acid, which is combined with *a*-naphthylamine, the product being diazotised and combined with phenyl- or tolyl-*a*-naphthylamine-8-sulphonic acid. The violet aqueous solution gives a greyish-blue precipitate with hydrochloric acid. Solution in sulphuric acid is blue, becoming greener and giving a blue precipitate on dilution. Similar dyes are **Sulphone Black 3 B, 4 BT** (By.) (*cf.* D. R. P. 75571).

Literature.—D. R. P. 118655.

Sulphoncyamine Black B, 2 B (By.); **Tolyl Black B, BB** (M.). *a*-Naphthylamine-5-sulphonic acid is diazotised and combined with *a*-naphthylamine (or with Cleve's acids), the product being diazotised and combined with phenyl-*a*-naphthylamine-8-sulphonic acid. The aqueous solution is violet, and that in sulphuric acid dark blue.

Literature.—D. R. P. 118655.

Brilliant Croceine 9 B (C.):

$$(HSO_3)_2C_{10}H_5{\cdot}N_2{\cdot}C_6H_4{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)_2{\cdot}OH$$

β-Naphthylamine-6 : 8-disulphonic acid is diazotised and combined with aniline, the product being diazotised and combined with a mixture of *β*-naphthol-3 : 6- and 6 : 8-disulphonic acids. The bluish-red aqueous solution becomes darker and bluer with hydrochloric acid, and brownish with sodium hydroxide. The solution in sulphuric acid is blue, changing to bluish-red on dilution.

Fast Sulphone Black F, FB (K. S.):

$$HSO_3{\cdot}C_{10}H_6{\cdot}N_2{\cdot}C_{10}H_3(SO_3H)_2(OH){\cdot}N_2{\cdot}C_{10}H_6{\cdot}OH$$

Naphthionic acid is diazotised and combined with 1 : 8-aminonaphthol-3 : 6-disulphonic acid (H-acid), the product diazotised and combined with *β*-naphthol. The solution in water is greenish-black, and in sulphuric acid blackish-violet.

Literature.—E. P. 14768 of 1903; D. R. P. 158134.

C. Tetrazo- Colouring Matters.

Anthracene Yellow C (C.) (By.); **Fast Mordant Yellow GI** (B.); **Acid Alizarine Yellow RC** (M.):

$$S\left\langle\begin{array}{l}C_6H_4{\cdot}N_2{\cdot}C_6H_3(CO_2H){\cdot}OH\\ C_6H_4{\cdot}N_2{\cdot}C_6H_3(CO_2H){\cdot}OH\end{array}\right.$$

Prepared from tetrazotised thioaniline and salicylic acid (2 mols.). The light yellowish-brown aqueous solution gives a greenish-brown precipitate with hydrochloric acid. The solution in sulphuric acid is dark reddish-violet, giving a yellowish-grey precipitate on dilution.

Milling Red G (C.):

$$S\left\langle\begin{array}{l}C_6H_4{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}OH\\ C_6H_4{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}OH\end{array}\right.$$

Similarly prepared from tetrazotised thioaniline and *β*-naphthol-6-sulphonic acid (Schäffer's). The orange-red aqueous solution gives a brown precipitate with hydrochloric acid. The solution in sulphuric acid is reddish-violet, giving a brown precipitate on dilution.

Cotton Yellow G (B.); **Benzo Fast Yellow 5 GL** (By.); **Diamine Fast Yellow 3 G** (C.):

$$CO\left\langle\begin{array}{l}NH{\cdot}C_6H_4{\cdot}N_2{\cdot}C_6H_3(CO_2H){\cdot}OH\\ NH{\cdot}C_6H_4{\cdot}N_2{\cdot}C_6H_3(CO_2H){\cdot}OH\end{array}\right.$$

p-Aminoacetanilide is diazotised and combined with salicylic acid, the product hydrolysed and treated with carbonyl chloride. The yellow aqueous solution gives a brown precipitate with hydrochloric acid, and becomes rather more orange with sodium hydroxide. The solution in sulphuric acid is orange-red, giving a bluish-violet precipitate on dilution.

Literature.—E. P. 15258 of 1888; D. R. P. 46737, 47902; A. P. 430535.

Benzo Fast Pink 2 BL (By.):

$$CO\left\langle\begin{array}{l}C_6H_3(SO_3H){\cdot}N_2{\cdot}C_{10}H_4(SO_3H)(OH){\cdot}NH_2\\ C_6H_3(SO_3H){\cdot}N_2{\cdot}C_{10}H_4(SO_3H)(OH){\cdot}NH_2\end{array}\right.$$

Prepared from tetrazotised di-*p*-aminodiphenylcarbamidedisulphonic acid and 7-amino-*a*-naphthol-3-sulphonic acid (*γ*-acid; 2 mols.) in neutral or acid solution. The red aqueous solution becomes reddish-violet with hydrochloric acid and yellower with sodium hydroxide. The solution in sulphuric acid is blue, giving an almost black precipitate on dilution.

Literature.—E. P. 11766 of 1901; D. R. P. 129388, 131513; F. P. 311339; A. P. 687171; Zeitsch. Farben.-Ind. 1902, 1, 192; Chem. Zeit. 1902, 26, 485.

Milling Red R (D.):

$$CH_2\left\langle\begin{array}{l}C_6H_4{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)_2{\cdot}OH\\ C_6H_4{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)_2{\cdot}OH\end{array}\right.$$

Prepared from tetrazotised diaminodiphenylmethane and *β*-naphthol-3 : 6-disulphonic acid (R-salt; 2 mols.). The corresponding colour from diaminodixylylmethane is **Cinnabar Scarlet BF** (B. K.), and that from diaminodixylylphenylmethane is **Cotton Ponceau** (B. K.); **Cinnabar Scarlet G, R** (B. K.). They are all also used for the preparation of lakes.

Literature.—D. R. P. 43644.

Bismarck Brown (most firms); **Manchester Brown**; **Phenylene Brown**; **Vesuvine**; **Leather Brown**; **Cinnamon Brown**; **English Brown**; **Brown A** (P.):

$$(NH_2)_2C_6H_3{\cdot}N_2{\cdot}C_6H_4{\cdot}N_2{\cdot}C_6H_3(NH_2)_2$$

Prepared by adding a solution of 42·5 kilos of sodium nitrite and 127·5 kilos of hydrochloric acid to a solution of *m*-phenylenediamine prepared by reducing 250 kilos of *m*-dinitrobenzene. The commercial product is the hydrochloride. The aqueous solution gives a brown precipitate with sodium hydroxide. The solution in sulphuric acid is brown, becoming red on dilution.

Literature.—E. P. 3307 of 1863; Zeitsch. f. Chem. 1867, 3, 278; Ber. 1897, 30, 2111, 2203, 2899.

Azo Alizarine Bordeaux W (D. H.):

$$CO_2H{\cdot}C_6H_3(OH){\cdot}N_2\,C_6H_4{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}OH$$

p-Aminoacetanilide is diazotised and combined with salicylic acid, the product hydrolysed and diazotised and combined with *a*-naphthol-4-sulphonic acid. The aqueous solution is red, and that in sulphuric acid is blue.

Literature.—E. P. 1033 of 1899; D R. P. appl. D 9290; F. P. 284775; A. P. 631089.

Azo Alizarine Black I (D. H.). Prepared as the preceding, except that the end-component is 1 : 8 dihydroxynaphthalene-3 : 6-di (or 4-mono)-sulphonic acid The aqueous solution is violet, and that in sulphuric acid blue.

Literature.—E P. 1033 of 1899; D R. P. appl. D. 9290; F. P. 284775; A. P. 640010, 628721.

Violet Black (B.):

$$NH_2{\cdot}C_{10}H_6{\cdot}N_2{\cdot}C_6H_4{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}OH$$

p-Aminoacetanilide is diazotised and combined with 1 mol. of *a*-naphthol 4-sulphonic acid. The acetyl- group is then removed by heating with alkali, and the amino- compound is diazotised and combined with 1 mol. of *a*-naphthylamine. Aqueous solution brownish-red, giving violet precipitate with mineral acids and reddish-violet colouration with acetic acid or with sodium hydroxide; blue solution in sulphuric acid giving violet precipitate on dilution.

Literature.—D. R P. 42814.

Ingrain Black C (*H.*):

$$HSO_3\,C_{10}H_5(NH_2){\cdot}N_2{\cdot}C_6H_4\,C_{10}H_4(SO_3H)(OH)\,NH_2$$

p-Aminoacetanilide is diazotised and combined with *a*-naphthylamine-6 (or 7)-sulphonic acid (Cleve's acid), the product hydrolysed, diazotised, and combined with 1 mol of 7-amino-*a*-naphthol-3-sulphonic acid (γ-acid).

Acid Alizarine Black SE (M.); **Palatine Chrome Black F** (B.):

$$HSO_3{\cdot}C_6H_2(OH)(N_2\,C_{10}H_6{\cdot}OH)_2$$

Prepared from tetrazotised 2 : 6-diaminophenol-4-sulphonic acid and *β*-naphthol (2 mols.). Dark-blue aqueous solution gives a red precipitate with hydrochloric acid and a greenish-blue precipitate with sodium hydroxide. The solution in sulphuric acid is violet, giving a red precipitate on dilution.

Literature.—E. P. 18624 of 1900, 16811 and 2397 of 1901; D. R. P. 147880, 150373; F. P. 304694, 308588, 310597, 313671; A. P. 665696, 677231.

Acid Alizarine Black SN (M.); **Palatine Chrome Black S** (B.). Similar to the above, except that 1 mol. of *β*-naphthol and 1 mol. of *β*-naphthol-6-sulphonic acid are used as components. The blue aqueous solution gives a red precipitate with hydrochloric acid, and becomes violet with sodium hydroxide. The solution in sulphuric acid is violet, giving a reddish-brown precipitate on dilution.

Literature.—E. P. 2397 and 16811 of 1901; *D. R. P. 148212, 150373; F. P. 308000, 310597,* 313671; A. P. 680283, 677227.

Manchester Brown EE (C.) (Lev.); **Bismarck Brown R** (I.) (By.) (O.) (H.) (Central Dyestuff and Chemical Co.) (Ault and Wiborg Co.), &c.; **Bismarck Brown 2 R. conc.** (T. M.); **Bismarck Brown T** (D. H.); **Vesuvine B** (B.); **Brown N** (P.); **Buffalo Brown 53** (Sch.):

$$(NH_2)_2C_7H_5{\cdot}N_2{\cdot}C_7H_6{\cdot}N_2{\cdot}C_7H_5(NH_2)_2$$

Prepared in the same manner as Bismarck brown, but *m*-tolylenediamine is used instead of *m*-phenylenediamine. The reddish-brown aqueous solution becomes yellowish-brown with hydrochloric acid, and gives a light-brown precipitate with sodium hydroxide. The solution in sulphuric acid is dark brown, becoming first red and then brown on dilution.

Literature.—Griess, Ber. 1878, 11, 627.

Toluylene Brown G (O.) (By.):

$$HSO_3{\cdot}C_7H_5\begin{smallmatrix}\diagup N_2 \diagdown\\ \diagdown N_2 \diagup\end{smallmatrix}C_6H_2(NH_2)_2$$

Prepared by the action of tetrazotised tolylenediaminesulphonic acid ($CH_3 \cdot NH_2 : SO_3H : NH_2$ = 1 : 2 : 4 : 6) on 1 mol. of *m*-phenylenediamine. Solution in water is brown, and in sulphuric *acid brownish-red.*

Literature.—E P. 17546 of 1892; D. R. P. 65853; A. P. 516380.

Toluylene Yellow (O.). Prepared from the same tetrazo-compound as the preceding, and 2 mols. of 6-nitro-*m*-phenylenediamine in hydrochloric acid solution. The yellowish-brown aqueous solution gives brown precipitates with hydrochloric acid and sodium hydroxide. The solution in sulphuric acid is brown.

Literature.—E. P. 1331 of 1896; D. R. P. 86940; A. P. 568549.

Toluylene Orange RR (O.). Prepared from the same tetrazo-compound as before, and 2 mols. of *β*-naphthylamine. The yellowish-red aqueous solution gives a brownish-red precipitate with hydrochloric acid, and a yellowish-red precipitate with sodium hydroxide. The solution in sulphuric acid is bluish-grey.

Literature.—E. P. 17546 of 1892; D. R. P. 70147; A. P. 497032.

Diamine Gold Yellow (C.):

$$C_2H_5{\cdot}O{\cdot}C_6H_4{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)_2{\cdot}N_2{\cdot}C_6H_4{\cdot}O{\cdot}C_2H_5$$

Prepared from tetrazotised 1 : 5-naphthylenediamine-3 : 7-disulphonic acid and phenol (2 mols.), the product then being ethylated. The yellow aqueous solution gives a brownish-yellow precipitate with hydrochloric acid and a yellow precipitate with sodium hydroxide. The solution in sulphuric acid is reddish-violet, becoming green and then yellow on dilution.

Literature.—E. P. 15346 of 1890; D. R. P. 61174; F. P. 182063, 208526; A. P. 472121.

Naphthylene Violet (C.):

$$NH_2{\cdot}C_{10}H_6{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)_2{\cdot}N_2{\cdot}C_{10}H_6{\cdot}NH_2$$

Prepared from the preceding tetrazo- compound and *a*-naphthylamine (2 mols.). The Bordeaux-red aqueous solution gives a blue precipitate with hydrochloric acid, and a red precipitate with sodium hydroxide. The solution in sulphuric acid is blue, and gives a violet precipitate on dilution. The colouring matter is usually diazotised and developed on the fibre or treated on the fibre with nitrous acid, the latter colour being known as **Diamine Cutch**, which is a fast brown shade.

Literature.—E. P. 15346 and 15347 of 1890; D. R. P. 62075; F. P. 208526, 208570; A. P. 464566.

Coomassie Navy Blue (Lev.):

$$(HSO_3)_2C_{10}H_4(OH)\cdot N_2\cdot C_{10}H_5(SO_3H)\cdot N_2\cdot C_{10}H_6\cdot OH$$

Prepared by diazotising 1 : 4-naphthylenediamine-2-sulphonic acid (only one amino-group can be diazotised), combining with β-naphthol-3 : 6-disulphonic acid, diazotising the product (the second amino- group can now be diazotised), and combining with β-naphthol. Dark-blue aqueous solution becomes violet with sodium hydroxide. Solution in sulphuric acid is blue-green, becoming dark blue on dilution.

Literature.—E. P. 2946 of 1896; D. R. P. 102160; F. P. 256862; A. P. 619194, 634009, 639748.

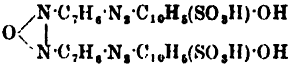
Diphenyl Fast Black[1] (G.):

$$NH\left<\begin{array}{l}C_7H_6\cdot N_2\cdot C_{10}H_4(OH)(NH_2)\cdot SO_3H\\ C_7H_6\cdot N_2\cdot C_7H_5(NH_2)_2\end{array}\right.$$

Prepared from tetrazotised *p*-diaminoditolylamine and 1 mol. of 7-*amino*-α-naphthol-3-sulphonic acid (γ-acid) and 1 mol. of *m*-tolylenediamine. The violet-black aqueous solution gives with hydrochloric acid a bluish-black precipitate, and with sodium hydroxide a black precipitate. The solution in sulphuric acid is dark blue, and gives a black precipitate on dilution.

Literature.—E. P. 16582 of 1896; F. P. 258521; A. P. 575904.

Dianthine (Claus & Co); **St. Denis Red** (P.); **Rosophenine 4 B** (Cl. Co.); **Rosanol 4 B** (K.); **Cotton Red S** (B.):

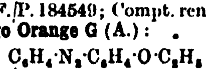


$$O\left<\begin{array}{l}N\cdot C_7H_6\cdot N_2\cdot C_{10}H_5(SO_3H)\cdot OH\\ \vert\\ N\cdot C_7H_6\cdot N_2\cdot C_{10}H_5(SO_3H)\cdot OH\end{array}\right.$$

Prepared from tetrazotised diaminoazoxytoluene and α-naphthol-4-sulphonic acid (2 mols) The red aqueous solution gives red precipitates with hydrochloric acid and sodium hydroxide. The solution in sulphuric acid is red, and gives a red precipitate on dilution

Literature.—E. P. 9315 and 11976 of 1887, 5736 of 1890, 19891 of 1892; D. R. P. 44045, 44554; F. P. 184549; Compt. rend. 1901, 132, 985

Congo Orange G (A.):

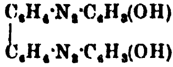


$$\begin{array}{l}C_6H_4\cdot N_2\cdot C_6H_4\cdot O\cdot C_2H_5\\ \vert\\ C_6H_4\cdot N_2\cdot C_{10}H_4(SO_3H)_2\cdot NH_2\end{array}$$

Prepared from tetrazotised benzidine[2] and 1 mol. of β-naphthylamine-3 : 6-disulphonic acid, and 1 mol. of phenol, the product being ethylated. The orange-yellow aqueous solution gives a brown precipitate with hydrochloric acid. The solution in sulphuric acid is blue, becoming reddish-violet on dilution, and finally giving a brown precipitate. The corresponding colouring matter from tolidine is **Congo Orange R** (A.).

Literature.—E. P. 17957 of 1889; D. R. P. 52328; F. P. 160722.

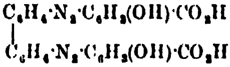
Pyramidol Brown BG (Farbwerk Ammersfoort):



$$\begin{array}{l}C_6H_4\cdot N_2\cdot C_6H_3(OH)_2\\ \vert\\ C_6H_4\cdot N_2\cdot C_6H_3(OH)_2\end{array}$$

Prepared from tetrazotised benzidine and resorcinol (2 mols.). The orange-brown aqueous solution gives a brown precipitate with hydrochloric acid, and becomes Bordeaux-red with sodium hydroxide. The solution in sulphuric acid is reddish-violet, giving a brown precipitate on dilution. Cotton dyed red with this colouring matter is converted into a deep brown when treated with a diazo- compound on the fibre.

Chrysamine G (By.) (A) (Lev.) (H.) (L.) (T. M.) (K. S.) (Barking Chemicals Co.) (Marden, Orth, and Hastings Corporation) (Calco Chemical Co.); **Azidine Yellow G** (C. J); **Direct Yellow CG** (Sch.):

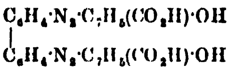


$$\begin{array}{l}C_6H_4\cdot N_2\cdot C_6H_3(OH)\cdot CO_2H\\ \vert\\ C_6H_4\cdot N_2\cdot C_6H_3(OH)\cdot CO_2H\end{array}$$

Prepared by the action of tetrazotised benzidine on salicylic acid (2 mols) in alkaline solution. Used for dyeing cotton goods yellow directly from a soap-bath. Aqueous solution orange, becoming redder on addition of sodium hydroxide; orange flocculent precipitate, with dilute sulphuric acid. Soluble in sulphuric acid, with a magenta-red colour, becoming orange and precipitating on dilution. The homologue from tetrazoditolyl is **Chrysamine R** (By.) (A.) (L) (Lev) (T M.) (K. S.).

Literature.—E. P. 9162 and 9606 of 1884; D. R. P. 31658; A. P. 329638.

Cresotine Yellow G (M) (O.):

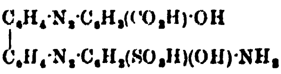


$$\begin{array}{l}C_6H_4\cdot N_2\cdot C_7H_5(CO_2H)\cdot OH\\ \vert\\ C_6H_4\cdot N_2\cdot C_7H_5(CO_2H)\cdot OH\end{array}$$

Prepared from tetrazotised benzidine and hydroxytoluic acid ($OH : CH_3 : CO_2H = 1 : 2 : 6$). Yellow aqueous solution gives a brownish-yellow precipitate with hydrochloric acid and becomes yellowish-red with sodium hydroxide. Solution in sulphuric acid is reddish-violet, precipitating on dilution. The corresponding colouring matter from tolidine is **Cresotine Yellow R** (O.); **Azidine Yellow R** (C. J.).

Literature.—E. P. 7097 of 1888; A. P. 394841.

Brilliant Orange G (A.) (By.):

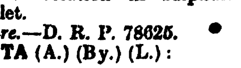


$$\begin{array}{l}C_6H_4\cdot N_2\cdot C_6H_3(CO_2H)\cdot OH\\ \vert\\ C_6H_4\cdot N_2\cdot C_6H_2(SO_3H)(OH)\cdot NH_2\end{array}$$

Prepared from tetrazotised benzidine and 1 mol. each of salicylic acid and aminophenolsulphonic acid III. Yellowish-brown aqueous solution gives a violet-brown precipitate with hydrochloric acid. Solution in sulphuric acid is reddish-violet.

Literature.—D. R. P. 78625.

Orange TA (A.) (By.) (L.):



$$\begin{array}{l}C_6H_4\cdot N_2\cdot C_{10}H_5(SO_3H)\cdot NH_2\\ \vert\\ C_6H_4\cdot N_2\cdot C_7H_7\cdot OH\end{array}$$

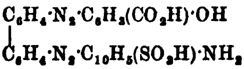
---

[1] **Diamine Deep Black** (C.) is derived from *p*-diaminodiphenylamine; **Pluto Black** (By.) also belongs to the same class.

[2] Benzidine or *p*-diaminodiphenyl is prepared by reducing nitrobenzene with zinc-dust and alkali to hydrazobenzene and converting this by means of acids into benzidine. The homologues of benzidine are prepared in a similar manner.

Prepared from tetrazotised benzidine and 1 mol. each of naphthionic acid and cresol. Reddish-brown aqueous solution gives a violet-blue precipitate with hydrochloric acid, and becomes redder with sodium hydroxide. Solution in sulphuric acid is blue, giving a blue precipitate on dilution.

Benzo Orange R (By.) (K. S.) (Marden, Orth, and Hastings Corporation):



$$\begin{array}{l} C_6H_4{\cdot}N_2{\cdot}C_6H_3(CO_2H){\cdot}OH \\ | \\ C_6H_4{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}NH_2 \end{array}$$

Prepared from tetrazotised benzidine and 1 mol. each of salicylic acid and naphthionic acid. The orange-yellow aqueous solution becomes reddish-violet with hydrochloric acid, and gives a reddish-yellow precipitate with sodium hydroxide. Solution in sulphuric acid is violet-blue, giving a greyish-violet precipitate on dilution.

Literature.—E. P. 2213 of 1886; D. R. P. 44797; A. P. 447303.

Bordeaux COV (A.); **Bordeaux extra** (By.); **Bordeaux BL extra** (T. M.); **Azidine Violet R** (C. J.); **New Bordeaux L** (B.):

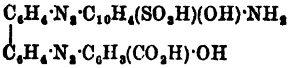
Prepared from tetrazotised benzidine and β-naphthol-8-sulphonic acid (2 mols.). Bordeaux-red solution in water, and violet in sulphuric acid.

Literature.—E. P. 8495 of 1884; D. R. P. 30077.

Diamine Fast Red F (C.); **Dianol Fast Red F** (Lev.); **Azidine Fast Red F** (C. J.); **Oxamine Fast Red F** (B.); **Naphthamine Red H** (K.); **Dianil Fast Red PH** (M.); **Benzo Fast Red FC** (By.); **Columbia Fast Red F** (A.); **Triazol Fast Red C** (O.); **Diphenyl Fast Red** (G.); **Hessian Fast Red F** (L.); **Benzamine Fast Red F** (D.); **Direct Fast Red F** (Sch.) (I.):

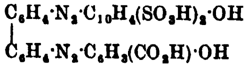


$$\begin{array}{l} C_6H_4{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)(OH){\cdot}NH_2 \\ | \\ C_6H_4{\cdot}N_2{\cdot}C_6H_3(CO_2H){\cdot}OH \end{array}$$

Prepared from tetrazotised benzidine and 1 mol. of 7-amino-α-naphthol-3-sulphonic acid (γ-acid) combined in acid solution, and 1 mol. of salicylic acid. Red aqueous solution gives a brown precipitate with hydrochloric acid. The solution in sulphuric acid is reddish-blue, and gives a brown precipitate on dilution.

Literature.—E. P. 16699 of 1889; D. R. P. 57857; F. P. 201770.

Crumpsall Direct Fast Red R (Lev.):



$$\begin{array}{l} C_6H_4{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)_2{\cdot}OH \\ | \\ C_6H_4{\cdot}N_2{\cdot}C_6H_3(CO_2H){\cdot}OH \end{array}$$

Prepared from tetrazotised benzidine and 1 mol. each of β-naphthol-3 : 6-disulphonic acid (R-salt) and salicylic acid.

Literature.—E. P. 2213 of 1886; D. R. P. 44797; A. P. 447303.

Diamine Brown M (C.); **Chlorazol Brown M** (H.); **Renol Brown MB, conc.** (T. M.); **Azidine Brown M** (C. J.); **Naphthamine Brown H** (K.); **Crumpsall Direct Fast Brown B** (Lev.); **Dianil Brown MH** (M.); **Benzamine Brown M** (D.); **Direct Dark Brown M** (L.); **Direct Brown M** (I.); **Direct Brown 3 RB** (Sch.); **Oxamine Brown R** (B.):

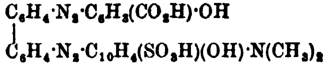
Prepared from tetrazotised benzidine and 1 mol. each of salicylic acid and 7-amino-α-naphthol-3-sulphonic acid (γ-acid); the latter being combined in alkaline solution. The reddish-brown aqueous solution gives a brown precipitate with hydrochloric acid and a reddish-brown precipitate with sodium hydroxide. The solution in sulphuric acid is violet, changing to brown on dilution.

Literature.—D. R. P. 57857; F. P. 201770.

Diphenyl Brown BN (G.):

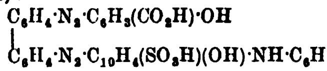


$$\begin{array}{l} C_6H_4{\cdot}N_2{\cdot}C_6H_3(CO_2H){\cdot}OH \\ | \\ C_6H_4{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)(OH){\cdot}N(CH_3)_2 \end{array}$$

Prepared from tetrazotised benzidine and 1 mol. each of salicylic acid and 7-dimethylamino-α-naphthol-3-sulphonic acid. [The corresponding colouring matter from the monomethylamino-compound is **Diphenyl Brown RN** (G.).] The dark-brown solution gives a red precipitate with hydrochloric acid. The solution in sulphuric acid is bluish-violet, giving a red precipitate on dilution. When tolidine is used instead of benzidine, **Diphenyl Brown 3 GN** (G.) is obtained.

Literature.—E. P. 2771 of 1896; D. R. P. 103149; F. P. 250697; A. P. 567413.

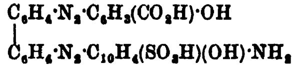
Diamine Brown B (C.); **Crumpsall Brown M** (Lev.):



$$\begin{array}{l} C_6H_4{\cdot}N_2{\cdot}C_6H_3(CO_2H){\cdot}OH \\ | \\ C_6H_4{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)(OH){\cdot}NH{\cdot}C_6H_5 \end{array}$$

Prepared from tetrazotised benzidine and 1 mol. each of salicylic acid and 7-phenylamino-α-naphthol-3-sulphonic acid. The dark-brown aqueous solution gives a Bordeaux-red precipitate with hydrochloric acid, and becomes redder with sodium hydroxide. The solution in sulphuric acid is violet, giving a brown precipitate on dilution.

Oxamine Maroon (B.):



$$\begin{array}{l} C_6H_4{\cdot}N_2{\cdot}C_6H_3(CO_2H){\cdot}OH \\ | \\ C_6H_4{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)(OH){\cdot}NH_2 \end{array}$$

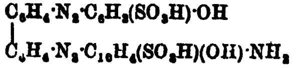
Prepared by combining tetrazotised benzidine with 1 mol. of 5-amino-α-naphthol-3-sulphonic acid in alkaline solution, and adding 1 mol. of salicylic acid to the product. The ruby-red aqueous solution does not change with acids or alkalis. The solution in sulphuric acid is dark violet, changing to wine-red on dilution.

Literature.—E. P. 2370 of 1893; D. R. P. 82572; F. P. 229263; A. P. 558344.

Oxamine Red (B.). Isomeric with the preceding. 6-Amino-α-naphthol-3-sulphonic acid is used instead of the 5-amino- acid. The red aqueous solution is not changed by hydrochloric acid, but becomes slightly more violet with sodium hydroxide. The solution in sulphuric acid is blue, changing to wine-red on dilution.

Literature.—E. P. 2614 of 1893; D. R. P. 93276; F. P. 227892; A. P. 555359.

Wool Red G (B.):



$$\begin{array}{l} C_6H_4{\cdot}N_2{\cdot}C_6H_3(SO_3H){\cdot}OH \\ | \\ C_6H_4{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)(OH){\cdot}NH_2 \end{array}$$

Prepared from tetrazotised benzidine and 1 mol. each of phenol-*o*-sulphonic acid and 7-amino-*α*-naphthol-3-sulphonic acid (γ-acid), the latter being combined in acid solution. The red aqueous solution gives a brown precipitate with hydrochloric acid, and becomes dark-red with sodium hydroxide. Solution in sulphuric acid is violet, giving a brown precipitate on dilution.

Literature.—D. R. P. appl. B. 29649 of 1901; F. P. 313533.

Diamine Scarlet B (C.); **Dianil Ponceau G** (M.)[1]:

$$\begin{array}{l} C_6H_4\cdot N_2\cdot C_6H_4\cdot O\cdot C_2H_5 \\ | \\ C_6H_4\cdot N_2\cdot C_{10}H_4(SO_3H)_2\cdot NH_2 \end{array}$$

Tetrazotised benzidine is combined first with 1 mol. of *β*-naphthylamine-6 : 8-disulphonic acid, then with 1 mol. of phenol and the product is ethylated. The red aqueous solution becomes brownish-red with hydrochloric acid. The solution in sulphuric acid is violet, becoming brown on dilution.

Literature.—E. P. 12560 of 1889; D. R. P. 54084; F. P. 200152; A. P. 426345.

Pyramine Orange 2 R (B.):

$$\begin{array}{l} C_6H_4\cdot N_2\cdot C_{10}H_4(SO_3H)_2\cdot NH_2 \\ | \\ C_6H_4\cdot N_2\cdot C_6H_2(NH_2)_2\cdot NO_2 \end{array}$$

Prepared from tetrazotised benzidine and 1 mol. each of *β*-naphthylamine-3 : disulphonic acid and *p*-nitro-*m*-phenylenediamine. The yellow aqueous solution is not changed by acids or alkalis. The solution in sulphuric acid is blue, becoming yellowish-red on dilution.

Literature.—E. P. 6827 of 1899; D. R. P. 107731; F. P. 280914; A. P. 631611.

Pyramine Orange 3 G (B.):

$$\begin{array}{l} C_6H_4\cdot N_2\cdot C_6H_2(NH_2)_2\cdot NO_2 \\ | \\ C_6H_4\cdot N_2\cdot C_6H(SO_3H)_2(NH_2)_2 \end{array}$$

Prepared from tetrazotised benzidine and 1 mol. each of *m*-phenylenediamine-4 : 6-disulphonic acid and *p*-nitro-*m*-phenylenediamine. The yellowish-red aqueous solution is not changed by acids or alkalis. The solution in sulphuric acid is yellowish-red, becoming brownish-yellow on dilution.

Literature.—E. P. 18506 of 1898; D. R. P. 105349; F. P. 280914; A. P. 631610.

Congo Red (Lev.) (A.) (By.) (L.) (K. S.) (B. K.) (Sch.) (Marden, Orth, and Hastings Corporation); **Congo Red R** (H.); **Cosmos Red** (B.); **Cotton Red conc.** (T. M.); **Cotton Red C** (I.) (P.); **Cotton Red B** (K.); **Dianil Red R** (M.); **Cotton Red 4 B** (O.); **Direct Red C** (Farb werk Ammersfoort):

$$\begin{array}{l} C_6H_4\cdot N_2\cdot C_{10}H_5(SO_3H)\cdot NH_2 \\ | \\ C_6H_4\cdot N_2\cdot C_{10}H_5(SO_3H)\cdot NH_2 \end{array}$$

Prepared by the action of tetrazotised benzidine on naphthionic acid (2 mols.). It can also be obtained by oxidising benzeneazonaphthionic acid with manganese dioxide in sulphuric acid solution (E. P. 6697 of 1895; D. R. P. 84893; F. P. 248210). The red aqueous solution becomes blue on addition of dilute acids; substance dissolves in sulphuric acid with a slaty blue, giving a bluish precipitate on dilution.

Literature.—E. P. 4415 of 1884; D. R. P. 28753; F. P. 160722; Ber. 1886, 19, 1719.

Diazo Black B (By.). Isomeric with the preceding. Prepared from tetrazotised benzidine and *α*-naphthylamine-5-sulphonic acid (L-acid; 2 mols.). The violet aqueous solution becomes blue with hydrochloric acid, and gives a blue precipitate with sodium hydroxide. The solution in sulphuric acid is blue, remaining blue on dilution. The colouring matter is generally diazotised and developed on the fibre.

Congo Rubine (A.) (Lev.) (By.) (L.) (B. K.); **Azidine Bordeaux** (C. J.); **Congo Rubine A** (K. S.); **Congo Rubine B** (K.); **Cotton Rubine** (B.); **Renol Rubine, extra** (T. M.); **Direct Crimson B** (Sch.):

$$\begin{array}{l} C_6H_4\cdot N_2\cdot C_{10}H_5(SO_3H)\cdot NH_2 \\ | \\ C_6H_4\cdot N_2\cdot C_{10}H_5(SO_3H)\cdot OH \end{array}$$

Prepared from tetrazotised benzidine and 1 mol. each of *β*-naphthol-8-sulphonic acid and naphthionic acid. The cherry-red aqueous solution gives a blue precipitate with hydrochloric acid and a violet-red one with sodium hydroxide. The solution in sulphuric acid is blue, giving a blue precipitate on dilution.

Literature.—D. R. P. 62659.

Congo Corinth (A.) (By.) (L.) (Lev.) (K. S.) (B. K.); **Cotton Corinth G** (B.) (O.); **Dianil Bordeaux G** (M.); **Renol Corinth G** (T. M.); **Buffalo Garnet R** (Sch.):

$$\begin{array}{l} C_6H_4\cdot N_2\cdot C_{10}H_5(SO_3H)\cdot OH \\ | \\ C_6H_4\cdot N_2\cdot C_{10}H_5(SO_3H)\cdot NH_2 \end{array}$$

Prepared from tetrazotised benzidine, *α*-naphthylamine-4-sulphonic acid and *α*-naphthol-4-sulphonic acid. Aqueous solution red; violet precipitate with hydrochloric acid and colouration with acetic acid. Solution in sulphuric acid blue, giving violet precipitate on dilution.

Literature.—E. P. 15296 of 1885, 2213 of 1886; D. R. P. 39096; F. P. 160722, 163172; A. P. 344971, 358865.

Brilliant Congo G (A.) (L.):

$$\begin{array}{l} C_6H_4\cdot N_2\cdot C_{10}H_4(SO_3H)_2\cdot NH_2 \\ | \\ C_6H_4\cdot N_2\cdot C_{10}H_5(SO_3H)\cdot NH_2 \end{array}$$

From tetrazotised benzidine, *β*-naphthylamine-3 : 6-disulphonic acid and *β*-naphthylamine-6-sulphonic acid (Brönner's). Aqueous solution gives a brownish-violet precipitate with hydrochloric acid. Solution in sulphuric acid blue, giving violet precipitate on dilution.

Literature.—E. P. 6687 of 1887; D. R. P. 41095; F. P. 160722.

Heliotrope 2 B (A.) (By.) (L.):

$$\begin{array}{l} C_6H_4\cdot N_2\cdot C_{10}H_5(SO_3H)\cdot OH \\ | \\ C_6H_4\cdot N_2\cdot C_{10}H_4(SO_3H)_2\cdot OH \end{array}$$

Prepared from tetrazotised benzidine and 1 mol. each of *α*-naphthol-4 : 8- (or 3 : 8-) disulphonic acid and *β*-naphthol-8-sulphonic acid. Reddish-violet aqueous solution gives a bluish-violet precipitate with hydrochloric acid, and becomes redder with sodium hydroxide. Solution in sulphuric acid is blue, becoming reddish-violet on dilution, and finally giving a violet precipitate.

---

[1] **Diamine Scarlet 3 B** (C.), **Dianil Ponceau 2 R** (M.) belongs to the same group, but is bluer.

Literature.—E. P. 1346 of 1888; D. R. P. 45342.

Trisulphone Violet B (K. S.); **Trisulphone Blue R** (K. S.); **Trisulphone Blue B** (K. S.):

$$\begin{array}{l}C_6H_4{\cdot}N_2{\cdot}C_{10}H_3(SO_3H)_3{\cdot}OH\\ |\\ C_6H_4{\cdot}N_2{\cdot}C_{10}H_6{\cdot}OH\end{array}$$

The first-named (for which the formula is given) is prepared from tetrazotised benzidine and 1 mol. each of α-naphthol-3 : 6 : 8-trisulphonic acid and β-naphthol. The second and last colouring matters are prepared from tetrazotised tolidine and dianisidine respectively instead of benzidine. The solutions in water are violet to blue, and give bluish-violet to blue precipitates with hydrochloric acid. With sodium hydroxide the aqueous solutions become reddish-violet. The solutions in sulphuric acid are greenish-blue, giving violet precipitates on dilution.

Literature.—E. P. 4703 of 1897; F. P. 264279; A. P. 584981.

Chicago Blue 4 R (A.); **Benzo Blue 4 R** (By.); **Diamine Blue C 4 R** (C.):

$$\begin{array}{l}C_6H_4{\cdot}N_2{\cdot}C_{10}H_5(OH){\cdot}SO_3H\\ |\\ C_6H_4{\cdot}N_2{\cdot}C_{10}H_4(OH)(NH_2){\cdot}SO_3H\end{array}$$

Prepared from benzidine, and 1 mol. each of 1 : 8 aminonaphthol-4-sulphonic acid and β-naphthol-8-sulphonic acid. Violet-blue aqueous solution becomes blue with hydrochloric acid, and reddish-violet with sodium hydroxide. Solution in sulphuric acid is blue, giving a violet precipitate on dilution.

Columbia Blue R (A.); **Benzo Red Blue R** (By.); **Diamine Blue LR** (C.). α-Naphthol-3 : 8-disulphonic acid is used instead of β-naphthol-8-sulphonic acid in the preceding dye. The blue aqueous solution gives a blue precipitate with hydrochloric acid, and is unchanged by sodium hydroxide. Solution in sulphuric acid is blue, giving a violet precipitate on dilution.

Diamine Violet N (C.); **Chlorazol Violet B** (H.); **Dianol Violet N** (Lev.); **Azidine Violet DV** (C. J.); **Naphthamine Violet N** (K.); **Dianil Violet H** (M.); **Direct Violet R** (Sch.); **Benzo Fast Violet NC** (By.):

$$\begin{array}{l}C_6H_4{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)(OH){\cdot}NH_2\\ |\\ C_6H_4{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)(OH){\cdot}NH_2\end{array}$$

Prepared by the action of tetrazotised benzidine on 2 mols. of 7-amino-α-naphthol-3-sulphonic acid (γ-acid) in acid solution. The reddish-violet aqueous solution gives a violet-black precipitate with hydrochloric acid. The solution in sulphuric acid is greenish-blue, giving a reddish-violet precipitate on dilution.

Literature.—E. P. 16699 of 1889; D. R. P. 55648; F. P. 201770.

Diamine Black RO (C.); **Naphthamine Black BVE** (K.); **Dianol Black RO** (Lev.); **Oxamine Black 2 R** (B.); **Melantherine RO** (I.). Isomeric with the preceding. The combination is effected in alkaline solution whereby the azo- group enters the 2-position with respect to the hydroxy-group, whereas in the preceding case the azo-group enters the 8- position (ortho to the amino- group). The violet-black aqueous solution gives a blue precipitate with hydrochloric acid, and becomes violet with sodium hydroxide. The solution in sulphuric acid is blue, giving a reddish-blue precipitate on dilution.

Literature.—As above.

Naphthamine Black RE (K.):

$$\begin{array}{l}C_6H_4{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)(OH){\cdot}NH_2\\ |\\ C_6H_4{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)(OH){\cdot}NH_2\end{array}$$

Prepared from tetrazotised benzidine and 2 mols. of 1 : 8-aminonaphthol-6-sulphonic acid.

Literature.—E. P. 515 of 1894; D. R. P. appl. K. 11223; A. P. 563386.

Benzo Violet R (By.):

$$\begin{array}{l}C_6H_4{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}OH\\ |\\ C_6H_4{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)_2{\cdot}OH\end{array}$$

Prepared from tetrazotised benzidine and 1 mol. each of α-naphthol-4-sulphonic acid and α-naphthol-3 : 6-disulphonic acid. The reddish-violet aqueous solution gives a soluble violet precipitate with hydrochloric acid, and becomes red with sodium hydroxide. The solution in sulphuric acid is violet, giving a violet precipitate on dilution.

Naphthylamine Diazo Black (K.):

$$\begin{array}{l}C_6H_4{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)(OH){\cdot}NH_2\\ |\\ C_6H_4{\cdot}N_2{\cdot}C_{10}H_3(SO_3H)_2(OH){\cdot}NH_2\end{array}$$

Prepared from tetrazotised and benzidine 1 mol. each of 8-amino-α-naphthol-3 : 5-disulphonic acid (K- acid), and 7-amino-α-naphthol-3-sulphonic acid (γ-acid).

Literature.—E. P. 515 of 1894; D. R. P. 99164; A. P. 563386.

Diamine Brown V (C.):

$$\begin{array}{l}C_6H_4{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)(OH){\cdot}NH_2\\ |\\ C_6H_4{\cdot}N_2{\cdot}C_6H_3(NH_2)_2\end{array}$$

Prepared from tetrazotised benzidine and 1 mol. each of 7-amino-α-naphthol-3-sulphonic acid (γ-acid) and *m*-phenylenediamine. Brown-red aqueous solution gives a chocolate-brown precipitate with hydrochloric acid, and purplish-brown precipitate with sodium hydroxide. Solution in sulphuric acid is bluish-violet, giving a purplish-brown precipitate on dilution.

Literature.—E. P. 16699 of 1889; D. R. P. 57857; F. P. 201770.

Dianil Garnet B (M.); **Benzo Fast Red 9 BL** (By.):

$$\begin{array}{l}C_6H_4{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)(OH){\cdot}NH_2\\ |\\ C_6H_4{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)_2{\cdot}NH_2\end{array}$$

Prepared from tetrazotised benzidine and 1 mol. each of γ- acid and β-naphthylamine-3 : 6-disulphonic acid. Bordeaux-red aqueous solution gives a blackish-blue precipitate with hydrochloric acid. Solution in sulphuric acid is blue.

Literature.—D. R. P. 190694.

Zambesi Brown G, 2 G (A.):

$$\begin{array}{l}C_6H_4{\cdot}N_2{\cdot}C_{10}H_4(NH_2)_2{\cdot}SO_3H\\ |\\ C_6H_4{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)(OH){\cdot}NH_2\end{array}$$

Prepared from tetrazotised benzidine and 1 mol. each of γ- acid and 2 : 7-naphthylenediamine-sulphonic acid. Cotton is dyed corinth brown (G) or violet (2 G).

Literature.—D. R. P. appl. A. 3775.

Diamine Black BH (C.); **Dianol Blue BH** (Lev.); **Diazo Black BHN** (By.); **Renolamine Black BH** (T. M.); **Azidine Black BHN** (C. J.); **Ingrain Black 2 B** (H.); **Naphthamine Black CE** (K.); **Dianil Black ES** (M.); **Melantherine BH** (I.); **Direct Black HB** (L.); **Diazine Black BH extra** (Sch.); **Oxamine Black BHN** (B.); **Direct Black BD** (P.):

$$\begin{array}{l} C_6H_4{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)(OH){\cdot}NH_2 \\ | \\ C_6H_4{\cdot}N_2{\cdot}C_{10}H_3(SO_3H)_2(OH){\cdot}NH_2 \end{array}$$

Prepared from tetrazotised benzidine and 1 mol. each of 7-amino-α-naphthol-3-sulphonic acid and 8-amino-α-naphthol-3 : 6-disulphonic acid (H-acid). The reddish-blue aqueous solution becomes violet with hydrochloric acid and reddish-violet with sodium hydroxide. The solution in sulphuric acid is blue, giving a violet precipitate on dilution.

Literature.—E. P. 1742 and 6972 of 1891; D. R. P. 68462; F. P. 233032.

Benzo Cyanine R (By.); **Diamine Cyanine R** (C.); **Congo Cyanine R** (A.). Prepared as the preceding, except that 1 : 8-aminonaphthol-4-sulphonic acid is used instead of γ-acid. The solution in water or sulphuric acid is blue. The corresponding **B** marks are prepared from tolidine, and the **3 B** from dianisidine.

Literature.—D. R. P. appl. F. 5667; A. P. 533508, 578432.

Oxamine Violet (B.); **Chlorazol Violet R** (H.); **Naphthamine Violet BE** (K.); **Dianil Violet BE** (M.); **Oxydiamine Violet BF** (C.); **Benzo Violet O** (By.); **Direct Violet O** (I.):

$$\begin{array}{l} C_6H_4{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)(OH){\cdot}NH_2 \\ | \\ C_6H_4{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)(OH){\cdot}NH_2 \end{array}$$

Prepared from tetrazotised benzidine and 6-amino-α-naphthol-3-sulphonic acid (2 mols.). The combination is effected in alkaline solution. The reddish-violet aqueous solution gives a violet precipitate with acids or alkalis. The solution in sulphuric acid is blue, giving a violet precipitate on dilution.

Literature.—E. P. 2614 of 1893; D. R. P. 75469; F. P. 227892; A. P. 521096.

Diamine Blue BB (C.) (Central Dyestuff and Chemical Co.); **Benzo Blue BB** (By.) (Lev.); **Congo Blue 2 BX** (A.); **Direct Blue V** (P.); **Azidine Blue 2 B** (C. J.); **Chlorazol Blue RB** (H.); **Naphthamine Blue 2 BX** (K.); **Dianil Blue HZG** (M.); **Benzamine Blue 2 B** (D.); **Niagara Blue 2 B** (Sch.):

$$\begin{array}{l} C_6H_4{\cdot}N_2{\cdot}C_{10}H_3(SO_3H)_2(OH){\cdot}NH_2 \\ | \\ C_6H_4{\cdot}N_2{\cdot}C_{10}H_3(SO_3H)_2(OH){\cdot}NH_2 \end{array}$$

Prepared by combining tetrazotised benzidine in alkaline solution with 8-amino-α-naphthol-3 : 6-disulphonic acid (H-acid; 2 mols.). The reddish-blue aqueous solution is unchanged by acids or alkalis. The solution in sulphuric acid is blue, becoming violet on dilution.

Literature.—E. P. 13443 of 1890, 1742 of 1891; D. R. P. 74593; F. P. 210033; A. P. 464135.

Diphenyl Blue Black (G.):

$$\begin{array}{l} C_6H_4{\cdot}N_2{\cdot}C_{10}H_3(SO_3H)_2(OH){\cdot}NH_2 \\ | \\ C_6H_4{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)(OH){\cdot}NH{\cdot}C_6H_5 \end{array}$$

Prepared from tetrazotised benzidine and 1 mol. each of H-acid and 7-ethylamino-α-naphthol-3-sulphonic acid. The dark-blue aqueous solution gives a violet precipitate with hydrochloric acid, and becomes dark violet with sodium hydroxide. The solution in sulphuric acid is blue, giving a dark violet precipitate on dilution.

Literature.—E. P. 2771 of 1896; D. R. P. 103149; F. P. 250697; A. P. 556164, 567413.

Naphthamine Blues 2B, 3B, and 5B (K.). These are derived from tetrazotised benzidine, tolidine, &c., and 8-amino-α-naphthol-3 : 5-disulphonic acid (K-acid). The blue aqueous solution gives a blue precipitate with hydrochloric acid, and turns reddish-violet with sodium hydroxide. The solution in sulphuric acid is bluish-green.

Literature.—E. P. 515 of 1894; D. R. P. 99164; A. P. 563385, 563386.

Direct Gray R (I.):

$$\begin{array}{l} C_6H_4{\cdot}N_2{\cdot}C_{10}H_3(OH)_2(CO_2H){\cdot}SO_3H \\ | \\ C_6H_4{\cdot}N_2{\cdot}C_{10}H_3(OH)_2(CO_2H){\cdot}SO_3H \end{array}$$

Prepared from tetrazotised benzidine and 1 : 7-dihydroxy - 6 - carboxynaphthalene-3-sulphonic acid (2 mols.). The violet aqueous solution gives a bluish-grey precipitate with hydrochloric acid and becomes dull violet-red with sodium hydroxide. The solution in sulphuric acid is blue, giving a bluish-grey precipitate on dilution. The corresponding colour from tolidine is **Direct Gray R.**

Literature.—E. P. 14253 of 1892; D. R. P 75258; F. P. 220468; A. P. 493564.

Direct Violet R (I.).

$$\begin{array}{l} C_6H_4{\cdot}N_2{\cdot}C_{10}H_3(OH)_2(CO_2H){\cdot}SO_3H \\ | \\ C_6H_4{\cdot}N_2{\cdot}C_7H_5(NH_2)_2 \end{array}$$

Prepared from tetrazotised benzidine and 1 mol. each of the above dihydroxycarboxynaphthalenesulphonic acid and *m*-tolylenediamine. The solution in water is violet, and in sulphuric acid blue.

Literature.—A. P. 527070.

Dianol Red 2 B (Lev.); **Azidine Purpurine 10 B** (C. J.):

$$\begin{array}{l} C_6H_3Cl{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}NH_2 \\ | \\ C_6H_3Cl{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}NH_2 \end{array}$$

Prepared from tetrazotised dichlorobenzidine (NH_2 : Cl=4 : 3), and naphthionic acid (2 mols.). The red aqueous solution becomes violet with hydrochloric acid. The solution in sulphuric acid is blue, changing to violet on dilution.

Literature.—E. P. 25725 of 1896; D. R. P. 94410; F. P. 265135; A. P. 625174, 640743.

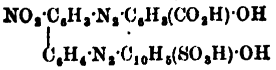
Dianol Brilliant Red extra (Lev.); **Toluylene Red** (O.); **Chlorantine Red 8 B** (I.); **Acetopurpurine 8 B** (A.); **Diphenyl Red 8 B** (G.); **Azidine Brilliant Red 8 B** (C. J.); **Oxamine Scarlet B** (B.):

$$\begin{array}{l} C_6H_3Cl{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)_2{\cdot}NH_2 \\ | \\ C_6H_3Cl{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)_2{\cdot}NH_2 \end{array}$$

Prepared from tetrazotised dichlorobenzidine and β-naphthylamine-3 : 6-disulphonic acid. The bluish-red aqueous solution becomes slightly darker with hydrochloric acid. The solution in sulphuric acid is blue, becoming red on dilution.

Literature.—E. P. 25725 of 1896; D. R. P. 94410, 97101; F. P. 265135; A. P. 625174, 640743.

Anthracene Red (I.) (By.)



$$\begin{array}{l}\mathrm{NO_2\cdot C_6H_3\cdot N_2\cdot C_6H_3(CO_2H)\cdot OH}\\ |\\ \mathrm{C_6H_4\cdot N_2\cdot C_{10}H_5(SO_3H)\cdot OH}\end{array}$$

Prepared by combining tetrazotised nitrobenzidine first with 1 mol. of salicylic acid and then with 1 mol. of *a*-naphthol-4-sulphonic acid. (The same colour is not produced by inverting the order of combination.) The red aqueous solution gives a red precipitate with hydrochloric acid. The solution in sulphuric acid is carmine-red, giving a brownish-red precipitate on dilution.

Literature.—E. P. 13475 of 1892; D. R. P. 72867; F. P. 223176; A. P. 493583.

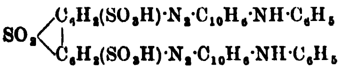
Salicine Red G (K.). Prepared from tetrazotised nitrobenzidine and 1 mol. each of salicylic acid and *β*-naphthol, the product being sulphonated.

Literature.—E. P. 9454 of 1895; D. R. P. 87484.

Salicine Yellow G (K.). Prepared from tetrazotised nitrobenzidine and salicylic acid (2 mols.), the product being sulphonated. The orange aqueous solution is precipitated with hydrochloric acid and becomes reddish-brown with sodium hydroxide. The solution in sulphuric acid is orange-yellow, and gives a brown precipitate on dilution.

Literature.—As above, and Chem. Ind. 1896, 19, 552.

Sulphone Azurine (By.) (A.) (L.) (Lev.):

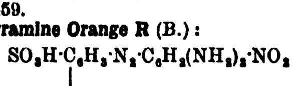


$$\mathrm{SO_2}\left\langle\begin{array}{l}\mathrm{C_6H_2(SO_3H)\cdot N_2\cdot C_{10}H_6\cdot NH\cdot C_6H_5}\\ |\\ \mathrm{C_6H_2(SO_3H)\cdot N_2\cdot C_{10}H_6\cdot NH\cdot C_6H_5}\end{array}\right.$$

Prepared from tetrazotised benzidinesulphonedisulphonic acid and phenyl-*a*-naphthylamine (2 mols.). The blue aqueous solution gives blue precipitates with hydrochloric acid and sodium hydroxide. The solution in sulphuric acid is violet, giving a blackish-violet precipitate on dilution.

Literature.—E. P. 1074 and 1099 of 1884; D. R. P. 27954, 33088; A. P. 432989; Ber. 1889, 22, 2459.

Pyramine Orange R (B.):

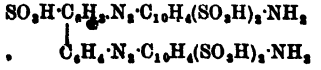


$$\begin{array}{l}\mathrm{SO_3H\cdot C_6H_3\cdot N_2\cdot C_6H_2(NH_2)_2\cdot NO_2}\\ |\\ \mathrm{SO_3H\cdot C_6H_3\cdot N_2\cdot C_6H_2(NH_2)_2\cdot NO_2}\end{array}$$

Prepared from tetrazotised benzidinedisulphonic acid and 6-nitro-*m*-phenylenediamine (2 mols.). The orange-red aqueous solution gives a yellowish-red precipitate with hydrochloric acid or sodium hydroxide. The solution in sulphuric acid is yellow, giving a yellowish-red precipitate on dilution.

Literature.—E. P. 8564 of 1894; D. R. P. 80973; F. P. 238340; A. P. 545333.

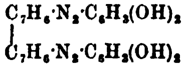
Trypan Red (M.):



$$\begin{array}{l}\mathrm{SO_3H\cdot C_6H_3\cdot N_2\cdot C_{10}H_4(SO_3H)_2\cdot NH_2}\\ |\\ \mathrm{C_6H_4\cdot N_2\cdot C_{10}H_4(SO_3H)_2\cdot NH_2}\end{array}$$

Prepared from tetrazotised benzidinemonosulphonic acid and *β*-naphthylamine-3 : 6-disulphonic acid (2 mols.). It is a brown powder, soluble in water, and the solution gives a blue precipitate with hydrochloric acid. It is used in medicine.

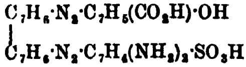
Pyramidol Brown T (Farbwerk Ammersfoort):



$$\begin{array}{l}\mathrm{C_7H_6\cdot N_2\cdot C_6H_3(OH)_2}\\ |\\ \mathrm{C_7H_6\cdot N_2\cdot C_6H_3(OH)_2}\end{array}$$

Prepared from tetrazotised tolidine and resorcinol (2 mols.). The reddish-brown aqueous solution gives a brown precipitate with hydrochloric acid, and becomes brownish-red with sodium hydroxide. The solution in sulphuric acid is violet, giving a blackish-brown precipitate on dilution. When the fibre is treated with diazo- solutions a deep brown is obtained.

Toluylene Orange G (O.) (By.) (A.) (L.); **Azidine Orange G** (C. J.); **Dianil Orange N** (M.); **Alkali Orange GT** (D.); **Renol Orange G** (T. M.); **Direct Orange G** (I.); **Direct Orange Y** (Sch.); **Oxydiamine Orange G** (C.); **Pluto Orange G** (By.); **Direct Orange G** (P.):

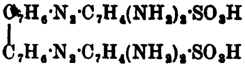


$$\begin{array}{l}\mathrm{C_7H_6\cdot N_2\cdot C_7H_5(CO_2H)\cdot OH}\\ |\\ \mathrm{C_7H_6\cdot N_2\cdot C_7H_4(NH_2)_2\cdot SO_3H}\end{array}$$

Prepared from tetrazotised tolidine and 1 mol. each of hydroxytoluic acid ($\mathrm{CH_3 : OH : CO_2H = 1 : 2 : 3}$) and *m*-tolylenediaminesulphonic acid ($\mathrm{CH_3 : NH_2 : NH_2 : SO_3H = 1 : 2 : 4 : 5}$). The brownish-yellow aqueous solution gives a yellowish-brown precipitate with hydrochloric acid, and becomes reddish-orange with sodium hydroxide. The solution in sulphuric acid is magenta-red, giving a brown precipitate on dilution.

Literature.—E. P. 7997 of 1888; D. R. P. 44797, 47235; A. P. 386634.

Toluylene Orange R (O.) (M.) (L.) (K. S.); **Azidine Orange R** (C. J.); **Alkali Orange RT** (D.); **Renol Orange R** (T. M.); **Direct Orange R** (I.) (Sch.); **Pyramine Orange RT** (B.); **Oxydiamine Orange R** (C); **Pluto Orange R** (By.):

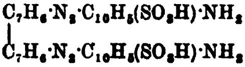


$$\begin{array}{l}\mathrm{C_7H_6\cdot N_2\cdot C_7H_4(NH_2)_2\cdot SO_3H}\\ |\\ \mathrm{C_7H_6\cdot N_2\cdot C_7H_4(NH_2)_2\cdot SO_3H}\end{array}$$

Prepared from tetrazotised tolidine and the above *m*-tolylenediaminesulphonic acid (2 mols.). The orange aqueous solution gives a bluish-red precipitate with hydrochloric acid. The solution in sulphuric acid is brown, giving a reddish precipitate on dilution.

Literature.—E. P. 4492 of 1887; D. R. P. 40905.

Benzopurpurine B (By.) (A.) (L.) (Lev.) (H.) (T. M.) (O.) (Central Dyestuff and Chemical Co.): **Cotton Red B** (I.):



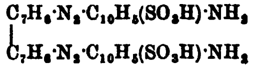
$$\begin{array}{l}\mathrm{C_7H_6\cdot N_2\cdot C_{10}H_5(SO_3H)\cdot NH_2}\\ |\\ \mathrm{C_7H_6\cdot N_2\cdot C_{10}H_5(SO_3H)\cdot NH_2}\end{array}$$

Prepared by the action of tetrazotised tolidine on *β*-naphthylamine-6-sulphonic acid (2 mols.) in presence of alkali. Aqueous solution, orange-red; unchanged by sodium hydroxide; a brownish-red precipitate by dilute sulphuric acid. Dissolves in sulphuric acid with a blue colour, giving a brown precipitate on dilution.

Literature.—E. P. 3803 of 1885: D. R. P. 35615; A. P. 329633.

Benzopurpurine 4 B (By.) (A.) (Lev.) (T. M.) (L.) (O.) (K. S.) (Farbwerk Ammersfoort) (B. K.)

(Sch.) (H.); **Cotton Red 4 B** (B.) (K.) (I.); **Cotton Red BP** (P.); **Diamine Red 4 B** (C.); **Dianil Red 4 B** (M.); **Direct Red 4 B** (Sch.):



$$\begin{array}{l} C_7H_6{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}NH_2 \\ | \\ C_7H_6{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}NH_2 \end{array}$$

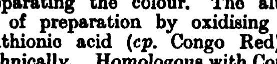
Prepared by the action of tetrazotised tolidine on naphthionic acid (2 mols.). About twice the theoretical amount of naphthionic acid is used, the excess being regained from the filtrate after separating the colour. The alternative method of preparation by oxidising toluene-azonaphthionic acid (*cp.* Congo Red) is not used technically. Homologous with Congo Red, and isomeric with the last. Aqueous solution orange-red, giving a red precipitate with excess of sodium hydroxide; blue precipitate with hydrochloric acid; dissolves in sulphuric acid with a pure blue colour.

Literature.—E. P. 3803 of 1885, 6697 of 1895; D. R. P. 35615, 84893; F. P. 167876, 248210; A. P. 329632.

Benzopurpurine 6 B (Lev.) (By.) (A.) (L.) (T. M.) (O.); **Dianil Red 6 B** (M.); **Cotton Red 6 B** (I.); **Diamine Red 6 B** (C.). Prepared as above from tetrazoditolyl and α-naphthylamine-5-sulphonic acid. Colouring matter very similar in properties to the preceding. The same constitution is assigned to **Diazo Brilliant Black B** (By.), which gives blues or blacks when diazotised and developed on the fibre.

Literature.—E. P. 3803 of 1885; D. R. P. 35615.

Diamine Red B (A.):



$$\begin{array}{l} C_7H_6{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}NH_2 \\ | \\ C_7H_6{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}NH_2 \end{array}$$

Prepared from tetrazoditolyl and 1 mol. of 2-naphthylamine-7-sulphonic acid and 1 mol. of the 6-sulphonic acid. **Deltapurpurine 5 B** (By.) (A.) (Lev.) (L.) (M.) (B. K.) (K.) (K. S.); **Cotton Purple 5 B** (B.); **Cotton Red D** (I.) is prepared from 2 mols. of the crude β-naphthylamine-δ-sulphonic acid. It is therefore a mixture of Diamine Red B (50 p.c.), Diamine Red 3 B (25 p.c.), and Benzopurpurine B (25 p.c.). Aqueous solution red, giving a brown colouration with acetic acid, and a brown precipitate with hydrochloric acid. Red precipitate with sodium hydroxide. Solution in sulphuric acid blue, giving a brown precipitate on dilution.

Literature.—E. P. 5846 of 1886; D. R. P. 42021; F. P. 180728; Ber. 1887, 20, 1430, 2910, 3160, 3353.

Diamine Red 3 B (A.); **Deltapurpurine 7 B** (Lev.). Isomeric with the preceding. Prepared from tetrazotised tolidine and β-naphthylamine-7-sulphonic acid. The colouring matter is precipitated from its aqueous solution by acetic acid, and forms an insoluble calcium salt. Red precipitate with sodium hydroxide. Solution in sulphuric acid blue, giving brown precipitate on dilution.

Literature.—E. P. 4846 and 12908 of 1886; D. R. P. 41201, 48074; F. P. 178979; Ber. 1887, 20, 2910, 3160.

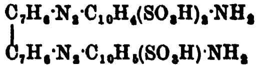
Rosazurine G (By.) (A.):

$$\begin{array}{l} C_7H_6{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}NH{\cdot}C_2H_5 \\ | \\ C_7H_6{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}NH_2 \end{array}$$

Prepared from tetrazotised tolidine and 1 mol each of β-naphthylamine-7-sulphonic acid an ethyl-β-naphthylamine-7-sulphonic acid. Whe 2 mols. of the latter acid are employed th product is known as **Rosazurine B.** Both dye give a cherry-red aqueous solution, which give a reddish-violet precipitate with hydrochlori acid. Their solutions in sulphuric acid ar blue, giving a violet precipitate on dilution.

Literature.—E. P. 17083 of 1886; D. R. P 41761; F. P. 180727.

Brilliant Purpurine R (A.) (By.) (L.):

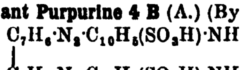


$$\begin{array}{l} C_7H_6{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)_2{\cdot}NH_2 \\ | \\ C_7H_6{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}NH_2 \end{array}$$

Prepared from tetrazotised tolidine and 1 mol each of β-naphthylamine-3:6-disulphonic aci and naphthionic acid. The red aqueous solutio gives a black precipitate with hydrochloric acid and a red one with sodium hydroxide. The solution in sulphuric acid is blue, giving blue-black precipitate on dilution.

Literature.—E. P. 6687 of 1887; D. R. P 41095; F. P. 160722.

Brilliant Purpurine 4 B (A.) (By.):

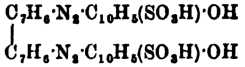


$$\begin{array}{l} C_7H_6{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}NH_2 \\ | \\ C_7H_6{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}NH_2 \end{array}$$

Prepared from tetrazotised tolidine and 1 mol each of β-naphthylamine-6-sulphonic acid an naphthionic acid. The yellowish-red aqueou solution gives a violet-blue precipitate wit hydrochloric acid. The solution in sulphuri acid is violet-blue, giving a violet-blue precipi tate on dilution.

Literature.—E. P. 15296 of 1885; D. R. P 39096; F. P. 160722.

Azo Blue (By.) (A.) (Lev.); **Benzoin Blue** (B. K.):

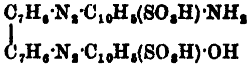


$$\begin{array}{l} C_7H_6{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}OH \\ | \\ C_7H_6{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}OH \end{array}$$

Prepared by the action of tetrazotised tolidin on α-naphthol-4-sulphonic acid. Aqueous solu tion of colouring matter violet, becoming crimso on addition of sodium hydroxide; restored t violet by dilute sulphuric acid. Dissolves i sulphuric acid with a pure blue colour, givin violet precipitate on dilution.

Literature.—E. P. 9510 of 1885; D. R. P 35341; F. P. 171133; A. P. 366078.

Congo Corinth B (By.) (A.) (Lev.) (B. K.) (L.) (K. S.); **Cotton Corinth B** (O.); **Reno Corinth B** (T. M.); **Buffalo Violet 4 R** (Sch.) **Dianil Bordeaux B** (M.):



$$\begin{array}{l} C_7H_6{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}NH_2 \\ | \\ C_7H_6{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}OH \end{array}$$

From tetrazotised tolidine, naphthionic acid and α-naphthol-4-sulphonic acid. Aqueous solu tion magenta-red, giving violet precipitate wit mineral acids. Blue solution in sulphuric acid violet precipitate on dilution.

Literature.—E. P. 15296 of 1885; 2213 an 6687 of 1886; D. R. P. 39096; A. P. 358865.

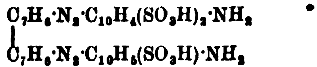
Congo Red 4 R (A.) (By.):

$$\begin{array}{l} C_7H_6{\cdot}N_2{\cdot}C_6H_3(OH)_2 \\ | \\ C_7H_6{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}NH_2 \end{array}$$

From tetrazotised tolidine, resorcinol, and naphthionic acid. Aqueous solution brownish-red, violet precipitate with mineral acids, brown precipitate with acetic acid. Solution in sulphuric acid blue, giving violet precipitate on dilution.

Literature.—E. P. 15296 of 1885; 2213 of 1886; D. R. P. 39096; F. P. 160722 (addition).

Brilliant Congo R (A.) (By.) (L.); **Brilliant Dianil Red R** (M.); **Azidine Scarlet R** (C. J.):

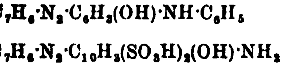


$$\begin{array}{l}\mathrm{C_7H_6{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)_2{\cdot}NH_2}\\ |\\ \mathrm{C_7H_6{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}NH_2}\end{array}$$

From tetrazotised tolidine, β-naphthylamine-3 : 6-disulphonic acid and β-naphthylamine-6-sulphonic acid (Brönner's). Aqueous solution brownish-red, giving a similarly coloured precipitate with mineral acids. Solution becomes bluer with acetic acid. Orange precipitate with sodium hydroxide. Blue solution in sulphuric acid, giving dark-brown precipitate on dilution.

Literature.—E. P. 6687 of 1887; D. R. P. 41095.

Azo Black Blue B, R (O.):

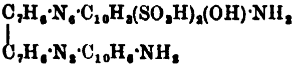


$$\begin{array}{l}\mathrm{C_7H_6{\cdot}N_2{\cdot}C_6H_3(OH){\cdot}NH{\cdot}C_6H_5}\\ |\\ \mathrm{C_7H_6{\cdot}N_2{\cdot}C_{10}H_3(SO_3H)_2(OH){\cdot}NH_2}\end{array}$$

Prepared from tetrazotised tolidine and 1 mol. each of *m*-hydroxydiphenylamine and 8-amino-α-naphthol-3 : 6-disulphonic acid (H-acid). Solution in water is brownish-violet and in sulphuric acid blue, giving a bluish-violet precipitate on dilution.

Literature.—E. P. 10861 of 1891; D. R. P. 70201; A. P. 402415.

Azo Mauve B (O.):

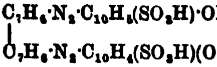


$$\begin{array}{l}\mathrm{C_7H_6{\cdot}N_6{\cdot}C_{10}H_3(SO_3H)_2(OH){\cdot}NH_2}\\ |\\ \mathrm{C_7H_6{\cdot}N_2{\cdot}C_{10}H_6{\cdot}NH_2}\end{array}$$

Prepared from tetrazotised tolidine and 1 mol. each of 8-amino-α-naphthol-3 : 6-disulphonic acid (H-acid) and α-naphthylamine. Violet aqueous solution gives a violet precipitate with hydrochloric acid, and becomes rather bluer with dilute acetic acid. Solution in sulphuric acid is blue, becoming violet on dilution. When β-naphthylamine is used instead of the α-compound the product is **Naphthazurine B** (O.), the reactions of which are similar to the above.

Literature.—As above and A. P. 462415, 608999.

Chicago Blue 2 R (A.); **Benzo Blue 2 R** (By.); **Diamine Blue C 2 R** (C.); **Azidine Wool Blue R** (C. J.):

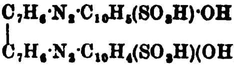


$$\begin{array}{l}\mathrm{C_7H_6{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}OH}\\ |\\ \mathrm{C_7H_6{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)(OH){\cdot}NH_2}\end{array}$$

Prepared from tetrazotised tolidine and 1 mol. each of β-naphthol-8-sulphonic acid and 8-amino-α-naphthol-5-sulphonic acid. The violet-blue aqueous solution gives a dark-blue precipitate with hydrochloric acid, and becomes reddish-violet with sodium hydroxide. Solution in sulphuric acid is blue, giving a blue precipitate on dilution. The corresponding colour from dianisidine is **Azidine Wool Blue B** (C. J.).

Literature.—E. P. 27609 of 1907; D. R. P. 203535, 209269; F. P. 383747; A. P. 888036.

Oxamine Blue 4 R (B.); **Azidine Blue 3 RN** (C. J.); **Naphthamine Blue 3 RE** (K.); **Dianil Azurine 3 R** (M.); **Benzoazurine 3 R** (By.) (O.):

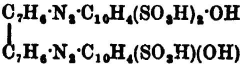


$$\begin{array}{l}\mathrm{C_7H_6{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}OH}\\ |\\ \mathrm{C_7H_6{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)(OH){\cdot}NH_2}\end{array}$$

Prepared from tetrazotised tolidine and 1 mol. each of 6-amino-α-naphthol-3-sulphonic acid and α-naphthol-4-sulphonic acid. Violet aqueous solution is precipitated with hydrochloric acid or sodium hydroxide. Solution in sulphuric acid is blue, giving a violet precipitate on dilution.

Literature.—E. P. 2614 of 1893; D. R. P. 93276; F. P. 227892; A. P. 521095.

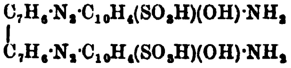
Columbia Blue G (A.); **Benzo Red Blue G** (By.); **Diamine Blue LG** (C.):



$$\begin{array}{l}\mathrm{C_7H_6{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)_2{\cdot}OH}\\ |\\ \mathrm{C_7H_6{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)(OH){\cdot}NH_2}\end{array}$$

Prepared from tetrazotised tolidine and 1 mol. each of α-naphthol-3 : 8-disulphonic acid and 8-amino-α-naphthol-5-sulphonic acid. Blue aqueous solution gives a blue precipitate with hydrochloric acid, and a reddish-violet one with sodium hydroxide. Solution in sulphuric acid is greenish-blue, giving a reddish-violet precipitate on dilution.

Chicago Blue R (A.) (By.); **Diamine Blue CR** (C.):



$$\begin{array}{l}\mathrm{C_7H_6{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)(OH){\cdot}NH_2}\\ |\\ \mathrm{C_7H_6{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)(OH){\cdot}NH_2}\end{array}$$

Prepared from tetrazotised tolidine and 8-amino-α-naphthol-5-sulphonic acid (2 mols.). The violet-blue solution gives a dark-violet precipitate with hydrochloric acid. The solution in sulphuric acid is cornflower blue, giving a bluish-violet precipitate on dilution. The corresponding colour from dianisidine is **Chicago Blue B** (A.) (By.); **Diamine Blue CB** (C.).

Literature.—A. P. 506284.

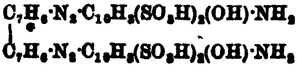
Dianil Blue B (M.):

$$\begin{array}{l}\mathrm{C_7H_6{\cdot}N_2{\cdot}C_{10}H_3(SO_3H)_2(OH)_2}\\ |\\ \mathrm{C_7H_6{\cdot}N_2{\cdot}C_{10}H_3(SO_3H)_2(OH)_2}\end{array}$$

Prepared from tetrazotised tolidine and 2 mols. of 1 : 8-dihydroxynaphthalene-3 : 6-disulphonic acid (chromotrope acid). The blue aqueous solution is not changed with hydrochloric acid or sodium hydroxide. The solution in sulphuric acid is deep-blue, becoming bluish-violet on dilution.

The corresponding colour from benzidine is **Dianil Blue R**, and from dianisidine **Dianil Blue G**, and when 1 mol. each of chromotrope acid and α-naphthol-4-sulphonic acid are used the product is **Dianil Blue 2 R** (M.); **Naphthamine Brilliant Blue 2 R** (K.); **Benzo New Blue 2 B** (By.).

Diamine Blue 3 B (C.); **Benzo Blue 3 B** (By.); **Congo Blue 3 B** (A.) (Lev.); **Azidine Blue 3 B** (C. J.); **Chlorazol Blue 3 B** (H.); **Naphthamine Blue 3 BX** (K.); **Dianil Blue H 3 G** (M.); **Benzamine Blue 3 B** (D.); **Niagara Blue 3 B** (Sch.):



$$\begin{array}{l}\mathrm{C_7H_6{\cdot}N_2{\cdot}C_{10}H_3(SO_3H)_2(OH){\cdot}NH_2}\\ |\\ \mathrm{C_7H_6{\cdot}N_2{\cdot}C_{10}H_3(SO_3H)_2(OH){\cdot}NH_2}\end{array}$$

Prepared from tetrazotised tolidine and 8-amino-α-naphthol-3 : 6-disulphonic acid (H-acid; 2 mols.). When used in medicine it is known as **Trypan Blue** (M.). The violet aqueous solution becomes bluer with hydrochloric acid, and gives a precipitate with excess. The solution in sulphuric acid is blue, giving a violet precipitate on dilution.

Literature.—E. P. 13443 of 1890; 1742 of 1891; D. R. P. 74593; F. P. 201770, 210033.

Eboli Blue B (L.). Isomeric with the above, 8-amino-α-naphthol-4 : 6-disulphonic acid being used instead of H-acid. The blue aqueous solution gives a blue precipitate with hydrochloric acid, and becomes reddish-violet with sodium hydroxide. The solution in sulphuric acid is blue.

Literature.—E. P. 19253 of 1895; D. R. P. appl. F. 8626; A. P. 606436, 606437, 606438, 606439.

Diamine Blue BX (C.); **Benzo Blue BX** (By.); **Congo Blue BX** (A.) (Lev.); **Azidine Blue BX** (C. J.); **Naphthamine Blue BXR** (K.); **Dianil Blue HG** (M.); **Eboli New Blue 2 B** (L.); **Benzamine Blue BX** (D.); **Niagara Blue BX** (Sch.):

$$\begin{array}{l} C_7H_6{\cdot}N_2{\cdot}C_{10}H_3(SO_3H)_2(OH){\cdot}NH_2 \\ | \\ C_7H_6{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}OH \end{array}$$

Prepared from tetrazotised tolidine and 1 mol. each of α-naphthol-4-sulphonic acid and 8-amino-α-naphthol-3 : 6-disulphonic acid (H-acid). The bluish-violet aqueous solution gives a violet precipitate with hydrochloric acid, and becomes bluish-red with sodium hydroxide. The solution in sulphuric acid is blue, giving a violet precipitate on dilution.

Literature.—E. P. 1742 of 1891; D. R. P. 74593; F. P. 201770 addition.

Direct Blue R (I.).

$$\begin{array}{l} C_7H_6{\cdot}N_2{\cdot}C_{10}H_3(CO_2H)(OH)_2{\cdot}SO_3H \\ | \\ C_7H_6{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}OH \end{array}$$

Prepared from tetrazotised tolidine and 1 mol. each of 1 : 7-dihydroxy-6-carboxynaphthalene-3-sulphonic acid and α-naphthol-4-sulphonic acid. The violet aqueous solution gives a violet precipitation with hydrochloric acid, and becomes violet-red with sodium hydroxide. The solution in sulphuric acid is blue. The corresponding colour from dianisidine is **Direct Blue B** (I.).

Literature.—E. P. 14161 and 14253 of 1892; D. R. P. 67000, 75258; F. P. 219875, 220468; A. P. 493563, 493564.

Indazurine RM (I.). Isomeric with the preceding. A different naphthoic acid, viz.: 1 : 7-dihydroxy-2 - carboxynaphthalene - 4 - sulphonic acid is used, the other constituents being the same. The violet-blue aqueous solution becomes bluer with hydrochloric acid and red with sodium hydroxide. The solution in sulphuric acid is blue, giving a violet precipitate on dilution. The corresponding colour from dianisidine is **Indazurine GM** (I.).

Literature.—A. P. 524070.

Indazurine TS (I.):

$$\begin{array}{l} C_7H_6{\cdot}N_2{\cdot}C_{10}H_3(CO_2H)(OH)_2{\cdot}SO_3H \\ | \\ C_7H_6{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)(OH){\cdot}NH_2 \end{array}$$

Prepared as the preceding, except that 7-amino-α-naphthol-3-sulphonic acid is used instead of α-naphthol-4-sulphonic acid. The violet-blue aqueous solution becomes redder with acids or alkalis. The solution in sulphuric acid is blue, giving a violet precipitate on dilution.

Literature.—As above.

Milling Scarlet 4 R (M.); **Acid Anthracene Red 3 B** (By.); **Florida Red R** (L.):

$$\begin{array}{l} HSO_3{\cdot}C_7H_5{\cdot}N_2{\cdot}C_{10}H_6{\cdot}OH \\ | \\ HSO_3{\cdot}C_7H_5{\cdot}N_2{\cdot}C_{10}H_6{\cdot}OH \end{array}$$

Prepared from tetrazotised tolidinodisulphonic acid and β-naphthol (2 mols.). The carmoisine-red aqueous solution gives a violet precipitate with hydrochloric acid. The solution in sulphuric acid is violet-red.

Diamine Yellow N (C.):

$$\begin{array}{l} C_2H_5{\cdot}O{\cdot}C_6H_3{\cdot}N_2{\cdot}C_6H_3(CO_2H){\cdot}OH \\ | \\ C_6H_4{\cdot}N_2{\cdot}C_6H_4{\cdot}O{\cdot}C_2H_5 \end{array}$$

Prepared by combining tetrazotised ethoxybenzidine first with salicylic acid (1 mol.) and then with phenol (1 mol.) and ethylating the product. The yellow aqueous solution gives a greenish precipitate with hydrochloric acid and a reddish-yellow with sodium hydroxide. The solution in sulphuric acid is violet, giving a greenish-brown precipitate on dilution.

Literature.—E. P. 14464 of 1887; D. R. P. 46134; F. P. 186566, 186567; A. P. 380067.

Diamine Blue 3 R (C.):

$$\begin{array}{l} C_2H_5{\cdot}O{\cdot}C_6H_3{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}OH \\ | \\ C_6H_4{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}OH \end{array}$$

Prepared from tetrazotised ethoxybenzidine and α-naphthol-4-sulphonic acid (2 mols.). The reddish-blue aqueous solution is not changed with hydrochloric acid, but becomes reddish-violet with sodium hydroxide. The solution in sulphuric acid is dark-blue, giving a violet precipitate on dilution.

Literature.—As above.

Diamine Blue B (C.):

$$\begin{array}{l} C_2H_5{\cdot}O{\cdot}C_6H_3{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)_2{\cdot}OH \\ | \\ C_6H_4\ N_2{\cdot}C_{10}H_5(SO_3H){\cdot}OH \end{array}$$

Prepared from tetrazotised ethoxybenzidine and 1 mol. each of β-naphthol-3 : 7-disulphonic acid and α-naphthol-4-sulphonic acid. The blue aqueous solution gives a blue precipitate with hydrochloric acid, and becomes reddish-blue with sodium hydroxide. The solution in sulphuric acid is blue, giving a blue precipitate on dilution.

Literature.—As above.

Diamine Blue Black E (C.):

$$\begin{array}{l} C_2H_5{\cdot}O{\cdot}C_6H_3{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)_2{\cdot}OH \\ | \\ C_6H_4{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)(OH){\cdot}NH_2 \end{array}$$

Prepared as the preceding, except that 7-amino α-naphthol-3-sulphonic acid is used instead o α-naphthol-4-sulphonic acid. The combinatio is effected in alkaline solution. The blackish-blue aqueous solution gives a blue precipitate with hydrochloric acid, and is not changed with sodium hydroxide. The solution in sulphuric acid is blackish-blue, giving a blue precipitate on dilution.

Literature.—E. P. 16699 of 1889; D. R. P. 57857; F. P. 201770.

Diazurine B (By.):

$$\begin{array}{l}CH_3\cdot O\cdot C_6H_3\cdot N_2\cdot C_{10}H_5(SO_3H)\cdot NH_2\\ \quad\;|\\ CH_3\cdot O\cdot C_6H_3\cdot N_2\cdot C_{10}H_5(SO_3H)\cdot NH_2\end{array}$$

Prepared from tetrazotised dianisidine and α-naphthylamine-6-(or 7-)sulphonic acid (Cleve's acid) (2 mols.). The brownish-red aqueous solution gives a blue precipitate with hydrochloric acid and a soluble red one with sodium hydroxide. The solution in sulphuric acid is blue, giving a blue precipitate on dilution.

Literature.—D. R. P. 65262.

Benzopurpurine 10 B (By.) (Lev.) (K.) (L.) (A.) (O.) (K. S.) (T. M.); **Dianil Red 10 B** (M.); **Cotton Red 10 B** (I.) (P.); **Diamine Red 10 B** (C.); **Buffalo Cardinal 7 B** (Sch.). Isomeric with the preceding. Prepared from tetrazotised dianisidine and 2 mols. of naphthionic acid. The carmine-red aqueous solution gives a blue precipitate with hydrochloric acid and a red one with sodium hydroxide. The solution in sulphuric acid is blue, giving a blue precipitate on dilution.

Literature.—E. P. 14424 of 1885; D. R. P. 38802; F. P. 173042; A. P. 481954.

Azo- Violet (By.) (A.) (L.) (Lev.):

$$\begin{array}{l}CH_3\cdot O\cdot C_6H_3\cdot N_2\cdot C_{10}H_5(SO_3H)\cdot NH_2\\ \quad\;|\\ CH_3\cdot O\cdot C_6H_3\cdot N_2\cdot C_{10}H_5(SO_3H)\ OH\end{array}$$

Tetrazotised dianisidine (1 mol.) is combined with 1 mol. of naphthionic acid, and then with 1 mol. of α-naphthol-4-sulphonic acid. Aqueous solution reddish-violet, giving blue precipitate with mineral acids and bluish-violet colouration with acetic acid. Solution turned magenta by sodium hydroxide. Dissolves with a blue colour in sulphuric acid, giving a blue precipitate on dilution.

Literature.—E. P. 14424 of 1885; 7283 of 1886; D. R. P. 40247; F. P. 173042; A. P. 447302.

Benzoazurine G (By.) (A.) (L.) (Lev.) (K.) (O.) (K. S.); **Dianil Azurine G** (M.); **Renol Blue B** (T. M.); **Cotton Blue 3 G** (I.); **Benzoin Blue GN, 2GN, 5GN** (B. K.); **Direct Blue G extra** (Sch.); **Oxamine Blue A** (B.); **Azidine Blue BA** (C. J.):

$$\begin{array}{l}CH_3\cdot O\cdot C_6H_3\cdot N_2\cdot C_{10}H_5(SO_3H)\cdot OH\\ \quad\;|\\ CH_3\cdot O\cdot C_6H_3\cdot N_2\cdot C_{10}H_5(SO_3H)\cdot OH\end{array}$$

Prepared by the action of tetrazotised dianisidine on α-naphthol-4-sulphonic acid. Aqueous solution bluish-violet, becoming red on addition of sodium hydroxide; dark-violet precipitate with dilute hydrochloric acid. Dissolves in sulphuric acid with a blue colour, giving violet precipitate on dilution. **Benzoazurine R** (By.) (A.) (L.) (O.) is a mixture of benzoazurine G and azo blue.

Literature.—E. P. 14424 of 1885; D. R. P. 38802; F. P. 173042; A. P. 357273, 481954.

Benzoazurine 3 G (By.) (A.) (L.) (Lev.) (K.). Isomeric with the above. α-Naphthol-5-sulphonic acid (Laurent's acid) is used instead of the 4-sulphonic acid. Aqueous solution bluish-violet, giving bluish-violet precipitate with hydrochloric acid and becoming violet-red with sodium hydroxide. Solution in sulphuric acid is blue, giving violet precipitate on dilution.

Literature.—As above.

Congo Blue 2 B (By.):

$$\begin{array}{l}CH_3\cdot O\cdot C_6H_3\cdot N_2\cdot C_{10}H_4(SO_3H)_2\cdot OH\\ \quad\;|\\ CH_3\cdot O\cdot C_6H_3\cdot N_2\cdot C_{10}H_5(SO_3H)\cdot OH\end{array}$$

Prepared from tetrazotised dianisidine and 1 mol. each of β-naphthol-3 : 6-disulphonic acid and α-naphthol-4-sulphonic acid. Blue aqueous solution gives a dark-blue precipitate with hydrochloric acid, and becomes magenta-red with sodium hydroxide. Solution in sulphuric acid is blue, giving a blue precipitate on dilution.

Literature.—E. P. 7283 of 1886; D. R. P. 40247; F. P. 173042 (addition); A. P. 467162.

Chlorazol Blue R and 3 G (H.):

$$\begin{array}{l}CH_3\cdot O\cdot C_6H_3\cdot N_2\cdot C_{10}H_4Cl(SO_3H)\cdot OH\\ \quad\;|\\ CH_3\cdot O\cdot C_6H_3\cdot N_2\cdot C_{10}H_4Cl(SO_3H)\cdot OH\end{array}$$

Prepared from tetrazotised dianisidine and 2 mols. of chloro-α-naphthol-5- and -4-sulphonic acids respectively. The violet aqueous solution undergoes little change with hydrochloric acid, but turns crimson with sodium hydroxide. The solution in sulphuric acid is greenish-blue (R) or green (3 G).

Literature.—E. P. 12085 of 1898.

Diamine Brilliant Blue G (C.):

$$\begin{array}{l}CH_3\cdot O\cdot C_6H_3\cdot N_2\cdot C_{10}H_3Cl(SO_3H)_2\cdot OH\\ \quad\;|\\ CH_3\cdot O\cdot C_6H_3\cdot N_2\cdot C_{10}H_3Cl(SO_3H)_2\cdot OH\end{array}$$

Prepared from tetrazotised dianisidine and 2 mols. of 8-chloro-α-naphthol-3 : 6-disulphonic acid. Bluish-violet aqueous solution gives a soluble violet precipitate with hydrochloric acid, and becomes cherry-red with sodium hydroxide. Solution in sulphuric acid is greenish-blue, turning violet on dilution.

Literature.—E. P. 1920 of 1894; D. R. P. 79055, 82285; F. P. 235271; A. P. 532125, 535037.

Oxamine Blue B (B.):

$$\begin{array}{l}CH_3\cdot O\cdot C_6H_3\cdot N_2\cdot C_{10}H_5(SO_3H)\cdot OH\\ \quad\;|\\ CH_3\cdot O\cdot C_6H_3\cdot N_2\cdot C_{10}H_4(SO_3H)(OH)\cdot NH_2\end{array}$$

Prepared from tetrazotised dianisidine and 1 mol. each of 5-amino-α-naphthol-3-sulphonic acid and α-naphthol-4-sulphonic acid. Dark-blue aqueous solution turns reddish-violet with sodium hydroxide, and pale violet with hydrochloric acid. The solution in sulphuric acid is bluish-green, becoming violet on dilution.

Literature.—E. P. 2370 of 1893; D. R. P. 82572; F. P. 229263; A. P. 558344.

Chicago Blue 6 B (A.); **Brilliant Benzo Blue 6 B** (By.); **Diamine Sky Blue FF** (C.); **Azidine Sky Blue FF** (C. J.); **Chlorazol Sky Blue FF** (H.); **Dianol Brilliant Blue 6 B** (Lev.); **Oxamine Sky Blue 6 B** (B.); **Dianil Sky Blue PH** (M.):

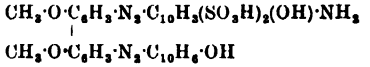
$$\begin{array}{l}CH_3\cdot O\cdot C_6H_3\cdot N_2\cdot C_{10}H_3(SO_3H)_2(OH)\cdot NH_2\\ \quad\;|\\ CH_3\cdot O\cdot C_6H_3\cdot N_2\cdot C_{10}H_3(SO_3H)_2(OH)\cdot NH_2\end{array}$$

Prepared from tetrazotised dianisidine and 2 mols. of 8-amino-α-naphthol-5 : 7-disulphonic acid (S-acid). The combination is effected in alkaline solution. Blue aqueous solution is not changed with hydrochloric acid, but becomes bluish-violet with sodium hydroxide. Solution in sulphuric acid is bluish-green, becoming pure blue on dilution.

Diamine Sky Blue (C.) ; **Benzo Sky Blue** (By.) ; **Congo Sky Blue** (A.) ; **Dianol Sky Blue** (Lev.) ; **Renol Pure Blue** (T. M.) ; **Azidine Sky Blue** (C. J.) ; **Chlorazol Blue 6 G** (H.) ; **Naphthamine Blue 7 B** (K.) ; **Dianil Blue H 6 G** (M.) ; **Oxamine Sky Blue 5 B** (B.) ; **Benzamine Sky Blue** (D.) ; **Benzoin Sky Blue** (B. K.) ; **Direct Blue RBA** (L.) ; **Niagara Blue 4 B** (Sch.). Isomeric with the preceding. Two mols. of 8-amino-α-naphthol-3 : 6-disulphonic acid (H-acid) are used as components. Blue aqueous solution is not changed with hydrochloric acid, but becomes redder with sodium hydroxide. Solution in sulphuric acid is bluish-green, becoming pure blue on dilution.

Literature.—E. P. 1742 of 1891 ; D. R. P. 74593 ; F. P. 201770 ; A. P. 464135.

Chicago Blue RW (A.) ; **Benzo Blue RW** (By.) ; **Diamine Blue RW** (C.) ; **Dianol Blue RW** (Lev.) :

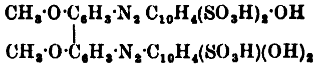


$$\begin{array}{l}\mathrm{CH_3{\cdot}O{\cdot}C_6H_3{\cdot}N_2{\cdot}C_{10}H_3(SO_3H)_2(OH){\cdot}NH_2}\\ \quad\quad\vert\\ \mathrm{CH_3{\cdot}O{\cdot}C_6H_3{\cdot}N_2{\cdot}C_{10}H_6{\cdot}OH}\end{array}$$

Prepared from tetrazotised dianisidine and 1 mol. each of 8-amino-α-naphthol-5 : 7-disulphonic acid and β-naphthol. Blue aqueous solution gives a blue precipitate with hydrochloric acid, and becomes violet with sodium hydroxide. Solution in sulphuric acid is green, giving a violet precipitate on dilution.

Chicago Blue 4 B (A.) ; **Benzo Sky Blue 4 B** (By.) ; **Diamine Sky Blue C 4 B** (C.). Instead of β-naphthol in the preceding colouring matter, 8-amino-α-naphthol-5-sulphonic acid is used. Blue aqueous solution gives a bluish-violet precipitate with hydrochloric acid, and is unchanged with sodium hydroxide. Solution in sulphuric acid is bluish-green, giving a blue precipitate on dilution.

Indazurine B (I.) :

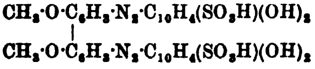


$$\begin{array}{l}\mathrm{CH_3{\cdot}O{\cdot}C_6H_3{\cdot}N_2\,C_{10}H_4(SO_3H)_2{\cdot}OH}\\ \quad\quad\vert\\ \mathrm{CH_3{\cdot}O{\cdot}C_6H_3{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)(OH)_2}\end{array}$$

Prepared from tetrazotised dianisidine and 1 mol. each of 1 : 7-dihydroxynaphthalene-4-sulphonic acid and β-naphthol-3 : 6-disulphonic acid. Blue aqueous solution turns bluer with hydrochloric acid and red with sodium hydroxide. Solution in sulphuric acid is blue, giving a reddish-blue precipitate on dilution. When *m*-tolylenediamine is used instead of R-salt the colour produced is called **Direct Violet BB** (I.). The violet aqueous solution shows the same reactions as the above, as does also the solution in sulphuric acid.

Literature.—D. R. P. 524069 ; A. P. 524069.

Brilliant Azurine 5 G (By.) (A.) (L.) :

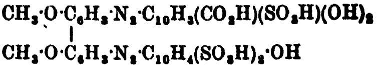


$$\begin{array}{l}\mathrm{CH_3{\cdot}O{\cdot}C_6H_3{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)(OH)_2}\\ \quad\quad\vert\\ \mathrm{CH_3{\cdot}O{\cdot}C_6H_3{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)(OH)_2}\end{array}$$

Prepared by combining tetrazotised dianisidine with 2 mols. of 1 : 8-dihydroxynaphthalene-4-sulphonic acid in acetic acid solution. Aqueous solution is bluish-violet ; with hydrochloric acid gives a blue precipitate, and with sodium hydroxide becomes red. Solution in sulphuric acid is greenish-blue, giving a dark reddish-blue precipitate on dilution.

Literature.—E. P. 14424 of 1885 ; 13665 of 1889 ; D. R. P. 57166 ; F. P. 173042 ; A. P. 417294.

Indazurine BB (I.) :

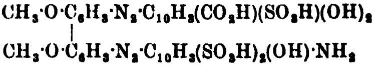


$$\begin{array}{l}\mathrm{CH_3{\cdot}O{\cdot}C_6H_3{\cdot}N_2{\cdot}C_{10}H_3(CO_2H)(SO_3H)(OH)_2}\\ \quad\quad\vert\\ \mathrm{CH_3{\cdot}O{\cdot}C_6H_3{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)_2{\cdot}OH}\end{array}$$

Prepared from tetrazotised dianisidine and 1 mol. each of 1 : 7-dihydroxy-2-carboxynaphthalene-4-sulphonic acid and β-naphthol-3 : 6-disulphonic acid (R-salt). Blue aqueous solution becomes slightly bluer with hydrochloric acid, and redder with sodium hydroxide. Solution in sulphuric acid is greenish-blue, giving a blue precipitate on dilution.

Literature.—A. P. 524070.

Indazurine 5 GM (I.) :

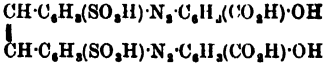


$$\begin{array}{l}\mathrm{CH_3{\cdot}O{\cdot}C_6H_3{\cdot}N_2{\cdot}C_{10}H_3(CO_2H)(SO_3H)(OH)_2}\\ \quad\quad\vert\\ \mathrm{CH_3{\cdot}O{\cdot}C_6H_3{\cdot}N_2{\cdot}C_{10}H_3(SO_3H)_2(OH){\cdot}NH_2}\end{array}$$

Prepared as the preceding, except that 8-amino-α-naphthol-3 : 6-disulphonic acid (H-acid) is used instead of R-salt. The pure blue aqueous solution is not changed with hydrochloric acid, but becomes redder with sodium hydroxide. The solution in sulphuric acid is bluish-green, becoming bluish-violet on dilution.

Literature.—As above.

Hessian Yellow (L.) :

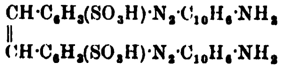


$$\begin{array}{l}\mathrm{CH{\cdot}C_6H_3(SO_3H){\cdot}N_2{\cdot}C_6H_3(CO_2H){\cdot}OH}\\ \Vert\\ \mathrm{CH{\cdot}C_6H_3(SO_3H){\cdot}N_2{\cdot}C_6H_3(CO_2H){\cdot}OH}\end{array}$$

Prepared from tetrazotised diaminostilbenedisulphonic acid[1] and salicylic acid. Aqueous solution ochreous, giving blackish precipitate with mineral acids. Solution reddened by sodium hydroxide. Reddish-violet solution in sulphuric acid, giving blackish precipitate on dilution.

Literature.—E. P. 4387 of 1886 ; D. R. P. 38735 ; A. P. 350299, 350230.

Hessian Purple N (L.) (By.).

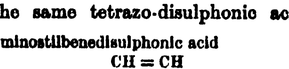


$$\begin{array}{l}\mathrm{CH{\cdot}C_6H_3(SO_3H){\cdot}N_2{\cdot}C_{10}H_6{\cdot}NH_2}\\ \Vert\\ \mathrm{CH{\cdot}C_6H_3(SO_3H){\cdot}N_2{\cdot}C_{10}H_6{\cdot}NH_2}\end{array}$$

From tetrazotised diaminostilbenedisulphonic acid and β-naphthylamine. Aqueous solution red, giving bluish-black precipitate with mineral acids, and violet-black precipitate with acetic acid. Red colouration or precipitate with sodium hydroxide. Blue solution in sulphuric acid, giving bluish-black precipitate on dilution.

References as in preceding.

Brilliant Yellow (L.) (A.) (By.) :

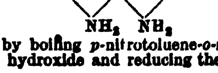


$$\begin{array}{l}\mathrm{CH{\cdot}C_6H_3(SO_3H){\cdot}N_2{\cdot}C_6H_4{\cdot}OH}\\ \Vert\\ \mathrm{CH{\cdot}C_6H_3(SO_3H){\cdot}N_2{\cdot}C_6H_4{\cdot}OH}\end{array}$$

From the same tetrazo-disulphonic acid and

---

[1] Diaminostilbenedisulphonic acid



is prepared by boiling *p*-nitrotoluene-*o*-sulphonic acid with sodium hydroxide and reducing the product with zinc-dust.

phenol. Aqueous solution orange, giving violet precipitate with mineral acids. Dissolves with a reddish-violet in sulphuric acid, giving a violet precipitate on dilution.

References as in preceding.

Chrysophenine G (K. S.) (L.) (A.) (By.); **Chrysobarine G extra conc.** (T. M.); **Phenine Yellow** (P.); **Azidine Yellow CP** (C. J.); **Direct Yellow CRG** (L.); **Aurophenine O** (M.); **Pyramine Yellow G** (B.); **Triazol Yellow G** (O.):

Prepared by ethylating the preceding colouring matter. Aqueous solution orange, giving brown precipitate with mineral acids. Dissolves with a reddish-violet colour in sulphuric acid, giving blue precipitate on dilution.

Literature.—E. P. 3994 of 1887; D. R. P. 42466; F. P. 182063; Ber. 1894, 27, 3357; 1903, 36, 2975.

Hessian Brilliant Purple (L.)

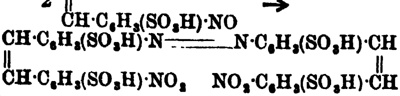
$$\begin{array}{l}\mathrm{CH{\cdot}C_6H_3(SO_3H){\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}NH_2}\\ \|\\ \mathrm{CH{\cdot}C_6H_3(SO_3H){\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}NH_2}\end{array}$$

Prepared from tetrazotised diaminostilbenedisulphonic acid, and 2 mols. of β-naphthylamine-6-sulphonic acid. Purple-red aqueous solution gives bluish-black precipitate with hydrochloric acid and carmine-red precipitate with sodium hydroxide. Solution in sulphuric acid blue, giving a bluish-black precipitate on dilution.

References as for Hessian Yellow.

Stilbene Colouring Matters.

The colouring matters which have hitherto been classified under this head are produced by alkaline condensation and oxidation of *p*-nitrotoluenesulphonic acid under various conditions. They have generally been considered to be nitroso- or azoxy- stilbene derivatives, but the recent researches of A. G. Green and his collaborators have shown that all the colouring matters of this group must be regarded as azo-dyes (Chem. Soc. Trans. 1904, 85, 1424, 1432; 1906, 89, 1602; 1907, 91, 2076; 1908, 93, 1721; J. Soc. Dyers, 1907, 23, 162). The first action of alkali hydroxide on *p*-nitrotoluenesulphonic acid leads to the formation of a dinitrosostilbenedisulphonic acid, one molecule of which is oxidised at the expense of a second molecule, and the remaining two nitrogen atoms of two molecules combine to form an azo- group in a distilbene molecule:

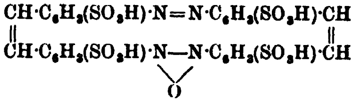


$$2\begin{array}{l}\mathrm{CH{\cdot}C_6H_3(SO_3H){\cdot}NO}\\ \|\\ \mathrm{CH{\cdot}C_6H_3(SO_3H){\cdot}NO}\end{array}\rightarrow$$

$$\begin{array}{lcr}\mathrm{CH{\cdot}C_6H_3(SO_3H){\cdot}N} & \text{——————} & \mathrm{N{\cdot}C_6H_3(SO_3H){\cdot}CH}\\ \| & & \|\\ \mathrm{CH{\cdot}C_6H_3(SO_3H){\cdot}NO_2} & & \mathrm{NO_2{\cdot}C_6H_3(SO_3H){\cdot}CH}\end{array}$$

The equation represents the formation of the greenest yellow of the series (stilbene yellow 8G: *see* below). The redder yellows and oranges may be regarded as formed therefrom by the reduction of the two nitro- groups, first to an azoxy- and finally to an azo- group.

Sun Yellow (G.) (K. S.); **Afghan Yellow** (H.); **Curcumine S** (L.) (A.); **Direct Yellow J** (P.); **Azidine Fast Yellow G** (C. J.); **Direct Yellow RT** (Cl. Co.); **Direct Yellow F** (Sch.); **Direct Yellow G** (I.); **Direct Yellow R** (P.) (O.); **Diamine Fast Yellow A** (C.). Prepared by heating *p*-nitrotoluenesulphonic acid with aqueous sodium hydroxide. Direct yellow RT, which was analysed by Green (*l.c.*), is considered to have the constitution.



(the colouring matter being, of course, the sodium salt).

Aqueous solution is brownish-yellow. Solution in sulphuric acid is violet, becoming yellow on dilution.

Literature.—E. P. 4387 of 1886; D. R. P. 38735; F. P. 175630; A. P. 360553; Bull. Mulhouse, 1887, 99; Ber. 1886, 19, 3234.

Naphthamine Yellow G (K.); **Direct Yellow R** (By.); **Renol Yellow R** (T. M.). Prepared as above, but the temperature of the reaction is 60°–85°. Reddish-yellow aqueous solution gives brown precipitate with excess of hydrochloric acid and a yellow precipitate with sodium hydroxide. Solution in sulphuric acid is cherry-red, becoming yellow on dilution.

Literature.—E. P. 23672 of 1892; D. R. P. 79241; F. P. 226635; Ber. 1893, 26, 2233; 1895, 28, 2281.

Mikado Yellow (A.); **Mikado Yellow G** (L.); **Mikado Gold Yellow 2 G, 4 G, 6 G, 8 G** (L.); **Naphthamine Yellow 2 G, 3 G** (K.); **Renol Yellow 2 G** (T. M.); **Dianil Direct Yellow S** (M.); **Formal Yellow** (G.); **Stilbene Yellow 3 G** (B.); **Paper Yellow** (M.). Prepared by treating the products of condensation of *p*-nitrotoluenesulphonic acid and sodium hydroxide with oxidising agents. Yellow aqueous solution gives a brownish-yellow precipitate with hydrochloric acid, and yellow solution or precipitate with sodium hydroxide. Solution in sulphuric acid is orange to red, becoming yellow on dilution.

Literature.—E. P. 23672 of 1892; D. R. P. 42466; F. P. 226635; Ber. 1893, 26, 2234; 1897, 30, 2618, 3097; 1898, 31, 354, 1078.

Stilbene Yellow G, 4 G, 6 G, 8 G (Cl. Co.). The constitution of the last brand has already been given. The colouring matters are alkaline condensation products of dinitrodibenzyldisulphonic acid, and dinitrostilbenedisulphonic acid. Solution in sulphuric acid is orange to yellowish-red, becoming yellow on dilution.

Literature.—E. P. 5351, 21553, 21399, of 1897; 3393 of 1898; D. R. P. 96107, 113513, 113514; F. P. 272384, 273018, 273037; Ber. 1897, 30, 3097; 1898, 31, 1087.

Diphenylcitronine G (G.). Prepared by condensing dinitrodibenzyldisulphonic acid with aniline in presence of sodium hydroxide or by condensing similarly dinitrostilbenedisulphonic acid. Yellow aqueous solution gives a brownish-yellow precipitate with hydrochloric acid, and an orange-yellow one with sodium hydroxide. Solution in sulphuric acid is orange, giving a brownish-yellow precipitate on dilution.

Literature.—E. P. 18990, 21399, 21553 of 1897; D. R. P. 101760, 113514; F. P. 269466, 273018; A. P. 613911.

Diphenyl Fast Yellow (G.). Prepared by condensing dinitrodibenzyldisulphonic acid or dinitrostilbenedisulphonic acid with primuline or dehydrothio-*p*-toluidinesulphonic acid in presence of sodium hydroxide. Yellow aqueous solution gives a brownish-orange yellow precipitate with hydrochloric acid, and an orange-yellow one with sodium hydroxide. Solution in sulphuric acid is red, giving a brownish-yellow precipitate on dilution.

Literature.—E. P. 18990, 21399, 21553 of 1897; D. R. P. 100613, 113514; F. P. 269406, 273018.

Mikado Brown B, 3 GO, M (L.). Prepared by the action of alkalis on *p*-nitrotoluenesulphonic acid in presence of oxidisable substances. Brown aqueous solution gives a brown precipitate with hydrochloric acid. Solution in sulphuric acid is violet-black, giving a brown precipitate on dilution.

Literature.—E. P. 2664 of 1888; D. R. P. 46252, 48528; F. P. 189697; A. P. 395115, 396527.

Mikado Orange G to **5 R** (L.); **Naphthamine Orange 2 R** (K.); **Direct Orange G** (G.); **Chloramine Orange G** (By.); **Stilbene Orange 4 R** (Cl. Co.); **Stilbene Yellow 3 G** (B.). Prepared by the same reaction as the preceding, and by the action of alkaline reducing agents on direct yellow. Orange-yellow aqueous solution gives a dark-brown precipitate with hydrochloric acid, and an orange one with sodium hydroxide. Solution in sulphuric acid is violet to blue, giving a brown precipitate on dilution.

Mikado Orange 3 RO (L.) has the constitution

$$\begin{array}{l} CH\cdot C_6H_3(SO_3H)\cdot N:N\cdot C_6H_3(SO_3H)\cdot CH \\ \| \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad \| \\ CH\cdot C_6H_3(SO_3H)\cdot N:N\cdot C_6H_3(SO_3H)\cdot CH \end{array}$$

Brands 4 RO and 5 RO are redder shades.

Literature.—E. P. 2664 of 1888; D. R. P. 46252, 48528, 96929; F. P. 189697; A. P. 395115, 396527; Ber. 1893, 26, 2233; 1895, 28, 2281.

Polychromine B (G.); **Fast Cotton Brown R** (G.); **Direct Brown R** (G.). Prepared by boiling equal molecules of *p*-nitrotoluenesulphonic acid and *p*-phenylenediamine with sodium hydroxide. Orange-brown aqueous solution gives a blue-black precipitate with hydrochloric acid. Solution in sulphuric acid is reddish-violet, giving a bluish-black precipitate on dilution.

Literature.—E. P. 15671 of 1890; D. R. P. 59290; F. P. 208626; A. P. 455952.

Diphenyl Orange RR (G.); **Azidine Orange D 2 R** (C. J.). Prepared by condensing 2 mols. of *p*-nitrotoluenesulphonic acid with 2 mols. of *p*-phenylenediamine in presence of concentrated aqueous sodium hydroxide. Orange-yellow aqueous solution gives a bluish-black precipitate with hydrochloric acid, and an orange one with sodium hydroxide. Solution in sulphuric acid is red, giving a bluish-black precipitate on dilution.

Literature.—E. P. 6651 of 1899; D. R. P. appl. G. 13069; F. P. 286620; A. P. 636065.

Chicago Orange G (G.). Prepared by condensing *p*-nitrotoluenesulphonic acid with benzidine in presence of sodium hydroxide. Orange-yellow aqueous solution gives a brown precipitate with hydrochloric acid, and an orange-brown one with sodium hydroxide. Solution in sulphuric acid is violet, giving a brown precipitate on dilution.

Literature.—E. P. 788 of 1893; D. R. P. 75326; F. P. 227271.

Arnica Yellow (G.). Prepared by condensing *p*-nitrotoluenesulphonic acid with *p*-aminophenol in presence of boiling aqueous sodium hydroxide. Brownish-yellow aqueous solution gives a brownish-black precipitate with hydrochloric acid. Solution in sulphuric acid is violet, giving a dark-brown precipitate on dilution.

Literature.—F. P. 222554.

Diphenyl Chrysoïne G (G.). Prepared by ethylating the preceding. The constitution is probably

$$\begin{array}{l} CH\cdot C_6H_3(SO_3Na)\cdot N:N\cdot C_6H_4\cdot O\cdot C_2H_5 \\ \| \\ CH\cdot C_6H_3(SO_3Na)\cdot N:N\cdot C_6H_4\cdot O\cdot C_2H_5 \end{array}$$

Golden-yellow aqueous solution gives a blackish brown precipitate with hydrochloric acid, and an orange one with sodium hydroxide. Solution in sulphuric acid is violet-red, giving a blackish-brown precipitate on dilution.

Literature.—E. P. 6651 of 1899; D. R. P. appl. G. 7525, 13069; F. P. 286620; A. P. 636065.

Diphenyl Chrysoïne RR (G.). Prepared by diazotising diphenyl orange RR (G.), combining the diazo- compound with phenol and ethylating the product. Reddish-orange aqueous solution gives a blackish-brown precipitate with hydrochloric acid, and a reddish-brown one with sodium hydroxide. Solution in sulphuric acid is pure blue, giving a brownish-black precipitate on dilution.

Literature.—E. P. 6651 of 1899; D. R. P. 117729; F. P. 286620; A. P. 644462.

Diphenyl Fast Brown G (G.). Prepared as the preceding, but the diazo- compound is combined with 7-phenylamino-*a*-naphthol-3-sulphonic acid. The dark yellowish-brown aqueous solution gives a blackish-brown precipitate with hydrochloric acid, and a dark-brown one with sodium hydroxide. Solution in sulphuric acid is dark blue, giving a blackish-brown precipitate on dilution.

References as above.

Diphenyl Catechine G (G.). Prepared as above, but the diazo- compound is combined with 7-dimethylamino-*a*-naphthol-3-sulphonic acid. Yellowish-brown aqueous solution gives a dark-brown precipitate with hydrochloric acid, and a brown one with sodium hydroxide. Solution in sulphuric acid is blackish violet-blue, giving a blackish-brown precipitate on dilution.

References as above.

Curcuphenine (Cl. Co.). Prepared by condensing *p*-nitrotoluenesulphonic acid with dehydrothio-*p*-toluidinesulphonic acid in presence of very dilute aqueous sodium hydroxide. Yellow aqueous solution gives a brown precipitate with hydrochloric acid. The solution in sulphuric acid is red, giving a brownish-yellow precipitate on dilution.

Literature.—E. P. 12922 of 1896; D. R. P. 99575; F. P. 264755.

Chlorophenine Orange (various marks) (Cl. Co.) are reduction products of the preceding.

IV. TRISAZO- COLOURING MATTERS.

These colours, as their name implies, contain three azo-groups.

Janus Brown B (M.):

$N(CH_3)_3Cl\cdot C_6H_4\cdot N_2\cdot C_{10}H_6\cdot N_2\cdot C_6H_2(NH_2)_2\cdot N_2\cdot C_6H_5$

Prepared by combining diazotised *m*-aminophenyltrimethylammonium chloride with *a*-naphthylamine, diazotising the product and combining with chrysoidine. Aqueous solution is brown, giving a soluble brown precipitate with hydrochloric acid or sodium hydroxide. Solution in sulphuric acid is dark green, becoming brown on dilution.

Literature.—E. P. 9343 of 1896; D. R. P. 95530.

Janus Brown R (M.) is prepared from diazotised *p*-aminobenzyldiethylamine and *a*-naphthylamine, the product being diazotised and combined with chrysoidine, resorcinol, or *m*-phenylenediamine. Reactions are similar to those given by the preceding colour.

Literature.—E. P. 19976 of 1896; D. R. P. 99127; F. P. 256156; A. P. 610345; *see* also D. R. P. 93499, 100420; F. P. 264579; A. P. 602638, 602639, 602640, 623697, 626913.

Melogene Blue BH (K. S.); **Diamine Beta Black** (C.)

$$N_2\left<\begin{array}{l}C_8H_8\cdot N_2\cdot C_{10}H_3(SO_3H)_2(OH)\cdot NH_2\\ C_{12}H_8\cdot N_2\cdot C_{10}H_3(SO_3H)_2(OH)\cdot NH_2\end{array}\right.$$

Tetrazotised benzidine is combined with 1 mol. of *p*-xylidine, the product diazotised and combined with 2 mols. of 8-amino-*a*-naphthol-3 : 6-disulphonic acid (H-acid). The violet-blue aqueous solution gives a violet precipitate with hydrochloric acid, and becomes violet with sodium hydroxide. The solution in sulphuric acid is blue, giving a bluish-violet precipitate on dilution.

Literature.—E. P. 28810 of 1896; F. P. 262109; A. P. 591616.

Diazo Blue Black RS (By.):

$$N_2\left<\begin{array}{l}C_{10}H_6\cdot N_2\cdot C_{10}H_3(SO_3H)_2(OH)\cdot NH_2\\ C_{12}H_8\cdot N_2\cdot C_{10}H_3(SO_3H)_2(OH)\cdot NH_2\end{array}\right.$$

Tetrazotised benzidine is combined with 1 mol. of *a*-naphthylamine, the product diazotised and combined with 2 mols. of H-acid. The dark blue aqueous solution gives a blue precipitate with hydrochloric acid, and becomes redder with sodium hydroxide. The solution in sulphuric acid is dark bluish-green, giving a blue precipitate on dilution.

Direct Black V and **RR** (P.) are analogous colours derived from benzidine, 8-amino-*a*-naphtholsulphonic acid, a primary amine, and a *m*-diamine.

Benzo Gray S extra (By.):

$$N_2\left<\begin{array}{l}C_{10}H_6\cdot N_2\cdot C_{10}H_5(SO_3H)\cdot OH\\ C_{12}H_8\cdot N_2\cdot C_6H_3(CO_2H)\cdot OH\end{array}\right.$$

The colouring matter from tetrazotised benzidine and 1 mol. each of salicylic acid and *a*-naphthylamine is diazotised and combined with *a*-naphthol-4-sulphonic acid. The Bordeaux-brown aqueous solution gives a black precipitate with hydrochloric acid. The solution in sulphuric acid is blue, giving a black precipitate on dilution.

Literature.—E. P. 13235 of 1890; D. R. P. 57331; F. P. 187365.

Benzo Olive (By.):

$$N_2\left<\begin{array}{l}C_{10}H_6\cdot N_2\cdot C_{10}H_3(SO_3H)_2(OH)\cdot NH_2\\ C_{12}H_8\cdot N_2\cdot C_6H_3(CO_2H)\cdot OH\end{array}\right.$$

Prepared as the preceding, except that 8-amino-*a*-naphthol-3 : 6-disulphonic acid (H-acid) is used as the end component. The dark moss-green aqueous solution gives a blackish-grey precipitate with hydrochloric acid, and becomes dark brown with sodium hydroxide. Solution in sulphuric acid is violet, giving a greenish-black precipitate on dilution.

Literature.—E. P. 3439 of 1891; D. R. P. 65480; F. P. 187365.

Congo Fast Blue R (A.); **Benzo Fast Blue R** (By.):

$$N_2\left<\begin{array}{l}C_{10}H_6\cdot N_2\cdot C_{10}H_4(SO_3H)_2\cdot OH\\ C_{14}H_{12}\cdot N_2\cdot C_{10}H_4(SO_3H)_2\cdot OH\end{array}\right.$$

Tolidine is tetrazotised and combined with 1 mol of *a*-naphthylamine, the product diazotised and combined with 2 mols. of *a*-naphthol-3 : 8-disulphonic acid (*ε*-acid). The blue aqueous solution is precipitated with acids or alkalis. The solution in sulphuric acid is blue, giving a blue precipitate on dilution.

Literature.—E. P. 6932 of 1890; D. R. P. 60921; F. P. 205615.

Benzo Black Blue R (By.):

$$N_2\left<\begin{array}{l}C_{10}H_6\cdot N_2\cdot C_{10}H_5(SO_3H)\cdot OH\\ C_{14}H_{12}\cdot N_2\cdot C_{10}H_5(SO_3H)\cdot OH\end{array}\right.$$

Tolidine is tetrazotised and combined with 1 mol. of *a*-naphthylamine and the intermediate product diazotised and combined with 2 mols. of *a*-naphthol-4-sulphonic acid. Bluish-violet aqueous solution gives a violet precipitate with hydrochloric acid. Solution in sulphuric acid is blue, giving a bluish-violet precipitate on dilution.

Literature.—E. P. 16484 of 1887; F. P. 187365; A. P. 440639.

Benzo Indigo Blue (By.):

$$N_2\left<\begin{array}{l}C_{10}H_6\cdot N_2\cdot C_{10}H_4(SO_3H)(OH)_2\\ C_{14}H_{12}\cdot N_2\cdot C_{10}H_4(SO_3H)(OH)_2\end{array}\right.$$

The same intermediate tetrazo-compound as above is combined with 2 mols. of 1 : 8-dihydroxynaphthalene-4-sulphonic acid (S-acid). The violet aqueous solution gives a bluish-violet precipitate with hydrochloric acid, and becomes reddish-violet with sodium hydroxide. Solution in sulphuric acid is greenish-blue, giving a violet-blue precipitate on dilution.

Literature.—E. P. 13665 of 1889; D. R. P. 57912; F. P. 200520; A. P. 501118.

Congo Fast Blue B (A.); **Benzo Fast Blue B** (By.):

$$N_2\left<\begin{array}{l}C_{10}H_6\cdot N_2\cdot C_{10}H_4(SO_3H)_2\cdot OH\\ C_{14}H_{12}O_2\cdot N_2\cdot C_{10}H_4(SO_3H)_2\cdot OH\end{array}\right.$$

Dianisidine is tetrazotised and combined with 1 mol. of *a*-naphthylamine and the intermediate product diazotised and combined with 2 mols. of *a*-naphthol-3 : 8-disulphonic acid (*ε*-acid). Blue aqueous solution gives a blue precipitate with acids or alkalis. Solution in sulphuric acid is cornflower blue, giving a blue precipitate on dilution.

Literature.—E. P. 6932 of 1890; D. R. P. 57444; F. P. 205615.

Columbia Black FB and **FF extra** (A.); **Azidine Black FF** (C. J.); **Titan Blacks** (H.);

Dianol Black FB. FF (Lev.); **Panama Black R, F** (Sch.); **Patent Dianil Black FF extra** (M.):

$$N_2 \Big\langle \begin{array}{l} C_6H_4{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}NH_2 \\ C_{10}H_4(SO_3H)(OH){\cdot}N_2{\cdot}C_6H_3(NH_2)_2 \end{array}$$

p-Aminoacetanilide is diazotised and combined with 7-amino-α-naphthol-3-sulphonic acid (γ-acid), the product saponified with sodium hydroxide, the resulting diamino-compound tetrazotised and combined first with 1 mol. of α-naphthylamine-6- (or 7)-sulphonic acid (Cleve's acids) and then with 1 mol. of *m*-phenylenediamine. The aqueous solution is violet-black, and is precipitated by acids or alkalis. Solution in sulphuric acid is blue, giving a precipitate on dilution.

Literature.—E. P. 12804 of 1900; D. R. P. 131986, 131987; F. P. 302499; A. P. 679221.

Direct Black BMP (P.) has the same or a very similar constitution, and dyestuffs belonging to the same class are **Carbon Blacks** (various marks) (K.), and **Naphthamine Direct Blacks FF, B, FG** and **CS** (K.). They are of the type described in D. R. P. 126671, viz. *p*-nitroaniline-*o*-sulphonic acid is diazotised and combined with Cleve's acids, the product reduced, tetrazotised and combined with 2 mols. of a meta-diamine.

Titan Black J (H.):

$$N_2 \Big\langle \begin{array}{l} C_6H_4{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}NH_2 \\ C_{10}H_4(SO_3H)(OH){\cdot}N_2{\cdot}C_6H_3(NH_2)_2 \end{array}$$

p-Aminoacetanilide is diazotised and combined with 6-amino-α-naphthol-3-sulphonic acid (J-acid), the product saponified, tetrazotised, and combined with 1 mol. each of α-naphthylamine-6-(or 7)-sulphonic acid (Cleve's acids) and *m*-phenylenediamine.

Oxydiamine Black N (C.):

$$N_2 \Big\langle \begin{array}{l} C_6H_4{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)(OH){\cdot}NH_2 \\ C_{10}H_4(SO_3H)(OH){\cdot}N_2{\cdot}C_6H_3(NH_2)_2 \end{array}$$

Prepared like Columbia black FB, except that 7-amino-α-naphthol-3-sulphonic acid (γ-acid) is used instead of Cleve's acid. Blue-black aqueous solution gives a black-violet precipitate with hydrochloric acid, and a red-violet one with sodium hydroxide. Solution in sulphuric acid is greenish-blue, giving a violet-black precipitate on dilution.

Literature.—A. P. 526763.

Isodiphenyl Black R (G.):

$$N_2 \Big\langle \begin{array}{l} C_6H_4{\cdot}N_2{\cdot}C_6H_3(OH)_2 \\ C_{10}H_4(SO_3H)(OH){\cdot}N_2{\cdot}C_6H_3(NH_2)_2 \end{array}$$

Prepared as Columbia black FB, except that resorcinol is used instead of Cleve's acid. Violet-black aqueous solution gives a black precipitate with acids or alkalis. Solution in sulphuric acid is blackish-blue, giving a black precipitate on dilution.

Literature.—E. P. 20278 of 1897; F. P. 270151; A. P. 615497.

Direct Black V (K. S.); **Diazo Direct Black** (Wiescher & Co.):

$$N_2 \Big\langle \begin{array}{l} C_{10}H_3(SO_3H)_2(OH){\cdot}N_2{\cdot}C_{10}H_6{\cdot}NH_2 \\ C_{12}H_8{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)(OH){\cdot}NH_2 \end{array}$$

7-Amino-α-naphthol-3 : 6-disulphonic acid (2 R-acid) is diazotised and combined with 1 mol. of α-naphthylamine in acid solution. The mono-azo-dyestuff is then dissolved by adding sodium hydroxide and tetrazotised benzidine added, the combination being effected in presence of sodium carbonate. To this intermediate product is then added 1 mol. of 7-amino-α-naphthol-3-sulphonic acid (γ-acid). Violet-black aqueous solution gives a blue-black precipitate with hydrochloric acid, and becomes reddish-violet with sodium hydroxide. Solution in sulphuric acid is blue, giving a blue-black precipitate on dilution.

Literature.—E. P. 15294 of 1896; D. R. P. 109161; F. P. 256950; A. P. 601033.

Direct Indone Blue R (K. S.):

$$N_2 \Big\langle \begin{array}{l} C_{10}H_3(SO_3H)_2(OH){\cdot}N_2{\cdot}C_{10}H_6{\cdot}NH_2 \\ C_{12}H_8{\cdot}N_2{\cdot}C_{10}H_3(SO_3H)_2(OH){\cdot}NH_2 \end{array}$$

Prepared as the preceding, except that 8-amino-α-naphthol-3 : 6-disulphonic acid (H-acid) is used as the end-component. Blue-black aqueous solution gives a dark-blue precipitate with hydrochloric acid, and becomes violet with sodium hydroxide. Solution in sulphuric acid is blue, giving a dark-blue precipitate on dilution.

References as above.

Diamine Bronze G (C.):

$$N_2 \Big\langle \begin{array}{l} C_{10}H_3(SO_3H)_2(OH){\cdot}N_2{\cdot}C_6H_3(NH_2)_2 \\ C_{12}H_8{\cdot}N_2{\cdot}C_6H_3(CO_2H){\cdot}OH \end{array}$$

The dyestuff from tetrazotised benzidine and 1 mol. each of salicylic acid and 8-amino-α-naphthol-3 : 6-disulphonic acid (H-acid) is diazotised and combined with 1 mol. of *m*-phenylenediamine. The chocolate-brown aqueous solution gives a purple-brown precipitate with hydrochloric acid, and becomes yellower with sodium hydroxide. Solution in sulphuric acid is bluish-violet, giving a black precipitate on dilution.

Literature.—E. P. 6972 of 1891; D. R. P. 75762; F. P. 201770.

Trisulphone Browns B, G and **GG** (K. S.). These are constituted similarly to the preceding, except that 7-amino-α-naphthol-3 : 6-disulphonic acid (2 R-acid) is employed instead of H-acid. The diamines used are benzidine (for **B**), tolidine (for **G**), and dianisidine (for **GG**). Each brand gives a brown solution in water, which yields a blackish-brown precipitate with hydrochloric acid, and becomes red with sodium hydroxide. The solution in sulphuric acid is bluish-violet, giving a dark-brown precipitate on dilution.

Literature.—E. P. 5746 of 1898; D. R. P. 114638; F. P. 275733; A. P. 608024.

Chlorazol Deep Brown B (H.):

$$N_2 \Big\langle \begin{array}{l} C_{10}H_3(SO_3H)_2(OH){\cdot}N_2{\cdot}C_7H_5(NH_2)_2 \\ C_{12}H_8{\cdot}N_2{\cdot}C_6H_3(CO_2H){\cdot}OH \end{array}$$

Benzidine is tetrazotised and combined with 1 mol. each of salicylic acid and 7-amino-α-naphthol-3 : 6-disulphonic acid (2 R-acid), the product being diazotised and combined with *m*-tolylenediamine.

Columbia Black R (A.):

$$N_2 \Big\langle \begin{array}{l} C_{10}H_3(SO_3H)_2(OH){\cdot}N_2{\cdot}C_7H_5(NH_2)_2 \\ C_{14}H_{12}{\cdot}N_2{\cdot}C_7H_5(NH_2)_2 \end{array}$$

Tolidine is tetrazotised and combined with 1 mol. each of 7-amino-α-naphthol-3 : 6-disulphonic acid (2 R-acid and *m*-tolylenediamine, and the product is diazotised and combined with *m*-tolylenediamine. Brown-black aqueous solution gives a black precipitate with hydrochloric acid, and becomes brown with sodium hydroxide. Solution in sulphuric acid is pure blue, giving a violet-black precipitate on dilution.

Literature.—E. P. 14895 of 1893; D. R. P. 102815; F. P. 231976.

Columbia Black B (A.); **Titan Black M** (H.); **Direct Blue Black B, 2 B** (By.). Prepared as the preceding, except that dianisidine is used instead of benzidine. The violet-black aqueous solution gives a dark flocculent precipitate with hydrochloric acid, and becomes reddish-violet with sodium hydroxide. Solution in sulphuric acid is blue-black, giving a violet-black precipitate on dilution.

Literature.—E. P. 14895 of 1893; D. R. P. 111744; F. P. 231976.

Columbia Blacks 2 BX and **2 BW** (A.) belong to the same class.

Benzo Black Blue G (By.):

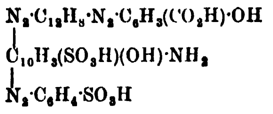
$$N_2\begin{cases} C_{10}H_6{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}OH \\ C_{12}H_6(SO_3H)_2{\cdot}N_2{\cdot}C_{10}H_5(SO_3H){\cdot}OH \end{cases}$$

Benzidinedisulphonic acid is tetrazotised and combined with 1 mol. of *a*-naphthylamine, the product diazotised and combined with 2 mols. of *a*-naphthol-4-sulphonic acid. The blue-black aqueous solution gives a black-blue precipitate with hydrochloric acid, and becomes blue with sodium hydroxide. The solution in sulphuric acid is blackish-green, giving a blackish-blue precipitate on dilution.

Literature.—E. P. 16484 of 1887; D. R. P. 44779; Ber. 1889, 22, 3463.

Benzo Black Blue 5 G (By.). As the preceding, except that 1 : 8-dihydroxynaphthalene-4-sulphonic acid is used instead of *a*-naphthol-4-sulphonic acid. The blackish-blue aqueous solution gives a dark greenish-blue precipitate with hydrochloric acid. The solution in sulphuric acid is black-green, giving a dark greenish-blue precipitate on dilution.

Columbia Green (A.); **Direct Green CO** (L.):

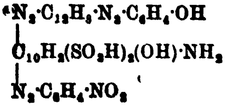


$$\begin{array}{l} N_2{\cdot}C_{12}H_8{\cdot}N_2{\cdot}C_6H_3(CO_2H){\cdot}OH \\ | \\ C_{10}H_3(SO_3H)(OH){\cdot}NH_2 \\ | \\ N_2{\cdot}C_6H_4{\cdot}SO_3H \end{array}$$

Benzidine is tetrazotised and combined with 1 mol. of salicylic acid, and the intermediate product is combined in alkaline solution with the product of the action of diazotised sulphanilic acid on 8-amino-*a*-naphthol-5-sulphonic acid (S-acid) in acid solution. The green aqueous solution gives a green precipitate with hydrochloric acid, and becomes greenish-black with sodium hydroxide. The solution in sulphuric acid is blue-violet, giving a green precipitate on dilution. When diazotised aniline is used instead of diazotised sulphanilic acid in the above, **Columbia Black Green D** (A.) is produced.

Literature.—D. R. P. appl. A. 3574.

Diamine Green B (C.); **Dianol Green B** (Lev.); **Renol Green B** (T. M.); **Direct Green BN** (P.); **Azidine Green 2 B** (C. J.); **Dianil Green B** (M.); **Alkali Green** (D.); **Oxamine Green B** (B.):



$$\begin{array}{l} N_2{\cdot}C_{12}H_8{\cdot}N_2{\cdot}C_6H_4{\cdot}OH \\ | \\ C_{10}H_2(SO_3H)_2(OH){\cdot}NH_2 \\ | \\ N_2{\cdot}C_6H_4{\cdot}NO_2 \end{array}$$

Prepared in a similar manner as the preceding. Tetrazotised benzidine is combined with 1 mol. of phenol and the product is combined with the azo-colour from diazotised *p*-nitroaniline and 8-amino-*a*-naphthol-3 : 6-disulphonic acid (H-acid). Dull-green aqueous solution gives a bluish-black precipitate with hydrochloric acid, and becomes yellower with sodium hydroxide. Solution in sulphuric acid is violet, giving a black precipitate on dilution.

Literature.—E. P. 15725 of 1891; D. R. P. 66351; F. P. 201770; A. P. 514599.

Diamine Green G (C.); **Chlorazol Green G** (H.); **Dianol Green G** (Lev.); **Azidine Green 2 G** (C. J.); **Alkali Green D** (D.); **Dianil Green BBN, G** (M.); **Benzoin Dark Green** (B. K.); **Erie Direct Green MT, BT** (Sch.); **Oxamine Green G** (B.). Prepared as the preceding, except that salicylic acid is used instead of phenol.

Reactions and literature as above.

Eboli Green (various marks) (L.). Tetrazotised benzidine combined with 1 mol. of salicylic acid is combined with the product of the action of diazotised sulphanilic acid on 8-amino-*a*-naphthol-4 : 6-disulphonic acid.

Literature.—E. P. 19253 of 1895; D. R. P. appl. F. 8626; A. P. 606439.

Diphenyl Green G (G.). Prepared like diamine green B (above), except that *o*-chloro-*p*-nitroaniline is used instead of *p*-nitroaniline. The reactions are also similar to those given by this colour.

Literature.—A. P. 628233.

Diphenyl Green 3 G (G.). Prepared like diamine green G, *o*-chloro-*p*-nitroaniline being used instead of *p*-nitroaniline. The green aqueous solution gives a green precipitate with hydrochloric acid, and becomes duller with sodium hydroxide. Solution in sulphuric acid is reddish-violet, giving a green precipitate on dilution.

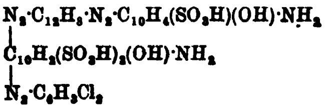
Reference as the preceding.

Chloramine Green B (K. S.). Prepared like diamine green B, 2 : 5-dichloroaniline being used instead of *p*-nitroaniline. The green aqueous solution gives a violet-black precipitate with hydrochloric acid, and becomes black-green with sodium hydroxide. Solution in sulphuric acid is violet, giving a violet-black precipitate on dilution.

Literature.—E. P. 8503 of 1899; D. R. P. 112820; F. P. 287971; A. P. 627679.

Chloramine Black N (K. S.). Tetrazotised benzidine is combined with 1 mol. of *m*-phenylenediamine and the product combined with the azo-colour from diazotised 2 : 5-dichloroaniline and H-acid. The dark bluish-green aqueous solution gives a blue precipitate with hydrochloric acid, and a bluish-green precipitate with sodium hydroxide. Solution in sulphuric acid is blue, giving a blue precipitate on dilution.

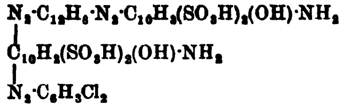
Chloramine Blue HW (K. S.):



$$\begin{array}{l} N_2{\cdot}C_{12}H_8{\cdot}N_2{\cdot}C_{10}H_4(SO_3H)(OH){\cdot}NH_2 \\ | \\ C_{10}H_2(SO_3H)_2(OH){\cdot}NH_2 \\ | \\ N_2{\cdot}C_6H_3Cl_2 \end{array}$$

Tetrazotised benzidine is combined with 1 mol. of *γ*-acid in alkaline solution and then, also in alkaline solution, with the product of the action of diazotised 2 : 5-dichloroaniline on H-acid (1 mol.) in acid solution.

Chloramine Blue 3 G (K. S.):



$$N_2\cdot C_{12}H_8\cdot N_2\cdot C_{10}H_3(SO_3H)_2(OH)\cdot NH_2 \,|\, C_{10}H_2(SO_3H)_2(OH)\cdot NH_2 \,|\, N_2\cdot C_6H_3Cl_2$$

Tetrazotised benzidine is combined with 1 mol. of 8-amino-α-naphthol-3 : 6-disulphonic acid (H-acid) and then with 1 mol. of H-acid to which has been added 1 mol. of diazotised dichloroaniline in acid solution.

References for the last two colours as for chloramine green B.

$$N_2<\begin{matrix}C_{10}H_2(SO_3H)_2(OH)(NH_2)\cdot N_2\cdot C_6H_5\\ C_{12}H_8\cdot N_2\cdot C_6H_3(NH_2)_2\end{matrix}$$

Tetrazotised benzidine is combined with 1 mol· of H-acid in acid solution, after making alkaline 1 mol. of diazotised aniline is added, and then 1 mol. of *m*-phenylenediamine. When *m*-tolylenediamine is used in the last combination the colour is known as **Erie Direct Black RX** (Sch.); **Renol Black R** (T. M.); **Patent Dianil Black EBV** (M.); **Direct Deep Black RW** (By.); **Cotton Black E** (B.). The aqueous solutions of both dyes become violet with hydrochloric acid and blue with sodium hydroxide and the sulphuric acid solutions are violet blue. With phenol as end component **Erie Direct Green ET** (Sch.) is obtained. The green aqueous solution becomes blue with hydrochloric acid and greenish black with sodium hydroxide. The solution in sulphuric acid is bluish-green, becoming blue on dilution.

Literature.—E. P. 12305 of 1902; D. R. P. 153557 and appl. A. 8974; F. P. 321626; A. P. 688478, 717550.

Diamine Black HW (C.); **Ingrain Black G** (H.); **Naphthamine Black H** (K.):

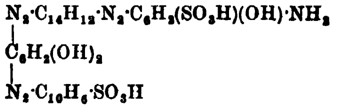
Prepared as the preceding, except that α-naphthylamine-5-sulphonic acid (Laurent's acid) is used instead of sulphanilic acid. Reactions and references as the preceding.

Benzamine Brown 3 GO (D.) is prepared as Congo brown G, except that *m*-phenylenediamine is used instead of resorcinol. The reddish-yellow aqueous solution gives a brown precipitate with hydrochloric acid, and becomes brownish-yellow with sodium hydroxide. Solution in sulphuric acid is brownish-violet, giving a brown precipitate on dilution.

Azo Corinth (O.):



$$N_2\cdot C_{14}H_{12}\cdot N_2\cdot C_6H_2(SO_3H)(OH)\cdot NH_2 \,|\, C_6H_2(OH)_2 \,|\, N_2\cdot C_{10}H_6\cdot SO_3H$$

Tetrazotised tolidine is combined with 1 mol. of 3-aminophenol-6-sulphonic acid (acid III.) and 1 mol. of resorcinol, and the colouring matter so obtained is treated with 1 mol. of diazotised naphthionic acid. Reddish-brown aqueous solution gives a reddish-brown precipitate with hydrochloric acid, and is turned bluish-red with sodium hydroxide. Solution in sulphuric acid is bluish-violet, giving a reddish-brown precipitate on dilution.

Literature.—E. P. 13402 of 1893; D. R. P. 71182; A. P. 516381.

V. TETRAKISAZO- COLOURING MATTERS.

These contain four azo-groups.

Benzo Brown G (By.) (Marden, Orth and Hastings Corporation):

$$C_6H_4<\begin{matrix}N_2\cdot C_6H_2(NH_2)_2\cdot N_2\cdot C_6H_4\cdot SO_3H\\ N_2\cdot C_6H_2(NH_2)_2\cdot N_2\cdot C_6H_4\cdot SO_3H\end{matrix}$$

Prepared by the action of diazotised sulphanilic acid (2 mols.) on Bismarck brown (1 mol

Reddish-brown aqueous solution gives a brown precipitate with acids and alkalis. Solution in sulphuric acid is violet-brown, giving a brown precipitate on dilution.

Literature.—E. P. 16493 of 1887; D. R. P. 46804; A. P. 384315.

Benzo Brown B (By.):

$$\mathrm{C_6H_4}\left<\begin{array}{l}\mathrm{N_2\cdot C_6H_2(NH_2)_2\cdot N_2\cdot C_{10}H_6\cdot SO_3H}\\ \mathrm{N_2\cdot C_6H_2(NH_2)_2\cdot N_2\cdot C_{10}H_6\,SO_3H}\end{array}\right.$$

Prepared as the preceding, except that naphthionic acid is used instead of sulphanilic acid.

Reactions and references as above.

Direct Brown J (I.). Prepared as benzo brown G, except that aminobenzoic acid is used instead of sulphanilic acid. The yellowish brown aqueous solution gives a dark brown precipitate with hydrochloric acid. Solution in sulphuric acid is brown, giving a brown precipitate on dilution.

Literature.—D. R. P. 76127; F. P. 219925; A. P. 491422.

Toluylene Brown R (O.); **Azidine Brown T 2 R** (C. J.); **Direct Brown R** (Sch.):

$$\mathrm{HSO_3\cdot C_7H_5}\left<\begin{array}{l}\mathrm{N_2\cdot C_6H_2(NH_2)_2\cdot N_2\cdot C_{10}H_6\cdot SO_3H}\\ \mathrm{N_2\cdot C_6H_2(NH_2)_2\cdot N_2\cdot C_{10}H_6\cdot SO_3H}\end{array}\right.$$

Prepared by treating the colour from tetrazotised 2 : 6-tolylenediamine-4-sulphonic acid and 2 mols. of *m*-phenylenediamine with 2 mols. of diazotised naphthionic acid. Brown aqueous solution gives a brown precipitate with hydrochloric acid. Solution in sulphuric acid is dull reddish-violet.

Literature.—E. P. 11000 of 1889; D. R. P. 58657; F. P. 199658; A. P. 465116.

Hessian Brown BBN (L.):

$$\mathrm{C_{12}H_8}\left<\begin{array}{l}\mathrm{N_2\cdot C_6H_2(OH)_2\cdot N_2\cdot C_6H_4\cdot SO_3H}\\ \mathrm{N_2\cdot C_6H_2(OH)_2\cdot N_2\cdot C_6H_4\cdot SO_3H}\end{array}\right.$$

Prepared by the action of tetrazotised benzidine on 2 mols. of the monoazo-dyestuff from diazotised sulphanilic acid and resorcinol. Aqueous solution is brown, giving a brown precipitate with hydrochloric acid, and becoming red with sodium hydroxide. Solution in sulphuric acid is violet-black, giving a brown precipitate on dilution.

Dianil Black PR (M.):

$$\mathrm{HSO_3\cdot C_{12}H_7}\left<\begin{array}{l}\mathrm{C_{10}H_4(SO_3H)(OH)\cdot N_2\cdot C_6H_3(NH_2)_2}\\ \mathrm{C_{10}H_4(SO_3H)(OH)\cdot N_2\cdot C_6H_3(NH_2)_2}\end{array}\right.$$

Benzidinesulphonic acid is tetrazotised and combined with 2 mols. of 7-amino-α-naphthol-3-sulphonic acid (γ-acid) in alkaline solution, and the product is tetrazotised and combined with 2 mols. of *m*-phenylenediamine. Black aqueous solution is precipitated with hydrochloric acid or sodium hydroxide. Solution in sulphuric acid is dark-blue, giving a black precipitate on dilution.

Literature.—E. P. 13743 of 1896; F. P. 257245; A. P. 578530.

Anthracene Acid Brown B (C.):

$$\left.\begin{array}{l}\mathrm{NO_2\cdot C_6H_2(CO_2H)(OH)\cdot N_2\cdot C_{10}H_6\cdot N_2}\\ \mathrm{NO_2\cdot C_6H_2(CO_2H)(OH)\cdot N_2\,C_{10}H_6\cdot N_2}\end{array}\right>\mathrm{C_6H_2(NH_2)_2}$$

Nitroaminosalicyclic acid is diazotised and combined with α-naphthylamine. Two mols. of this are diazotised and combined with 1 mol. of *m*-phenylenediamine. Brown aqueous solution gives a violet precipitate with hydrochloric acid. Solution in sulphuric acid is greyish-violet, giving a brown-violet precipitate on dilution.

Literature.—E. P. 2446 of 1896; D. R. P. 92655; F. P. 253834.

AZOFLAVIN *v.* Azo- colouring matters.

AZOGEN RED *v.* Azo- colouring matters.

AZOGRENADINES *v.* Azo- colouring matters.

AZOIMIDE (*Hydrazoic acid*) N_3H was first isolated in 1890 by Curtius (Ber. 1890, 23, 3023), although in the form of its phenyl derivative (diazobenzeneimide) $C_6H_5N_3$ it was known in 1866, having been then prepared by P. Griess (Annalen, 1866, 137, 65, 77).

Curtius obtained azoimide by the action of sodium nitrite and acetic acid on benzoyl hydrazine, the nitroso- derivative first formed passing into benzoyl azoimide by loss of water

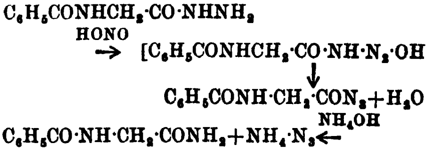
$$\mathrm{C_6H_5CO\cdot NH\cdot NH_2+HONO=}$$
$$\mathrm{H_2O+C_6H_5CO\cdot N(NO)\cdot NH_2\rightarrow H_2O+C_6H_5CON_3}$$

The benzoyl azide so obtained was dissolved in an equal weight of absolute alcohol and digested on the water-bath with 1 mol. proportion of sodium, also dissolved in absolute alcohol, when sodium azide was formed, and this was precipitated from the solution by the addition of ether:

$$\mathrm{C_6H_5CON_3+2NaOH}$$
$$\mathrm{=H_2O+C_6H_5COONa+NaN_3}$$

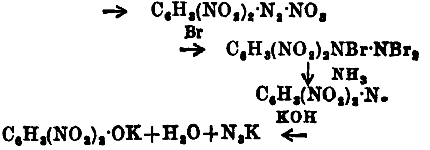
The following methods have also been employed for the preparation of azoimide and its salts.

1. Hippuryl hydrazine by the action of nitrous acid is converted into hippurazide, from which by the action of ammonia, ammonium azide is produced (Curtius, Ber. 1891, 24, 3341):



$$\begin{array}{l}\mathrm{C_6H_5CONHCH_2\cdot CO\cdot NHNH_2}\\ \qquad\xrightarrow{\mathrm{HONO}}\ \mathrm{[C_6H_5CONHCH_2\cdot CO\cdot NH\cdot N_2\cdot OH}\\ \qquad\qquad\qquad\qquad\qquad\downarrow\\ \qquad\qquad\qquad\mathrm{C_6H_5CONH\cdot CH_2\cdot CON_3+H_2O}\\ \mathrm{C_6H_5CO\cdot NH\cdot CH_2\cdot CONH_2+NH_4\cdot N_3}\xleftarrow{\mathrm{NH_4OH}}\end{array}$$

2. *o.p*-Diazobenzeneimide (prepared from *o.p*-Dinitro-aniline), on treatment with alcoholic potash, yields potassium azide (Nölting and Grandmougin, Ber. 1892, 25, 3328):



$$\begin{array}{l}o.p.\ \mathrm{C_6H_3(NO_2)_2\cdot NH_2\cdot HNO_3}\\ \qquad\xrightarrow{\mathrm{HONO}}\ \mathrm{C_6H_3(NO_2)_2\cdot N_2\cdot NO_3}\\ \qquad\qquad\qquad\xrightarrow{\mathrm{Br}}\ \mathrm{C_6H_3(NO_2)_2NBr\cdot NBr_2}\\ \qquad\qquad\qquad\qquad\qquad\downarrow\mathrm{NH_3}\\ \qquad\qquad\qquad\qquad\mathrm{C_6H_3(NO_2)_2\cdot N.}\\ \mathrm{C_6H_3(NO_2)_2\cdot OK+H_2O+N_3K}\ \xleftarrow{\mathrm{KOH}}\end{array}$$

3. The decomposition of diazotised amidoguanidine nitrate by caustic alkalis (Thiele. Annalen, 1892, 270, 1):

$$\begin{array}{l}\mathrm{HN:C(NH_2)\cdot NH\cdot NH_2\cdot HNO_3}\\ \qquad\qquad\xrightarrow{\mathrm{HONO}}\ \mathrm{HN:C(NH_2)\cdot NH\cdot N_2\cdot NO_3}\\ \qquad\qquad\rightarrow\quad\mathrm{CN\cdot NH_2+HNO_3+N_3H}\end{array}$$

4. The action of nitrous oxide on sodamide (W. Wislicenus, Ber. 1892, 25, 2084):

$$NaNH_2+N_2O=NaN_3+N_2O$$

5. The action of an aqueous solution of hydrazine on a benzene solution of nitrogen chloride (Tanatar, Ber. 1899, 32, 1399):

$$N_2H_4+NCl_3=N_3H+3HCl$$

6. The oxidation of a mixture of hydrazine sulphate and hydroxylamine hydrochloride by chromic acid mixture (Brown, Ber. 1905, 38, 1825).

7. The decomposition of hydrazine sulphate by potassium nitrite (Dennstedt, Chem. Zeit. 1897, 21, 876):

$$N_2H_4+HONO \rightarrow [NH_2{\cdot}N_2{\cdot}OH] \rightarrow H_2O+N_3H$$

8. The decomposition of hydrazine sulphate by a saturated aqueous solution of silver nitrite, crystalline silver azide being precipitated (Angeli, Ber. 1893, 26, 885, Ref.).

9. In nearly quantitative yield, the sodium salt may be prepared by mixing hydrazine hydrate with sodium methoxide, and adding an ether solution of ethyl nitrite to the mixture. If the free acid be required it is sufficient to shake hydrazine sulphate for several hours with sodium hydroxide solution and ethyl nitrite, about 80–84 p.c. of the hydrazine compound undergoing decomposition (Thiele, Ber. 1908, 41, 2681).

The free acid may be obtained by distilling the salts with dilute sulphuric acid. In the anhydrous condition it is a colourless mobile liquid of very unpleasant odour. It boils at 37° C., and is readily soluble in water. Azoimide is a most dangerous substance to handle on account of the fact that it decomposes with explosive violence on agitation. It somewhat resembles the halogen acids in that it forms difficultly soluble lead, silver and mercurous salts. It is very poisonous, its vapour attacks the mucous membrane rapidly, whilst the aqueous solution of the acid attacks the skin. The metallic salts of the acid all crystallise in the anhydrous state, and when heated, decompose, generally with explosive violence, leaving a residue of the pure metal.

Azoimide is a 'weak' acid, comparable in strength with acetic acid (West, Trans. 1900, 77, 705). The heat of formation of the acid has been measured by Berthelot and Matignon (Compt. rend., 1891, 113, 672), with the following result:

$$3N+H+aq=N_3Haq-61{,}600 \text{ cal.}$$

A 7 p.c. solution of the acid dissolves magnesium and zinc, with evolution of hydrogen. From solutions of ferric, aluminium, chromic and thallium salts the corresponding hydroxides are quantitatively precipitated on boiling with azoimide. On reduction with sodium amalgam, or by zinc and acid, azoimide is converted into ammonia and hydrazine; if, however, sodium sulphide or ferrous hydroxide be used as reducing agents, little hydrazine is formed.

The reaction $N_3H+HNO_2=N_2+N_2O+H_2O$ is quantitative, and can be used for the estimation of simple nitrites. In this method a known excess of sodium azide is added to the acid solution of the nitrite, and the mixture well shaken. The solution is made just alkaline by baryta water, boiled to expel nitrous oxide, acidified by acetic acid and the excess azoimide estimated by titration with iodine and sodium thiosulphate.

Hydrazine azide N_5H_5; is obtained by the action of lead azide on hydrazine sulphate. It crystallises in prisms and is very volatile. When rapidly heated it explodes with great violence.

Iodine azide N_3I is obtained as an unstable nearly colourless solid when silver azide is suspended in water and shaken with a solution of iodine in ether at 0° C. (Hantzsch, Ber. 1900, 33, 522). It decomposes readily, alkaline hydroxides converting it into the corresponding alkali azide $N_3I+2KHO=N_3K+H_2O+KIO$. The aqueous solution of the azide gradually decomposes on keeping $N_3I+H_2O=N_3H+HIO$.

Chlorine azide N_3Cl was prepared in 1908 by Raschig (Ber. 1908, 41, 4194), on adding sodium hypochlorite to sodium azide and acidifying the mixture. It is a colourless gas.

Phenyl azide (Diazobenzene imide) $C_6H_5N_3$ was first prepared by Griess (Annalen, 1866, 137, 65, 77) by decomposing diazobenzene perbromide with ammonia. It is a pale yellow oil boiling at 65·5°–66·5° C., and is volatile in steam. On heating with hydrochloric acid it yields *o*- and *p*-chloroaniline and nitrogen. Reduction in acid solution converts it into aniline and ammonia.

Benzyl azide $C_7H_7N_3$ is obtained as an aromatic smelling oil, by the action of warm acid on nitrosobenzylhydrazine, or by decomposing silver azide with benzyl iodide. It boils at 74° C. (11 mm.).

Azides of the above type may be obtained generally by the following methods:—

1. The decomposition of diazobenzene perbromides with aqueous ammonia:

$$C_6H_5NBr{\cdot}NBr_2+4NH_3=C_6H_5N_3+3NH_4Br$$

2. The decomposition of diazonium sulphates with hydroxylamine:

$$C_6H_5N_2\,HSO_4+NH_2OH=H_2SO_4+H_2O+C_6H_5N_3$$

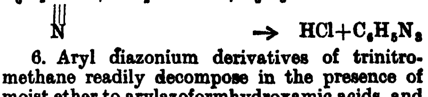
3. The action of nitrous acid on phenyl hydrazine hydrochloride:

$$C_6H_5NH{\cdot}NH_2 \rightarrow C_6H_5N(NO){\cdot}NH_2 \rightarrow H_2O+C_6H_5N_3$$

4. The decomposition of β-phenylsemicarbazides with sodium hypochlorite:

$$C_6H_5NH{\cdot}NH{\cdot}CONH_2 \rightarrow C_6H_5N:N{\cdot}CONH_2 \rightarrow C_6H_5N:N{\cdot}NH_2 \rightarrow C_6H_5N_3$$

5. The action of chloroamine on diazonium salts (M. O. Forster):

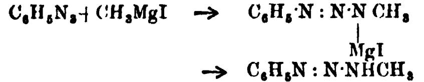


$$\begin{array}{l}C_6H_2{\cdot}\underset{\overset{|||}{N}}{N}{\cdot}Cl+NH_2Cl=HCl+C_6H_5N:N{\cdot}NHCl \\ \qquad\qquad\qquad\qquad \rightarrow HCl+C_6H_5N_3\end{array}$$

6. Aryl diazonium derivatives of trinitromethane readily decompose in the presence of moist ether to arylazoformhydroxamic acids, and the latter on heating with aqueous alkali hydroxides are converted into the corresponding azide (Ponzio, Gazz. 1915, 45, ii. 12; 1916, 46, ii. 56):

$$\begin{array}{lcl}ArN_2O{\cdot}ON:C(NO_2)_2 & \rightarrow & ArN:N{\cdot}CO{\cdot}NHOH \\ & & \quad\downarrow \\ & & ArN_3+CO_2+H_2\end{array}$$

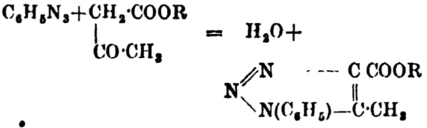
The aryl azides are decomposed on heating with hydrochloric acid, nitrogen being evolved and the corresponding chloro-anilines formed Similarly with sulphuric acid they yield aminophenols. Hot alcoholic potash converts the *o*- and *p*-nitro derivatives into azoimide and the nitrophenols. On condensation with the Grignard reagent and subsequent decomposition diazoamines (triazens) are formed (Dimroth):



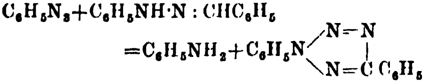
$$C_6H_5N_3+CH_3MgI \rightarrow C_6H_5\cdot N:N\cdot \underset{\textstyle MgI}{\underset{|}{N}}CH_3 \rightarrow C_6H_5N:N\cdot NHCH_3$$

Phenyl methyl triazen

Condensation with β-ketonic esters converts them into triazoles (Ber. 1902, 35, 4041):



whilst with benzaldehyde arylhydrazones they similarly yield tetrazoles (Ber. 1907, 40, 2402):



Methyl azide $CH_3\cdot N_3$ is prepared by the action of dimethyl sulphate on sodium azide (Dimroth and W. Wislicenus, Ber. 1905, 38, 1573). Magnesium methyl iodide converts it into dimethyltriazen $CH_3N:N\cdot NHCH_3$ (Dimroth, Ber. 1906, 39, 3905).

The acyl derivatives of azoimide may be prepared by the decomposition of acyl hydrazines with nitrous acid (sodium nitrite and acetic acid):

$$C_6H_5CO\cdot NH\cdot NH_2+HONO=C_6H_5CO\cdot N_3+2H_2O$$

Tetramethylammonium azide NMe_4N_3 is prepared by the gradual addition of a solution of tetramethylammonium iodide to an aqueous suspension of a slight excess of silver azide. Tetragonal crystals ($a:c=1:0\cdot7245$). Fairly stable substance; does not explode when struck with a hammer, or ground in a mortar, or when dropped on a hot plate. Dry salt begins to decompose at about 125° (Friedlander, J. Amer. Chem. Soc. 1918, 40, 1945).

Benzoyl azoimide $C_6H_5CON_3$ (Curtius, Ber. 1890, 23, 3024 *et seq.*) crystallises in colourless tables and melts at 32° C. It explodes on heating.

This type of azide shows characteristic decompositions, two-thirds of the nitrogen being eliminated, and the residual nitrogen linking up the aromatic nucleus with a carbonyl group. Thus when gently warmed in alcoholic solution a urethane is produced, on boiling with water a di-substituted urea is obtained, and on heating the solution of the azide in benzene it is transformed into an isocyanate:

$$C_6H_5CON_3+C_2H_5OH=N_2+C_6H_5NH\cdot COOC_2H_5$$
$$2C_6H_5CON_3+2H_2O=2N_2+2C_6H_5NH\cdot COOH$$
$$=2N_2+H_2O+CO_2+CO(NHC_6H_5)_2$$
$$C_6H_5CON_3=N_2+C_6H_5NCO$$

On the decomposition of the azides of the mono and dialkyl malonic acids, and of the α-hydroxy acids, *see* Festschrift Th. Curtius, 1907, p. lxxxii.

Some controversy has arisen over the structure of azoimide, the earlier given cyclic structure having been objected to by Thiele (Ber. 1911, 44, 2522) who considers that a straight chain formation best represents the reactions of the acid:

or HN : N : N

AZOIMIDES, AROMATIC *v.* Diazo compounds.

AZOLITMIN. A substance assumed by Kane to exist in litmus (Annalen, 39, 25).

AZOMETHANE *v.* Diazo compounds.

AZOORSEILLIN *v.* Azo- colouring matters.

AZOPHENYLENE *v.* Azines.

AZOPHOR -BLACK, -BLUE, -RED, -ROSE *v.* Azo- colouring matters.

AZOPHOSPHINES *v.* Azo- colouring matters.

AZO-REDS, AZORUBINES *v.* Azo- colouring matters.

AZOTE. A name given to nitrogen by Lavoisier, and hence commonly used in French literature to designate that element.

AZOTINE. An explosive made in Austria-Hungary (J Soc. Chem. Ind. 4, 360).

AZOTOL *v.* Azo- colouring matters.

AZOTOMETER. A term applied by W. Knop to an apparatus designed to measure the nitrogen evolved by the action of sodium hypochlorite or hypobromite on ammonium salts and certain organic substances.

AZO- TURKEY RED *v.* Azo- colouring matters.

AZOVERMIN. Trade name for acetylamino azotoluene.

AZOXINE COLOURING MATTERS *v.* Oxazine colouring matters.

AZOXYBENZENE $C_{12}H_{10}N_2O$. A product of the partial reduction of nitrobenzene with alcoholic potash (Zinin, J. pr. Chem. 36, 93; Schmidt and Schultz, Annalen, 207, 325; Ber. 12, 484); or with sodium amalgam containing 3·8 p.c. of sodium (Alexejeff, J. 1864, 525; Moltschanowsky, Ber. 15, 1575).

Preparation.—Azoxybenzene is best prepared by dissolving 1 part of sodium in 25 parts of methyl alcohol, adding 3 parts of nitrobenzene and heating for 5 or 6 hours on a water-bath in a flask provided with a reversed condenser. The methyl alcohol is then distilled off and the residue treated with water, which dissolves the sodium formate formed in the reaction, and leaves the azoxybenzene as a yellow oil; this soon solidifies, and is obtained pure by one crystallisation from alcohol (Klinger, Ber. 15, 866; Moltschanowsky, *l.c.* and Ber. 16, 81; Klinger, Ber. 16, 941, footnote).

Azoxybenzene is also prepared by the reduction of nitrobenzene with arsenious oxide and caustic soda (Loesner, Eng. Pat. 1555, J. Soc. Chem. Ind. 1895, 31); by the reduction of nitrobenzene with alkali sulphides in alkali hydroxide, the products being mainly azoxybenzene and azobenzene, in proportions varying with the amount of sulphide and the time of reduction (Farb. vorm. Meister, Lucius, and Bruning, D. R. P. 216246, J. Soc. Chem. Ind. 1909, 1310); by boiling nitrobenzene with 60 p.c. aqueous sodium hydroxide and iron pyrites, or other heavy sulphides, 90 p.c. of the product being azoxybenzene (Farbenfab. vorm. Fried. Bayer & Co., D. R. P. 204653, Chem. Soc. Abst. 1909, i. 272); by heating nitrobenzene with charcoal and alkali (Farbenfab. vorm. Fried. Bayer & Co., D. R. P. 210806; Chem. Zentr. 1909, ii. 163); and by the electrolytic reduction of nitrobenzene in the presence of alkali (Farb. vorm. Meister, Lucius, and Bruning, D. R. P. 127727; Chem. Zentr. 1902, i. 446, and Farb. vorm. Weiler-ter-Meer, D. R. P. 138496: Chem. Zentr. 1903, i. 372).

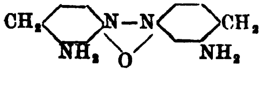
Azoxybenzene or its homologues can be obtained by heating nitrobenzene or the corresponding nitro- compound with an equal weight of zinc-dust and of an aqueous solution of calcium chloride boiling at 130°; aqueous solutions of other salts may be employed, and the reaction ensues at the boiling-point of the aqueous solution (*v.* Dechend, D. R P. 43230).

Properties.—Azoxybenzene crystallises in pale yellow rhombic needles, melts at 36°, and is soluble in alcohol or ether, insoluble in water. When heated with non-volatile substances, such as iron filings, it decomposes into aniline and azobenzene Weak reducing agents, such as sodium amalgam in alcoholic solution, convert it into hydrazobenzene (Alexejeff, J. 1867, 503): but more powerful agents, such as zinc chloride in acid solution, reduce it chiefly to aniline, a small quantity of hydrazobenzene and bases derived from it by molecular changes being also formed (Schmidt and Schultz). Azoxybenzene yields two isomeric nitroazoxybenzenes when heated with concentrated nitric acid (Linm, Annalen, 114, 217), and when heated with concentrated sulphuric acid to a moderate temperature is converted into the isomeric hydroxyazobenzene (Wallach and Kiepenheuer, Ber. 14, 2617).

In addition to azoxybenzene other azoxy-compounds have been prepared by reducing the corresponding nitro- derivatives either with sodium amalgam in methyl alcohol solution or with zinc-dust and soda (*cf.* Limpricht, Ber. 18, 1405; Klinger and Pitschke, Ber. 18, 2553; Janovsky and Reimann, Ber. 22, 41; *v.* Dechend, *l.c.*). The azoxy- compounds derived from metanitraniline, the nitrotoluidines melting at 78° and 107°, and the nitroxylidine melting at 123° yield, when diazotised and combined with phenols, amines or their sulphonic acids, a class of yellow, orange or red azo- dyes, which can be employed for cotton and wool (Poirrier and Rosenstiehl, D. R. P. 44045, 44554).

AZOXY-COLOURING MATTERS. The dyes formerly classified under this heading, of which 'sun yellow' is perhaps the best known, have been shown to be azo- dyes (*q.v.*).

***p*-AZOXY-*o*-TOLUIDINE**



is obtained by the alkaline reduction of *p*-nitro-*o*-toluidine (*q.v.*) by zinc dust or dextrose; m.p. 168°. Used in the manufacture of azo-dyes.

AZO-YELLOWS *v.* AZO-COLOURING MATTERS.

AZULENE $C_{15}H_{18}$, a hydrocarbon, an intensely blue, slightly viscid liquid, D_{25}0·9738, b.p. 295°–300° (185°–195°/25 mm.), found in the oils of cubebs, amyris, guaiacum wood, gurjun and eucalyptus, and to which their blue colour is due. When exposed to light and air is converted into a brown resin. Is soluble in sulphuric acid, giving a fluorescent solution, and forming a sulphonic acid, yielding a crystalline sodium salt, soluble in water, and giving a violet-coloured solution which becomes green when acidified. Is possibly identical with Piesse's Azulin (*q.v.*). It forms a *picrate*, m.p. 120°, lustrous black needles, by which the hydrocarbon may be identified. It appears that azulene is tricyclic and contains an aromatic nucleus, four ethylenic linkings, but no hydroaromatic conjugate double linkings, as it suffers no reduction when treated with sodium in alcohol (Sherndal, J. Amer. Chem. Soc. 1915, 37, 167 and 1537).

AZULIN. Blue colouring matter, contained in certain essential oils; *e.g.* chamomile, millefolium, and wormwood.

AZULIN *v.* TRIPHENYLMETHANE COLOURING MATTERS.

AZURE *v.* PIGMENT.

AZURIN $C_{35}H_{32}N_4O_3$. Obtained by heating salicylic aldehyde with *o*-tolylenediamine. Colourless tables, giving blue fluorescent solutions (Ladenburg, Ber. 11, 590).

AZURITE or Chessylite. Hydrated basic copper carbonate, $2CuCO_3{\cdot}Cu(OH)_2$, forming monoclinic crystals of an azure-blue colour. Finely crystallised specimens have been found in abundance in an old copper mine at Chessy, near Lyon in the south of France, and on this account the mineral is often known as chessylite (Brooke and Miller, 1852); the name azurite (F. S. Beudant, 1824) refers to the characteristic colour. Sp gr. 3·8; hardness 3½–4. It occurs as an alteration product of copper-pyrites and other sulphide ores of copper in the upper oxidised zones of mineral veins; and it is itself often altered to malachite, the green carbonate ($CuCO_3{\cdot}Cu(OH)_2$). Fine crystals are also found at Broken Hill in New South Wales, Tsumeb in South-West Africa, and at Bisbee in Arizona; at the last-named place it occurs, together with malachite, in sufficient abundance to be mined as an ore of copper. It was also formerly mined at Burra-Burra, in South Australia. From Arizona come pretty specimens, with azurite and malachite banded together, which are polished for use in cheap jewellery. Powdered azurite was formerly used as a pigment under the name 'mountain blue,' but this is now replaced by an artificial product. L. J. S.

B

BABBIT'S METAL. An alloy of 25 parts tin, 2 parts antimony, and 0·5 part copper, used as an anti-attrition metal (*v.* ANTIMONY).

BABLAH or **NEB-NEB.** Commercial names for fruits of several species of acacia; used in the East, in combination with alumina and iron mordants, to produce various shades of drab and fawn colour in calico-printing. East Indian bablah is largely obtained from *Acacia arabica* (Willd.) (*A. indica* (Benth.)): Senegal and

Egyptian Bablah largely from *Acacia arabica* (*A. nilotica* (Delil.)). The aqueous extracts contain a red colouring matter together with considerable quantities of gallic and tannic acids.

BABUL BARK. The bark from *Acacia arabica* (Willd.) which occurs in India, Arabia, and tropical Africa: its Indian vernacular name is 'babul.' Used in India as a tanning material.

BABUL GUM. An inferior kind of gum arabic from *Acacia arabica* (Willd.). Known also as 'Bengal gum' or 'Gond babul.'

BACTERIA, CHEMICAL ACTION OF, *v.* FERMENTATION.

BADDELEYITE. Native zirconium oxide, ZrO_2, crystallising in the monoclinic system. A few isolated crystals have been found in the gem-gravels of Ceylon, and a more abundant supply of small crystals was met with at about the same time in the iron mine of Jacupiranga, in São Paulo, Brazil. The latter, at first described under the name brazilite, occur as an accessory constituent of a magnetite-pyroxene rock called jacupirangite, which is associated with the deposits of magnetite. The crystals from Ceylon are black and opaque, with submetallic lustre, but small splinters are transparent and yellowish in colour; sp.gr. 5·72–6·025; ZrO_2 98·9 p.c. The smaller crystals from Brazil range from colourless to brown; sp.gr. 5·5; they contain ZrO_2 96·52 p.c., with small amounts of silica, alumina, ferric oxide, lime, &c. The mineral has also been identified in a rock resembling jacupirangite in the iron mines of the island of Alnö, Sweden. More recently, minute crystals have been detected in a sanidine bomb rich in zircon from Monte Somma, Vesuvius, and in a corundum-syenite from Bozeman, Montana.

A massive form of zirconia occurs much more abundantly in the Serra de Caldas region of Minas Geraes, Brazil, a region characterised by the occurrence of nepheline-syenite rocks. Pebbles of compact material are here found in the diamond washings, and are known to the diamond miners as 'favas' (meaning 'bean;' other 'favas' consist of titanium dioxide). These are pale-brown, slate-grey or blackish in colour, fine-grained, and hard. Sp.gr. 4·6–5·4; they contain ZrO_2 73–93 p.c., the principal impurity being silica, with some iron, alumina, and titanium. In the same region there has also been found, as a crust on weathered augite-syenite, mamillated or reniform masses with a radially-fibrous structure and concentric banding. It contains ZrO_2 97 p.c., and has sp.gr. 5·538. This variety appears to occur in considerable quantity, and in lumps weighing several kilograms. E. Hussak, in 1899, referred the massive form occurring as 'favas' to baddeleyite, but he was inclined in 1903 to regard the fibrous variety as a distinct modification of zirconia. The latter has recently been sold in America under the trade name *zirkite*, and it is stated to consist of a mechanical mixture of baddeleyite, zircon, and a new zirconium silicate. The mineral possesses a high degree of infusibility, high resistance to basic and acid slags, low thermal conductivity, and a very low coefficient of expansion. It is thus eminently suitable as a refractory material for the construction of crucibles, muffles, fire-bricks, and furnace linings. It is also employed as an opacifier and as an abrasive. (W. T. Schaller, Mineral Resources, U.S. Geol. Survey for 1916, 1917, ii. 377; A. Granger, Chem. News, 1919, 118, 115.)

L. J. S.

BADISCHE ACID. 2-naphthylamine-8-sulphonic acid. *V.* NAPHTHALENE.

BAEL FRUIT. The dried half-ripe fruit of *Ægle Marmelos* (Correa), from Malabar and Coromandel; is used in diarrhœa and dysentery, and the fresh pulp is sometimes employed as a laxative.

BAEUMLERITE. A potash-salt mineral found as thin bands in the rock-salt of the Desdemona salt mine in the Leine Valley, Prussia (O. Renner, 1912). It is colourless and transparent, extremely deliquescent, and has the composition $KCl{\cdot}CaCl_2$. F. Zambonini (1912) has suggested that this is identical with the Vesuvian mineral 'chlorocalcite,' first described by A. Scacchi in 1872, and later proved to be cubic and with the composition $KCl{\cdot}CaCl_2$.

L. J. S.

BAGASSE, BEGASS, or MEGASS. Terms applied to the refuse sugar-cane after crushing.

BAKELITE. A condensation product of phenol, cresol or other phenolic bodies, and formaldehyde, paraformaldehyde, hexamethylenetetramine, or other substances with a reactive methylene group, mixed with asbestos or some form of cellulose, and heated so as to convert it into a solid infusible resinoid mass capable of being moulded or worked.

In the actual manufacture of bakelite ordinary commercial carbolic acid, which consists largely of cresols, is employed, in connection with small quantities of various alkaline substances, which appear to act catalytically in promoting the action of the formaldehyde. The first products obtained are semi-solid resin-like bodies which under the influence of heat and pressure become hard, insoluble and infusible, and of a high chemical and mechanical resistance. This initial stage is variously termed 'Bakelite A, Liquid or Solid,' Resinil mass, &c. The final product is known as 'Bakelite C,' 'Resinite,' 'Condensite,' or 'Resite.' It is regarded by Baekeland, with whose name the invention and commercial application of the substance is associated, as a polymerised hydroxybenzylmethyleneglycolanhydride. To form it 'Bakelite A' is heated in a modified form of autoclave to about 170°, under pressure produced by compressed air or an inert gas, such as carbon dioxide. Instead of the autoclave the Bakelite A, after being mixed with the appropriate fibrous material, may be placed in a steel mould, and gradually hardened in a hot press during from 1 to 2 hours, at a temperature between 100° and 200°.

Bakelite C in its purest form is a colourless or light golden-yellow mass of sp.gr. 1·25. It is a bad conductor of heat and electricity, and a first rate insulating material. It resists pressure and shock, but has a comparatively low elasticity. It can be heated to 300° without change. At a higher temperature it chars, but does not inflame. It is non-hygroscopic, and resists the action of concentrated hydrochloric acid, oil of vitriol, nitric acid and bromine. It is less resistant to the action of alkalis. From the ease with which it can be worked it can be used for a great variety of articles, such as switch-boards, telephone receivers, armatures, and commutators for dynamos and motors, phonograph records, mouldings for kodaks, photographic developing trays, &c. Also for the manufacture of billiard-balls, razor handles, umbrella and stick handles, pen and pencil holders, cigar and cigarette holders, pipe mouthpieces, ornaments and beads for jewellery, &c. (Lebach, Jour. Soc. Chem. Ind. 1913, 32, 559).

The conditions of the formation of bakelite have been investigated by Matsumoto (J. Chem. Ind. (Tokyo) 18, No. 207), who found that all stages of the reactions are greatly accelerated by small additions of various substances. The best results, as regards yield and quality of product, were obtained by the use of sodium hydroxide and ammonia as condensing and hardening agent respectively. Sulphuric acid, hydrochloric acid, ammonia, hexamethylenetetramine, aniline, sodium sulphite and sodium carbonate were also satisfactory as condensing agents, but only basic substances, such as alkali hydroxides or ammonia were suitable as hardening agents (Jour. Chem. Soc. Ind. 1915, 34, 1104).

The General Bakelite Co. has a very complete plant at Perth, Amboy, and there are a large number of licensees in the United States; bakelite plants in Germany, France and England, and several factories where bakelite goods, such as buttons, are manufactured under licence.

Bakelite is amber-yellow when freshly made, but gradually acquires a wine-red colour under the action of daylight. If the red colour is not too strong it may be discharged by heating to 100°–150° for several hours. This colour change has proved objectionable when the substance is used for ornamental purposes (imitation amber), and has led to its abandonment in certain trades (Newbery and Lupton, Manchester Memoirs, 62 (1918), 13).

BAKERITE. A hydrated borosilicate of calcium, $8CaO{\cdot}5B_2O_3{\cdot}6SiO_2{\cdot}6H_2O$, containing B_2O_3 27·7 p.c. It is massive and snow-white, sometimes with a greenish tinge, and resembles unglazed procelain or fine-grained marble in appearance. D 2·73–2·93, H 4½. It occurs with howlite as veins and nodules of considerable size in the borate mines in the Mohave Desert, sixteen miles north-east of Daggett, in San Bernardino Co., California (W. B. Giles, Mineralog. Mag. 1903, xiii, 353). L. J. S.

BAKHAR. an artificial ferment prepared from rice, powdered roots and other parts of certain plants, by Indian natives, and used in the production of Hindu rice-beer (pachwai), and of the spirit distilled from it. It contains many varieties of moulds and fungi capable of saccharifying starch, of which the most active is *Aspergillus oryzæ*, and several yeasts capable of producing alcohol (Hutchinson and Ram Ayyar (Jour. Soc. Chem. Ind. 1916, 35, 751).

BAKING POWDERS are any powders used as substitutes for yeast. The bread or cake is rendered spongy by the carbon dioxide generated in the dough; this is effected by the action of an acid, such as tartaric acid, on sodium bicarbonate, and some farinaceous substance is added to act as diluent. To permit the use of discoloured flour, alum was frequently employed, this renders the bread white, but at the same time indigestible. In 1899 such articles as baking powder were included in the Sale of Food and Drugs Acts, and therefore the use of alum or any injurious matter was prohibited. All articles are perfectly dried before mixing, passed through a fine sieve, and kept in air-tight packages in a dry place. To every pound of flour, 1 teaspoonful of baking powder is added for bread, and 2 teaspoonfuls for cakes. General preparations are:

(1) 6 ozs. tartaric acid, 2 ozs. sodium bicarbonate, and 1·5 ozs. of farina.

(2) 16 ozs. sodium bicarbonate, 14 ozs. tartaric acid, and 6 ozs. magnesium carbonate, and 12 ozs. farina (Workshop Receipts, 1909).

(3) 2½ lbs. cream of tartar, 2½ lbs. sodium bicarbonate, 1 lb. acid calcium phosphate, and 4 lbs. cornflour (Pharm. Formulæ, 1908, p. 322).

(4) 3 lbs. acid potassium sulphate, 1 lb. sodium bicarbonate, and 1 lb. of cornflour (Pharm. Formulæ, 1908, p. 322).

(5) 5 ozs. tartaric acid, 15 ozs. cream of tartar, 20 ozs. sodium carbonate, and 40 ozs. rice flour (Workshop Receipts, 1909, p. 90).

(6) 20 parts acid sodium phosphate, 20 parts acid calcium phosphate, 25 parts sodium bicarbonate, and 35 parts starch (Hiscox, 1907, 102).

Crampton's powder: 2 parts cream of tartar, 1 part sodium bicarbonate, and 1 part corn starch.

Rumford's powder: (approx.) 7 ozs. sodium bicarbonate, 14½ ozs. sodium phosphate, and 3½ ozs. starch.

Royal powder: A mixture of cream of tartar, tartaric acid, sodium bicarbonate, and starch.

Goodall's powder is a mixture of 2 parts rice flour with 1 part tartaric acid and 1 part bicarbonate of soda.

Green's powder: 35 lbs. tartaric acid, 56 lbs. of sodium carbonate, and 1 cwt. of potato flour.

Horsford's powder consists of 2 packets: (1) acid calcium and magnesium phosphates, made up with a certain quantity of flour; (2) bicarbonate of soda with a little potassium chloride.

Borwick's powder is an artificial fermentation powder compounded with coarse maize.

Self-raising flour may be prepared by mixing 8 ozs. sodium bicarbonate, and 18 ozs. cream of tartar with 1 cwt. of flour.

Milk in the solid form, concentrated in a vacuum at 50°–60°, was used by Hooker, to replace inert farinaceous matter. It is claimed to have a better nutriment value and increased leavening power: 20 parts tartaric acid, 54 parts milk powder, and 1 part moisture. The soda is added before the milk is completely dry, then the whole dried and ground finely in a mortar (J. Soc. Chem. Ind. 27, 1908). Cream of tartar is soluble in hot water, but only slightly so in cold, whilst tartaric acid dissolves readily. Therefore a powder containing cream of tartar evolves carbon dioxide much more slowly than one compounded with tartaric acid. This is advantageous, as a dough containing it can be kept for some time before baking, also it does not darken the bread; on the other hand, it forms Rochelle salt which has a very slight saline taste. The best powders are made from a mixture of tartaric acid and cream of tartar. Good substitutes for tartaric acid are acid ammonium phosphate, and acid potassium sulphate, acid potassium and calcium phosphates, but they have a tendency to darken the bread. The acid calcium phosphate used in baking and self-raising flours occasionally contains an undue amount of calcium sulphate (J. M. Hamill, Report of the Local Gov. Board, 1911, Food Report, No. 13).

Ammonium carbonate is used in very light pastries, but it requires expert handling, and so is very rarely present in the make-up preparations.

BAKUIN. Russian mineral machine oils; recommended for lubricating heavy machinery on account of their high viscosity and great power of resisting cold (Seifenseid, Zeit. 31, 366; 32, 378; J. Soc. Chem. Ind. 3, 181).

BAKUOL. A name given by Mendeléeff to an illuminating oil, prepared from the crude oils of Baku by mixing ordinary kerosene of sp.gr. 0·82 to 0·83 and flashing point 20° to 30°, with the so-called intermediate oil, which has a sp.gr. of 0·86 to 0·88 at 15°, and is not inflammable at 100°. The mixture has a sp.gr. of 0·84 to 0·86, and flashes at temperatures varying from 50° to 70°. From 100 parts crude naphtha 20 to 30 parts of kerosene and 10 to 20 parts of intermediate oil can be obtained.

The following table gives the sp.gr., flashing-point, and luminiferous value of four bakuols examined by Ilimow:—

Specimen of oil	Sp. gr. at 17·°5	Flashing point at 760 mm.	Candle-power	Consumption per hour in Russian lbs.	
				For the lamp	Per candle power
No.					
1	0·8280	36·0	7·40	0·0588	0·0080
2	0·8310	37·5	10·40	0·0633	0 0060
3	0·8360	39·5	9·84	0·0633	0·0064
4	0·8310	49·5	8·30	0·0675	0·0081

Literature.—Mendeléeff, Zeitschr. Technik, 1886, No. 109; Chem. Zeit. 1883, 231; Ilimow, *ibid.* 10, 1459; J. Soc. Chem. Ind. 2, 238; 5, 661; 6, 135 (*v.* PETROLEUM, RUSSIAN).

BAKURIN. A lubricating oil, prepared by mixing 100 parts of crude Baku oil with 25 parts of castor oil and 60 to 70 parts of sulphuric acid of 66°B. After standing the mixture is stirred two or three times with water, the water run off, and the oil treated with soda or potash (Müller, D. R. P. 35141, Dingl. poly. J. 200, 240).

BALANCE. A generic term, designating a variety of machines for ascertaining the weight of a body in terms of the weight, at the time and place, of a standard *mass* (gram, ounce, pound, &c.), and thus determining its mass. By means of a balance and a set of 'weights,' we ascertain that a body has P times the weight of the unit piece of the set, and conclude that its mass is P times the mass of this piece likewise, whatever the chemical nature of the body may be. In justification of this inference we might refer to Newton's pendulum experiments, or to the often proved chemical axiom that the weight of any body or set of bodies is independent of the state of combination of its elements. But from the standpoint of the chemist it is sufficient to know that, supposing even each element had its own factor for converting 'weight' into mass, it would still follow that the weight of a body, however complex, is equal to the sum of the weights of what in any sense we may call its 'components,' and that the ratio of the weight W_1 of a body of fixed elementary composition to the weight W_2 of another body of even a different fixed composition is as constant, although perhaps not equal to the ratio of the masses $M_1 : M_2$. Of all balances the equal-armed lever balance, often called '*the* balance' *par excellence*, is by far the most important.

The balance exists in a variety of forms, all of which seek to realise the same ideal machine. An absolutely rigid beam, so suspended that whilst it can rotate freely about a certain axis (which goes across it somewhere above its centre of gravity, and of which every point holds a fixed position in reference to the stand) it is not capable of any other motion. From two points, *a* and *b*, which lie in the same plane as the axis of rotation—one near the left, the other near the right end of the beam—the pans are suspended by means of absolutely flexible linear strings. *a* and *b* are equidistant from the axis of rotation. So far all balances are alike. In now passing to the actual instrument, we shall confine ourselves in the main to the class of balances known as precision balances.

Of the difficulties involved in the construction of such balances, that of producing a sufficiently light and yet practically inflexible beam, seems to have rested most heavily on the minds of the earlier makers; but there can be no doubt that many of their efforts in this direction, which occasionally resulted in what we should now call fantastical beam-forms (hollow ellipsoids, monstrous skeleton-forms, &c.), must be traced back to their inability to reach a sufficient degree of precision in the geometric adjustment of the three pivots, and to their charging against the flexibility of the beam what was really owing to these defects in the adjustment. As these difficulties were overcome, beams assumed less fantastic forms. Sacré of Brussels, we believe, never uses any but plain rod-shaped beams (only perforated in the middle to insert the bearing of the central knife). Most balance makers, however, prefer the form of a largely perforated rhombus or isosceles triangle (cut out, virtually, of a plate of metal), and thus attain all that is needful without offending the eye by unduly stretching the middle section, and without using anything more intrinsically rigid than hammered brass or some kind of bronze. In reference to ordinary chemical balances (for charges up to say 100 grams), it would be no great exaggeration to say that any reasonably made beam is sufficiently rigid; only in the case of balances intended for very high charges, such as 5–10 kilogrammes, is it at all worth while to employ refinedly designed beam-forms, or to look out for a material of exceptionally high rigidity. For these particular balances hard steel would be the best material; but, unfortunately, steel beams are apt to become magnetic. With small assay-balances intended for charges up to, say, 5 grams, on the other hand, the question of rigidity is practically out of court, and the use of an exceptionally light material—such as aluminium, or, better, that alloy of 95 parts of aluminium and 5 of silver (which Sartorius of

Göttingen uses for small balances generally) is indicated.[1] In all balances the axis of rotation is realised in a straight knife-edge ground to a prism of hard material, which is firmly fixed to the beam, traversing it crosswise and resting on a hard bearing. In ordinary balances the middle knife is simply driven through the beam, and only its two ends are supported in cylindrical, or, what is better, roof-shaped bearings, which form secures to the edge a sufficient fixity of position, forward and back sliding being prevented by cutting off the ends of the knife obliquely, so that the edge terminates in two points, and closing the bearing at each end by a steel plate, so that the knife has just room between without jamming. In suspended balances the central bearing is fixed at the lower end of a light framework, terminating above in a hinged-on ring for suspending the instrument from a fixed hook or the thumb of the operator.

In all precision balances the central bearing is attached to a fixed pillar, and is plane; in the best balances the bearing is made of one piece, and the central knife-edge rests upon it in its entire length. A plane bearing necessarily involves an arrestment so constructed that, besides doing its primary duty, it assigns to each point of the central knife-edge a fixed position on its bearing. In former times hard steel was used exclusively for both knives and bearings; subsequently agate bearings came to be combined with steel knives. Robinson of London was the first to make both knives and bearings of agate. The agate knife adds nothing to the precision of a newly-made balance, but it always remains clean, while a steel knife, in a chemical laboratory more especially, is apt to rust. Steel knife-edges are generally ground to an angle of 60° (or 90° for very heavy charges). In agate knives, as made by Oertling, only the body of the agate prism is ground to 60°, while the edge is formed by two narrow facets, inclined to each other at a far more obtuse angle. Such an obtuse edge stands many years' constant use without wearing out. American makers have introduced the artificially made osmium-iridium, which is used for the tipping of stylograph pens, as a material for both knives and bearings.

For the realisation of the two point-pivots A and B, a great many combinations have been invented. A now obsolete construction of Weber's (Bib. 2) adapts itself very closely to our ideal conception. He provides the beam at its two ends with knife-edges turned sideways and suspends the pans by means of threads of unspun silk which are fixed somewhere in the back of the beam and hang over the edge. The axis of rotation is realised similarly. In ordinary balances, as a rule, a vertical slit is cut into each end of the beam, and this is traversed by a short prismatic knife, the edge of which is a circular arc of small radius which stands perpendicular to the line AB. From each such knife the pan is suspended by means of an 8 or 2-shaped steel hook. This construction, if well executed, may afford high precision, but the suspender-hook is apt to rub against the sides of the slit in the beam. Hence, wherever the hook-and-eye arrangement is adopted for precision balances, it is modified in this sense, that the knife-edge forms a circle of relatively large radius which lies entirely outside the body of the beam. This system, compared with those considered in the sequel, offers the advantage of easy adjustment. It used to be very popular with balance makers, and many excellent instruments have been produced with it especially by Deleuil of Paris. For small assay-balances it is indeed probably as good as any other that could be named; for balances intended for higher charges it does not possess sufficient durability, although, as the writer is able to say from his own experience, if well made, it lasts better than is generally supposed. In modern balances it is rarely seen; in these, as a rule, the pans are suspended from long straight knife-edges, similar to the central one, by means of broad bearings which, of course, must be arranged so that they neither twist nor slide. A very efficient and easily made arrangement is to give the bearing the form of a roof cut and of one side of a prismatic block of steel or agate, and to fix it to the upper end of a stirrup-shaped or ⅂-shaped holder which terminates below in an eye, from which the pan is suspended by a suitable hook. The eye stands at right angles to the knife-edge; its working point, when the instrument is in use, lies vertically below the centre of the respective end-edge, and the effect is the same as if the whole of the load were concentrated in that one centre-point, although the pressure of the bearing on the knife is equally distributed over the whole of its working length. This hook-and-eye arrangement is absolutely indispensable if the pans are suspended by stiff stirrups, because, if these were rigidly connected with their bearings, the virtual point of application of the load would shift forwards and backwards on the edge, and the least want of parallelism between it and the axis of rotation would cause the balance to give inconstant readings.

These roof-shaped bearings were formerly used almost exclusively by German makers, although an undoubtedly superior system had been introduced successfully by Robinson of London many years ago. In it the pans are suspended by *plane* bearings which a suitable extension of the arrestment keeps in their right positions. Robinson's balances were justly famous in Great Britain—a few of them are still working to this day—yet, after Robinson's death, Oertling was almost the only balance maker who followed him in this respect. The general plea against the system was that flat end-bearings were liable to twist; and some, after having adopted Robinson's plan, 'improved' upon it by cutting out a central portion of each end-knife, so that it worked only with its two ends; proving thereby that they did not understand their business, because a *really plane* bearing, as a matter of fact, does *not* twist on a *really straight* knife-edge, even if the pan oscillates strongly. The principal advantage of the Robinson system is that it enables one to do what the roof-shaped bearing prohibits, namely, to satisfy himself that the knives and bearings are geometrically perfect. But here, as in all analogous cases, we must not forget that the excellence of an instrument—supposing it to be based on a reasonable system—depends far more on the skill of the maker than on the theoretical perfection of the design.

---

[1] For a fuller discussion of this subject, *v.* the writer's Memoir (Bib. 6, 322).

From the bare realisation of the ideal machine, we now pass to the accessories which a balance needs in order to become a convenient instrument, and we will consider these in the order of their importance.

The arrestment is a mechanical contrivance to enable the beam to be arrested at any point of its angular motion, and to bring it to permanent rest in its '*normal*' position, in which the plane of three axes stands horizontal. If the three pivots are self-adjusting, there is, strictly speaking, no need of an arrestment; still for the rapid execution of precise weighings it is almost indispensable.

If the central bearing forms part of a suspended frame, an arrestment is easily devised in the ways illustrated by Figs 1 and 2. Fig. 1 explains itself; in Fig. 2 the balance is hinged on to the bent-down end of a flat bar which slides up and down in guides fixed to the pillar between two beds of rollers 2×2 in the guides on the front side of the bar, and one which is pressed against its back by a spring. At its lower end the bar has a small wheel which rests on the shorter end of the hinged lever by means of which the balance is raised or lowered. A small vertical adjusting screw below the shorter end of the lever defines the lowest position of the bar at which the pans just touch the table without slackening the chains. In either case it is an improvement to suspend a heavy block of metal at the lower end of the frame, to compel it to hang plumb, and to hinder it from oscillating. The specific advantage of *suspended* balances is that they need no horizontal table or levelling screws at the board on which they may be erected. But pillar-balances are on the whole more convenient. In the case of these (supposing plane bearings to be absent) a good system is to fix the central bearing to the top of a rod which slides up and down within the pillar—properly guided to prevent shaking and rotatory motion—and, with its lower end, rests on an eccentric concealed in the sole and governed by a lever- or disc shaped handle. The eccentric must be so adjusted that when it is at one of its extreme positions, the pans just touch the board and no more, while, when it is in its other extreme position, the beam is at its maximum angle of free play. In the excellent *Tarirwaagen* of Messrs. Becker's Sons, Rotterdam, this system of arrestment is realised to perfection.

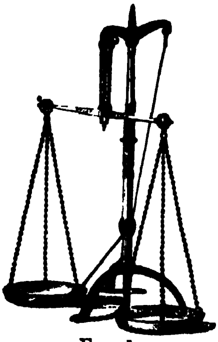


FIG. 1.

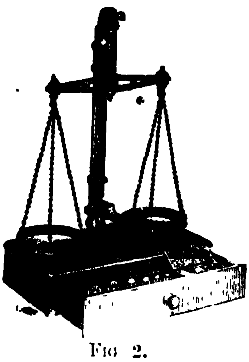

FIG. 2.

The system needs only be slightly modified to adapt itself to the case of a plane central bearing, but we prefer to at once pass to the case of *three* plane bearings, and in doing so cannot do better than describe a balance (for charges up to 5 kilos.) which Mr. Oertling made for us some years ago. As shown by Fig. 3, the instrument rests on three pillars standing on a hollow square block of iron which conceals the eccentric. Firmly fixed to the top ends of the pillars is a substantial brass frame which terminates at its two ends in V-shaped supports for the end-bearings. These latter are agate plates cemented each to the horizontal bar of a kind of stirrup, the bar terminating on each side in a cylindrical steel pin which, when the balance is at rest, lies in the corresponding V of the frame. The central pillar conceals a movable steel rod, provided at its lower end with a wheel which rests on the eccentric. Its upper end carries a substantial brass block which divides into two short piers above, whilst it expands below into a horizontal plate, pierced by a circular perforation near each end. These perforations fit exactly around two cylindrical steel pins, *r*, *r*, fixed to the top plate of the pillars, so that the rod, when moving up or down, cannot turn or shake in the slightest degree. The space between the two piers is bridged over by the central bearing, a plane agate plate fixed to a prismatic piece of brass, which is dovetailed into the tops of the piers, so that, while perfectly steady when in its place, it can without much effort be slid out or in (Fig. 4). It is inserted while the beam is being held in its intended position and passes through a large perforation in the beam into which the middle knife projects. The beam terminates at its left end in one, at its right end in two, horizontal steel pins whose shoulders are continuous but rapidly expanding surfaces of rotation, and these pins fit, the single one into a notch, the couple into a fork, forming part of the fixed arrestment frame. In the arrested balance each bearing is almost in contact with its knife; if the eccentric be now turned, the central bearing rises and lifts the whole, beams and end-bearings, to a greater or less height, and ultimately into that maximum height at which the eccentric stands still without being *held* in its position. If the eccentric be now turned the other way.

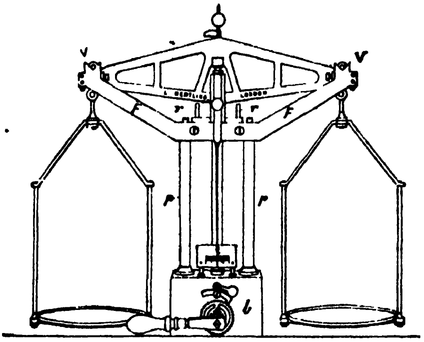

FIG. 3.

both the beam and the end-bearings fall back, ultimately, into their prescribed positions of rest, even if they should have twisted, which, however, they never do in the instrument under description. For a balance intended for quick work, and more especially for one used occasionally for the weighing out of predetermined quantities of solids or liquids, this system of arrestment is the best that we know of, because it enables the instrument to be handled pretty much like an ordinary pair of scales; only, to be able to do so to the best advantage, and without spoiling the terminal pivots, the pans must be suspended by flexible short-linked chains whose length is so adjusted that the pans just touch the table when the balance is fully arrested. Stirrup-shaped pan-suspenders (as represented in the figure) are more convenient than chains in many respects, but, for the purpose under consideration, they do not work with plane end-bearings. The ratchet-wheel visible in the figure was intended to enable the eccentric to be arrested at intermediate positions (in taring with garnets and similar operations) but was found not to work satisfactorily; it is simpler and better to have a block of wood so adjusted that when put under the handle it just raises the beam sufficiently to enable one to see which side goes down.

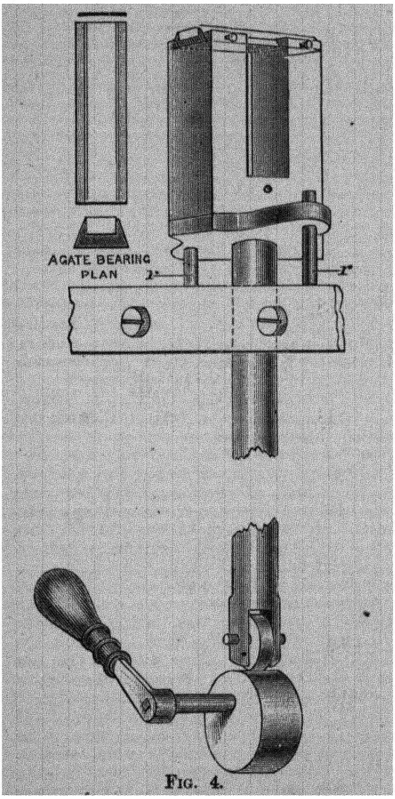

Fig. 4.

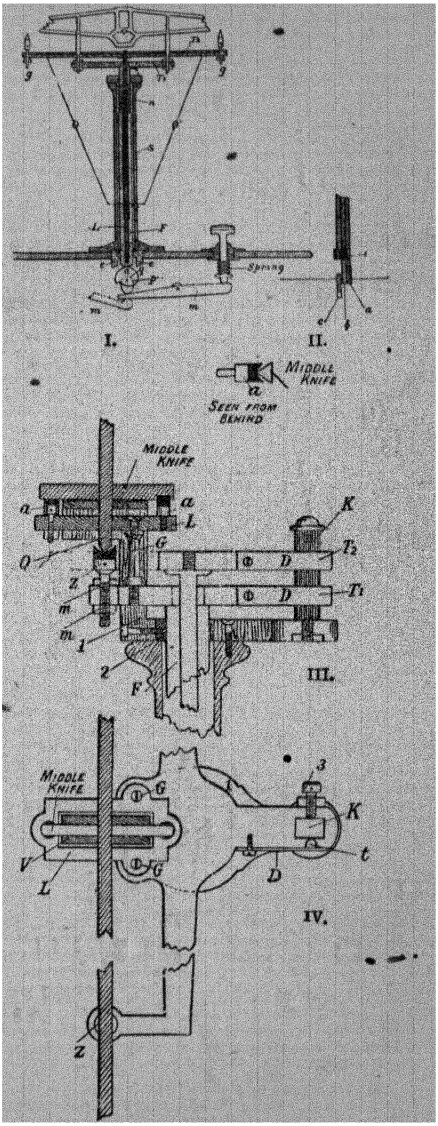
Instead of fixing the arrestment frame to the pillar and making the central bearing movable, we may of [illegible] the reverse, and this latter system, indeed, is generally preferred for precision balances of a higher order.



III. Section through pillar and middle knife; IV. Horizontal projection.

Fig. 5.

The kindness of Messrs. C. Staudinger's Nachfolger of Giessen, Germany, enables us to give a detailed description and drawing of the kind of movable frame arrestment which they are in the habit of applying to their best instruments.

As shown by Fig. 5 (I. to IV.) the pillar is hollow and accommodates a round bronze rod F. This rod itself, however, conceals a co-axial round rod L of nickelled steel. The bronze rod F, at its lower end, is guided by perforated blocks, *e*, *e*, Fig. I., while at its upper end it terminates in a thinner cylinder surrounded by a gently acting spiral spring *n*. The head of the pillar is perforated and guides the attenuated end of F in its up-and-down motion. The inner (steel) rod, L, is guided similarly within the bronze rod F and has a spring *i*, Fig. II., about its lower end to assist its natural tendency to sink. The two rods F and L carry two independent arrestment-bars; L the bar T_2 for the end-bearings, F the bar T_1 for the beam.

A square pillar K (Figs. III. and IV.), which rises from a prolongation of the head of the stand pillar S, by passing through perforations in the two bars T_1 and T_2, prevents any motion of these about the axis of their rods. As shown by Fig. IV., an adjusting screw, passing through the bar, and a flat spring *t* on one side of the square perforation of the bar (T_1 or T_2), enforce steadiness of motion.

The upright pins *g g* (I.), which are tipped with sharp agate cones, arrest the end-bearings by rising into corresponding conical hollows in the latter. (Fig. 6, though taken from an Oertling balance, will give an idea of the way in which these pins work.) The two slanting lines O O (Fig. I.) are meant to indicate two supports, which pass through slots in the pillar S and the bronze rod F, and are fixed to the inner rod L, to lend additional rigidity and steadiness of motion to the end-bearings arrestment.

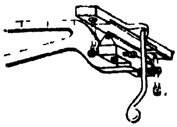


FIG. 6.

The arrestment of the beam is effected by two adjustable piers Z rising from the bar T_1 of the bronze rod. The tops of these piers carry roof-shaped agate bearings, in which the arrested beam lies with its lower (bevelled) edge. This would be sufficient to keep the beam from turning. To hinder it from moving progressively, there is a horizontal frame L (Figs. III. and IV.) united with bar T_1 by two little pillars G, G, and carrying two agate bearings, a roof-shaped one at the hinder end and a plane one at the front end of the middle (agate) knife. The roof-shaped bearing receives that end of the middle knife as the roof-shaped bearing of an ordinary balance would (so that by it, and the two beam-supports, three points of the arrested beam are fixed in prescribed positions); the plane bearing in front only supports the knife as it rises up to it on arresting. This plane bearing is adjustable by means of a screw, so that the arrested central knife-edge can be made rigorously parallel to the fixed central bearing of the working instrument.

There are three eccentrics, all attached to the same axis and governed by the same handle (Fig. II.), one, A, for the bronze rod F, a second, B, for the inner steel rod L, and a third, C, for a pan-arrestment, whose mode of acting will readily be seen by a glance at Fig. I. When the handle stands so that line *p* (Fig. I.) is vertical the beam is arrested; after this point has been passed, the beam-supports remain at the same altitude, but, on turning the handle further, bar T_2 is raised to lift the terminal bearings as soon as line *q* stands vertical. The last third of the motion of the handle arrests the pans.

The principal feature in Messrs. Staudinger's Nachfolger's arrestment obviously is the relative independence of the beam-arrestment and of the end-bearings arrestment. In most other movable frame systems there is only one frame for both, and things are arranged so that the middle edge is held fast after the end-bearings have been lifted by a hair's breadth, and that the upward motion comes to an end as soon as the middle knife is just visible above its bearing. A refinement upon this construction is to merely effect the three contacts, and then, by means of a special eccentric, to let the middle bearing drop through a distance of 0·1 or 0·2 mm.

Whilst all the several points of a rigid though movable arrestment-bar move up and down in vertical straight lines, the end-edges of the vibrating beam describe circular arcs. Hence whenever the bar is raised against the *slanting* beam, the end-bearings *tend* to slide over their knives and to spoil them. To preclude the possibility of this, Becker & Sons, in their finest balances, make the bar for the end bearings arrestment of two halves which are hinged on to the pillar in or very near the axis of rotation. Sartorius adopted this system and brought it into a slightly different form, regarding which we refer to Bibl. 4, where it is illustrated by a drawing.

In a balance which has only plane bearings, no kind of arrestment, of course, will give satisfaction, unless its several parts, and also the pillar and the sole, are sufficiently substantial to ensure absolute constancy of configuration and absolute steadiness of motion even after long-continued use. The old masters used to pay great attention to this important point, but it is sadly neglected by the majority of their present successors.

In a balance of which the end-pivots are self-adjusting, the movable arrestment frame assumes a very simple form. All that is needed is a small frame bearing V-shaped notches for arresting the middle knife in a prescribed position, and fixed to a horizontal bar with two projecting pins, in order, at the same time, to support the beam in a horizontal position. As these pins have no other function, the bar may be very light, and the whole system need not have that absolute steadiness of motion which is indispensable in the case of plane end-bearings.

The needle and scale serve to define the angular position of the beam. In all modern precision balances the needle points downwards, and is meant to embody a straight line passing through the axis of rotation and standing perpendicular on the line connecting the two point pivots A and B. The scale is attached to the pillar; its zero, if the stand is properly levelled, lies vertically below the axis of rotation. To enable the stand to be levelled, there must be either a plumb line or two spirit levels *fixed to the pillar*, and so adjusted that when they point to their zeros, the line connecting the zero of the scale with its projection on the middle edge is vertical. The scale should be so graduated that the needle-line, if produced, would cut, not the circle described by the needle's reference point, but the horizontal tangent to this circle, into pieces of equal length (*v. infra*). In most practical cases, however, this comes to the same as saying 'into pieces of equal angular value.' In balances provided with a fixed arrestment frame the scale should be made to move up and down with the beam, so that its position in reference to the needle remains constant. In most balances the end-point of the needle is just clear of the upper circular edge of the scale, but it is better to make its lowest portion almost linear, and let this project over the scale and almost touch it.

The rider.—Small weights are difficult to handle and easily lost. To avoid this inconvenience, Berzelius conceived the happy idea of dividing the right side of the beam, or rather the horizontal lever arm corresponding to it, into ten equal parts, and substituting one rider weighing ten centigrams for all the centigram and milligram pieces of the set of weights. Obviously the rider, when suspended at the first, second, &c. mark from the centre, acts like 1, 2, &c. centigrams placed in the pan, and it is equally obvious that every tenth of a division on the beam corresponds to one milligram of additional weight. This system was universally adopted and is still in use, only with this qualification, that we now apply it to the counting of the milligrams by means of a rider weighing ten milligrams. The reason for the change is obvious. In most balances the points 0 and 10 of the rider-scale are inaccessible. Becker & Sons avoid this inconvenience by dividing the arm into twelve parts, and supplying a rider weighing twelve milligrams. Other makers, for instance, Messrs. Verbeek & Peckholdt, of Dresden, make the top bar of their beams exactly horizontal, and, besides keeping it clear of impediments, make it project beyond the terminal edges. One of the advantages of this system is that, in the case of a short beam, it enables us to double the degrees of the rider scale, by dividing each arm into only five (integer) parts, numbering these from the left knife onwards and using a rider weighing five milligrams. Only, if we do so, the rider suspended at the zero must be counted part and parcel of the instrument. Bunge provides a special rider-bar so contrived that the path of the rider lies in the plane of the three axes. This, *theoretically*, is the most perfect arrangement.

A rider arrangement, to be complete, must be supplemented by a mechanical contrivance enabling one to shift the rider while the balance case is closed, and to do so with greater rapidity, ease, and certainty than would be afforded by a forceps, supposing the case to be open. Rider-guides fulfilling this latter condition are scarce; even with the best the rider drops down occasionally, and has to be searched for.

To avoid this source of annoyance Hempel does away with the rider and substitutes for it a vane with a limb graduated into milligrams (*v. infra*).

The gravity bob—a small button or disc of metal so attached to a wire standing vertically on the top of the beam exactly above the axis of rotation that it can be screwed up and down along the whole range of the wire. It enables one to raise or lower the centre of gravity of the beam, and thus to establish any desirable degree of sensibility.

A bob thus constructed meets all the requirements of the balance maker, but for the chemist who uses the balance it is desirable to have an arrangement which enables him at a moment's notice to establish any predetermined degree of sensibility. Such an arrangement was invented by the writer some years ago (Bibl. 8 and 5). It consists of a small bob fixed by mere friction to the upper end of the needle, which at that part has the form of a triangular prism, and is provided with a graduation. The mode of standardising the scale is explained below.

Some arrangement for establishing perfect equilibrium in the unloaded instrument is required. A small bob screwing along a horizontal wire fixed to some convenient part of the beam answers best. Less convenient is a 'vane,' meaning a little movable horizontal lever attached to the lowest point of the wire, which carries the ordinary gravity-bob, or to the upper part of the needle. To understand the working of the vane—and at the same time that of Hempel's invention above referred to—substitute for the vane an equivalent rigid line (Fig. 7). If the vane-line stands in the position OO—*i.e.*, if it is parallel to the middle knife—it adds no weight to either side, if turned through 90° into position O (10), it virtually adds, let us say, 10 milligrams to the charge of the right pan. Divide the line O (10) into ten equal parts, erect an ordinate in each point, and you find the points 0, 1, 2, 3, &c., of the circular path of the end-point of the vane, to which the vane-line must point, if the virtual addition to the right pan is to be equal to 0; 1, 2.... 10 milligrams. A glance at the figure shows one weak point in the vane contrivance. There is, however, no need of our dividing the circular limb exactly in the way of our figure. We may, for instance, place the zero at the −7 and the ten at the +7 of our figure, divide the interval between the projections on line (10) ($\overline{10}$) of +7 and −7 into ten equal parts, and so adjust the mass of the vane and its distribution that, by turning it from the new zero (at −7) to the new '10' (at +7), we virtually add 10 milligrams to the right charge. The degrees, corresponding each to 1 milligram, then become so nearly equal to one another that

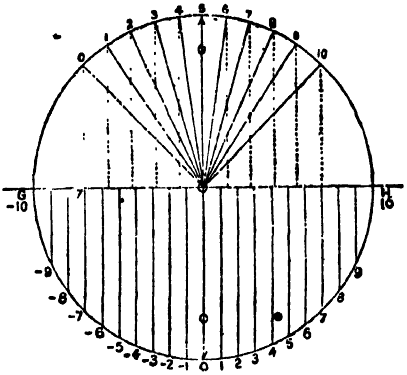

Fig. 7.

the subdivision of each into ten parts of equal angular value is permissible.

THE THEORY OF THE BALANCE.

For a first approximation imagine a balance which is ideally perfect, and assume it to be charged with P grams from the left and with P grams from the right point pivot. The balance, when free to vibrate, can remain at rest in only its normal position, and if brought out of it will vibrate about it as a pendulum, because the two charges are equivalent statically to one heavy particle weighing. 2P, situated in the central knife-edge. Now, put a small overweight Δ on, say, the right pan; the position of potential rest will shift, and the beam, to reach it, must turn (downwards on the right side) through a certain angle α, which depends only on Δ and on the weight W of the empty beam, which latter we may assume to be concentrated in its centre of gravity c, the force 2P being obviously out of consideration. But the two weights, Δ at *b* and W at c, are equivalent to a point weighing W+Δ and lying on the straight line *cb* at a point c′, not far from c. The new position of rest is gained as soon as c′ lies vertically below the axis of rotation, or, to put it in other words, the right side of the beam goes down until the leverage of Δ is so far reduced and that of W has so far increased, that the two *momenta statica* are equal to each other.

Imagine now the axis of rotation were shifted vertically upwards through a small height *h*, but remained parallel to itself. The imaginary point weighing 2P now, as soon as the beam turns, *has* a lever and helps the weight W; the beam will turn through a less angle α' to gain its new position of rest, and, supposing 2P to increase, α' becomes less as 2P increases.

Imagine now the axis of rotation to be shifted downwards towards the centre of gravity. The heavy point weighing 2P grams now helps Δ, and the angle which separates the two positions of rest will become greater than the original angle; the greater 2P the greater will be the actual angle α''. But the two weights, W concentrated in c, and 2P concentrated in the centre of the line *ab*, taken jointly, are equivalent to one point c′ weighing W+2P grams, and situated on the straight line connecting the two points; and supposing 2P to increase gradually from *nil* onwards, c′, in the second case, will rise and rise, and at a certain value of 2P fall into the axis of rotation. The balance then has no definite position of rest; and if c′ rises still higher, the balance upsets. However small an overweight Δ may be put on either side, the beam would have to turn upside down to reach its one (theoretical) position of stable equilibrium.

The balance maker of course takes care so to adjust his instrument that even if the sensibility is at the highest value which the balance is meant to afford, and the two-sided charge 2P at its maximum likewise, the centre of gravity of the whole system lies on the safe side of the axis of rotation.

Assuming this condition to be fulfilled, the balance to be exactly equal armed and to be charged with a pan weighing p_0 grams and a load of *p* grams on each side, the angle α of deviation is governed by the equation

$$tg\alpha = \frac{\Delta l}{Ws + 2(p_0 + p)h}, \quad . \quad . \quad (1)$$

where *l* stands for the arm-length, *s* for the distance of the centre of gravity of the empty beam from the axis of rotation, and *h* for the distance of the axis of rotation from the plane of the two end-edges, the axis being assumed to lie *above* the plane. In the opposite case *h* must be assumed to be negative, or the *plus* sign before the second term in the denominator be replaced by a *minus* sign. But $tg\alpha$ is the ratio of the absolute length of scale (measured tangentially, *v. supra*) corresponding to angle α to the distance I of the tangent-zero from the axis of rotation. Hence we have

$$n = \frac{\Delta l\mathrm{I}}{Ws + 3(p_0 + p)h} = \Delta . \text{`E'} \quad . \quad (2)$$

where, supposing I to be measured in tangential scale degrees, *n* may be read as meaning the number of degrees through which the needle turns in consequence of the addition of Δ. The product condensed into 'E' we will call the 'sensibility.'

The reciprocal of E, *i.e.* the number $\mathrm{E}^{-1} = \frac{1}{\mathrm{E}}$, is the weight-value of 1 degree of the scale—*i.e.* the particular Δ which makes $n = 1$. With a precision balance the milligram is a convenient unit for Δ.

For a balance provided with the writer's auxiliary bob, eq. (2) may conveniently be brought into the form

$$\frac{\Delta}{n} = \mathrm{E}^{-1} = \frac{(Ws + 2\mathrm{P}h) + b(y_0 + y)}{l\mathrm{I}} \quad . \quad (2a)$$

where *b* is the weight of the bob and $y_0 + y$ the distance of its centre of gravity from the axis of rotation y_0, being that distance which prevails when the bob is at its highest (zero) position. In a well-made balance the influence of P on E is small; we may therefore assume the P of the equation to be some average value, and, contracting constants, say, the weight-value of one degree is

$$\mathrm{E}^{-1} = \mathrm{A} + \mathrm{B}y \quad . \quad . \quad (3)$$

where A and B are constants; A obviously being that value which E^{-1} assumes when $y = 0$. —B is easily determined by one trial at $y =$ to its maximum, and the scale thus standardised.

The theory of the rider might be allowed to take care of itself if in general practice the rider's path exactly coincided with the plane of the three axes. But such is not the case; this path, as a rule, lies above the plane, and each mark at its own altitude H. Let us therefore assume that, after the balance had been charged with P on each side, a rider weighing *p* had been suspended at a point of the beam corresponding to the fraction *kl* of the arm-length (at the $10k$)th mark counting from the centre). If the beam stand horizontal, and a weight *kp* be placed in the opposite pan, the beam will remain in equilibrium, because we have $l(pk) = p(kl)$ whatever H may be; the rider where it is and the charge *kp* (virtually) in the left knife-edge are conjointly equivalent to a fixed point weighing $kp + p$, and situated on the straight line joining the left edge and the point ($10k$) where the rider is. And this equivalence holds for the slanting beam as well, and is independent of P. But the sensibility of the beam with the rider on is evidently greater than it was with the rider off. Statically speaking, the weight of the beam and the two charges P and P are equivalent to a fixed point C_0 weighing $W'=W+2P$, and situated vertically below the axis of rotation at a distance S_0, and this particle, conjointly with the one embodied in the rider, is equivalent to a point weighing $W+2P+p$, and situated on the straight line between C_0 and the point where the rider sits. Referring to a system of rectangular co-ordinates whose X-axis passes through the centre of the central edge and is parallel to AB, and whose Y-axis passes through the same centre, we have for the position of the resultant point the equations

$$x(W'+p)=lkp\text{ ; and }y(W'+p)=W's_0-pH$$

$$\therefore\frac{x}{y}=tg\alpha=kp\left\{\frac{l}{W's_0-pH}\right\}\quad.\quad.\quad(4)$$

We see that if H be constant—*i.e.* if the rider-path be parallel to the plane of the three axes—$tg\alpha$ is proportional to the overweight kp virtually added to the charge of the right pan; but it is as well to notice that the $tg\alpha$ of our equation is different from the $(tg\alpha)_0$ which is brought about if, instead of hanging the rider on the $(10k)^{th}$ mark, we actually put kp units into the right pan. Obviously

$$(tg\alpha)_0=(kp)\frac{l}{W's_0}\text{ and less than }tg\alpha\quad.\quad(5)$$

With a rider weighing only 10 milligrams, and, say, a hectogram balance, the term pH in the denominator comes to very little, but with a rider of ten times the weight it (as a rule) can no longer be neglected; such a rider cannot conveniently be used unless H is constant and the rider must always hang at the balance (at its zero, over, say, the central knife when it is not used as a weight), or else the sensibility has one value with the heavy rider on and another with the rider off. Another requisite is that notches cut into the beam be substituted for mere marks, and that the rider have a sharp edge to give sufficient constancy of position to its point of application.

From what we have said so far, it would appear that in a balance provided with a gravity-bob we can give the sensibility any value we may fancy. And so we can, but it does not follow that we can command any desired degree of *precision*. Because the three edges and bearings are not what they ought to be, and, as a little reflection shows, the effect of their defects is the same as if, say, the length of the right arm, instead of being at the constant value l, oscillated irregularly between $l-\lambda$ and $l+\lambda$, where λ is a very small length, which increases when W and P increase, but is independent of l. And this again is the same as if λ were *nil*, but the charge of, say, the right side, instead of being at a constant value P, varied irregularly from $P-\epsilon$ to $P+\epsilon$. In a given balance charged with a given P at each side ϵ is constant, but the corresponding angle of deviation β varies when the sensibility varies. Within this angle β the balance is, so to say, in a state of indifferent equilibrium. By going a little more deeply into the matter, we easily satisfy ourselves that, even allowing for the fact that we cannot substitute a longer for a shorter beam without increasing the beam-weight, ϵ will increase when l becomes less. In a balance meant to afford a certain degree of precision, we cannot allow the arm length to fall below some (very uncertain) value of l_0.

A glance at eq. (2) would show, if it were not clear without it, that, if the three axes lie in exactly the same plane—*i.e.* if $h=0$—the sensibility becomes independent of the charge, which is a great convenience. But h obviously cannot be equal to *nil* at all charges; hence in the case of the best instruments it is regulated so that it has a small negative value when only the pans are suspended, and, by the unavoidable deflection of the beam, becomes *nil* at some suitably selected medium charge, so that, from this charge upwards, it has small positive values. That such a degree of precision cannot be attained by purely constructive methods goes without saying; indeed, any precision balance requires to be '*adjusted*' before it is fit to be used. For this purpose the value of the h corresponding to the medium charge and the ratio of the actual arm-lengths $l':l''$ must be determined and the errors h and $\frac{l'}{l''}-1$ corrected. For the direct geometric measurement of h special apparatus have been constructed, which, in their present form, we believe, afford a sufficient degree of precision; but the final test always is (or at least was until lately) at a suitable position of the bob, to determine the weight-value E^{-1} of one degree of deviation for a series of charges, say, $p=0$, 50, 100 grams, &c., up to the maximum charge which the balance is intended to measure; and to at least *virtually* calculate the corresponding values h by means of eq. (2). Whether h is positive or negative, is of course seen from the values E^{-1} without calculation. Supposing now h has a greater value than can be tolerated, one of the knives must be lowered or raised until at a certain medium charge the three edges are as exactly as possible in one plane. Most mechanicians provide adjusting screws for this purpose which enable one to work in a systematic manner. Some, however (for instance, Becker & Sons, following the example of Deleuil), prefer to fix all the knives definitely and to alter the *form of the beam itself* by means of the hammer. If the central edge has to be lowered, the lower bar of the beam is struck (on both sides); if it is to be raised, the upper bar is struck, until the correction is presumably almost but not quite completely effected. The values E^{-1} are then again determined, and if they are not sufficiently near one another, the hammering is renewed until the adjustment is perfect. In a similar manner (or by means of adjusting screws) the two arms are made equal to each other. The test here is very simple. The balance, after having been brought to the highest degree of sensibility which it will stand at the highest charge P, is charged with *exactly* P grams on each side. The longer arm goes down, and by determining the small overweight which must be added to the other side to establish equilibrium, we can easily determine the ratio $l':l''$ numerically. All these adjustments are effected by the mechanician, and when once effected are final. Some mechanicians—for instance, the Beckers—fix even the centre of gravity, but this is a mistake. A balance, to be complete, *must* have a movable 'bob' to enable the operator to give the sensibility that value which suits him best. What degree of sensibility should we choose? Answer: In general, the lowest degree which suffices for the purpose in hand. Supposing, for instance, we can neglect the half-milligram, it is of no use to screw up the bob any higher than necessary for rendering the angle of deviation corresponding to 0·5 milligram conveniently visible and no more, because the less the sensibility, the greater the range of weights determinable by the method of vibration, the greater, as is easily shown from eq. (2), the relative independence of the sensibility from the charge, and last, not least, the less the time of vibration. The time of vibration can of course not be allowed to fall below a certain minimum, or else the centres of gravity of the charges will not be able to follow the oscillations of the beam with sufficient promptitude. But this clause, with larger balances wrought at high precision, usually takes care of itself. The exact relation in a balance between the time of vibration t (in seconds) and the sensibility E is given by equation:

$$t^2 = \frac{l}{\mathrm{R1}}\left\{k\mathrm{W} + 2\mathrm{P}\right\}\cdot\mathrm{E} \quad . \quad . \quad (6)$$

where R is the length of the mathematical pendulum beating seconds at the place of observation, P the total charge on one side, and k a numerical factor, $k\mathrm{W}l^2$ being the *momentum inertiæ* of the empty beam. With the customary perforated rhombus or triangle, k is very nearly equal to ⅓. From the equation we clearly see that with a 'bob' of sufficient range we can choose our own time of vibration or our own sensibility, but we cannot choose both, in a ready-made balance. It stands differently with a *balance to be constructed*. To avoid indefiniteness, let us assume that we wished to design a balance for weighing quantities up to 100 grams with a toleration of 0·1 mgr. Let us assume also that we had made up our minds regarding the material and the general form for the beam, and that we had defined the latter so that the relation between arm-length l, and weight W, were in accordance with an equation of the form

$$\mathrm{W} = \mathrm{C} + \mathrm{B}l \quad . \quad . \quad . \quad (7)$$

where W includes the empty pans, C designates the conjoint weight of all that which is independent of l; and B stands for the weight of the rest if the arm-length l=1. Our equation now assumes this form

$$t^2 = \frac{l}{\mathrm{R1}}\left\{\mathrm{C}^1 + 2p + bl\right\}\mathrm{E} \quad . \quad . \quad (8)$$

where p stands for the charge in each pan. This equation affords some guidance in the selection of l. Assuming for E a value which renders the decimilligram just visible, and taking p=0, we substitute for t the smallest admissible value and solve our equation in regard to l. Of course l cannot be allowed to fall below that minimum l_0 (*v. supra*) at which the inherent error would rise to anything like 0·1 mgr. Where does this limit value l_0 lie? Staudinger used to draw the line at 200, Oertling at 180 millimetres, and similar values were adopted by other makers, until Bunge, some twenty-five years ago, showed in the most direct manner possible that a sufficient degree of constancy can be attained with an arm-length of as little as 60 millimetres. Thanks to the general excellence of Bunge's work his short beams soon became very popular with chemists, and the fact that almost all other German makers have since come to adopt the Bunge system shows that the additional perfection in the pivots which the short beam undoubtedly demands is not so difficult to realise as an outsider might be inclined to think. *Assuming this difficulty to be overcome*, it cannot be denied that the short in opposition to the long beam does offer certain advantages. 1st. It is relatively light, and hence the working of the arrestment is a less effort. 2nd. It is less liable to irregularities through one-sided elevation or depression of temperature. Perhaps we may add that, 3rd, it is easier in its case than in that of the long beam to make a smooth-working arrestment, and on this account chiefly it enables one to weigh more quickly. 4th, and *least* in our opinion, it vibrates more quickly. Not that we value this last advantage at nothing. The writer's auxiliary bob indeed was invented with the very object of remedying the corresponding defect in the older form of the instrument, being originally intended to be used thus. In the outset, place the bob far down, say to the mark where 1° of deviation corresponds to 2 mgrs. or some other value securing great rapidity of vibration, and establish equilibrium as far as thus possible. Then raise the bob to the mark at which 1°=0·1 mgr., allow to vibrate, shift the rider correspondingly, and verify your result. The writer, however, soon came to find this method less convenient than he had expected, and adopted another very obvious expedient. It is easy in any beam to bring down the time of vibration to the least value one could reasonably wish for by screwing down the bob to the corresponding place. This, of course, may render the decimilligram invisible to the naked eye. But why not help the eye by optical means? An ordinary lens magnifying six times linearly affords more than there is any occasion for; only it magnifies the parallactic error as well, and the effort to avoid this error strains the eye very unpleasantly. This experience led the writer to the following combination, which he found to give perfect satisfaction. A narrow ivory scale divided into degrees of about 0·1 mm. is fixed slantingly to the needle pretty far down, yet far enough up for not obscuring the ordinary scale which does duty as usual; on the other hand, a compound microscope of feeble power, which passes through the central fixed portion of the front pane of the case, is fixed slantingly to the *pillar*. The microscope has one vertical 'wire' in its focus which acts as a needle. As the microscope inverts its images, the apparent motion of the wire in reference to the scale (which one easily persuades himself is fixed) is the same in sense as the real motion of the needle in reference to the ordinary scale, so that mistakes in regard to the + and − are avoided. The ordinary scale is graduated after the micro-scale so that each of its degrees is equal in angular value to 10° of the latter. The writer some five years ago caused Mr. Oertling to apply this arrangement to two of his balances, and he has found it to work very satisfactorily. Although it was originally intended chiefly for special occasions—the adjusting of weights, &c.—it is used even for our everyday work, as it was found that the microscope puts a less strain on the eye than the naked-eye reading of the ordinary scale. The microscopic arrangement described adds about 3*l.* to the cost of the balance. A cheaper arrangement is the following. A micro-scale, divided conveniently into fifth-millimetres, is fixed slantingly to the pillar, the needle at the corresponding part is shaped thus,

and a hair by means of capillary perforations is stretched out between *a* and *b*; the hair is parallel to the face of the scale, and only some 0·2 to 0·5 mm. removed from it. A short terrestrial telescope, fixed in the central (fixed) part of the front-pane of the case, serves for the readings. The object glass serves only to produce an image of the scale and hair within the tube, which the eye-piece (a compound microscope) magnifies as far as necessary. As the telescope need not be perfectly steady, it can be fixed at a relatively low cost. We have used this arrangement in connection with one of our balances for over two years, and found it to be almost as good as the one first described.

ON THE SETTING UP AND TESTING OF A PRECISION BALANCE.

A real precision balance, to be able to do justice to itself, must stand on a very steady support, in a room where it is not exposed to one-sided changes of temperature. The light should fall in from the back of the observer. The best support, of course, is a pillar of masonry, standing directly on the earth. Next after it (in a substantially built building) comes a shelf fixed to the wall by strong brackets. A good heavy table, however, suffices in practice. In a large city the street traffic becomes very inconvenient in weighing. Its effect can be minimised by putting small pieces of thick vulcanised-rubber plate between the legs of the case and the table. In the examination of a newly set-up balance we naturally begin by seeing that the arrestment, the rider-shifting apparatus, &c., are in good order, we then level the case, and next leave the balance to itself for some four hours at least, to enable it to acquire the temperature of the room. After these preliminaries we proceed to the following determinations.

Determination of the inherent error ϵ.—For this purpose we charge the balance equally on both sides with the highest weight which it is intended to measure (a hectogram balance, for instance, with a hundred-gram piece on each side), and after having established approximate equilibrium at the highest degree of sensibility which the balance will stand at this charge without giving obviously inconstant readings, determine the exact position of rest, first with the two hectograms in the centres of their pans, and then, in a series of successive experiments, with one or other of the hectograms placed at some point of the edge of its pan so as to give any non-parallelism in the axes or any other defect in the terminal pivots a good chance of influencing the result, taking care to interpolate occasionally an experiment with the two weights centrally placed in order to see if the balance still gives the same readings as it did at first. If it does not, this is probably owing to external causes, such as unequal heating of the two arms. To be able to translate degrees of deviation into differences of weight, we must at some stage make two successive determinations of the position of rest, one with P′ in the left and P″ in the right pan (P′ and P″ stand for the two hectogram-pieces) and another with, say, one milligram added to P″. For the precise determination of a position of rest, we cause the balance to vibrate moderately, and (neglecting the first reading as being in general liable to irregularities), record 3, 5, 7 . . . successive turning-points of the needle, applying a + to scale-points lying to the left, and a − to scale-points lying to the right of the zero (or *vice versâ*); an odd number in any case in order to correct for the retarding effect of the resistance of the air, &c.; those influences, in other words, through which the needle, supposing it to start from −4°, at the end of a double vibration, does not come back to exactly −4°, but perhaps to −3·7°. The algebraic sum of any two successive readings gives the point *a* of the scale at which the needle would come to rest, *in half-degrees*, and there is no reason why the half-degree should not be adopted as a convenient unit for the purpose in hand. Supposing the readings to be

$$\begin{array}{llllll} & a_1 & a_2 & a_3 & a_4 & a_5 \\ \text{(Example)} & +3{\cdot}7 & -2{\cdot}7 & +3{\cdot}5 & -2{\cdot}4 & +3{\cdot}5 \end{array}$$

we have for a the values: $a_1+a_2=+1{\cdot}0$; $a_2+a_3=+0{\cdot}8$; $a_3+a_4=+1{\cdot}1$; $a_4+a_5=+1{\cdot}1$—Mean $=+1{\cdot}0$.

The mean value of the four results is put down as *the* value of *a*. Supposing *a*, through the addition of Δ milligrams to the right charge to increase by *n* demi-degrees, then $E=\frac{n}{\Delta}$ (= 2 'E' in the sense of our equation (2)) is the sensibility in demi-degrees; and its reciprocal $E^{-1}=\frac{\Delta}{n}\left(=\frac{1}{2E}\ldots\text{ of equation (2)}\right)$ the weight-value of the demi-degree in milligrams. Supposing the values for *a* obtained with abnormal positions of the charges to be a_1, a_2, a_3, &c., instead of the mean value a_0, corresponding to the centrally placed charges, then $(a_0-a_1)E^{-1}=v_1$, $(a_0-a_2)E^{-1}=v_2$, &c., give each a value for the *inconstancy* of the balance in milligrams (or rather fractions of a milligram, it is to be hoped). According to a rule deduced from the law of frequency of error, the computation

$$r=\frac{0{\cdot}845}{\sqrt{n(n-1)}}(v_1+v_2+v_3+\ \ldots\ldots)$$

where all the *v*'s must be taken as positive, gives the 'probable' weight-value of the deviation of any one *a* from a_0, meaning that value of $(a_0-a)E^{-1}$ which, in a *very large number* of determinations, is as often exceeded as not reached. But in practice the number of determinations made is never sufficiently great to bring out anything like a close approximation to the law, and it suffices to take *r* as being equal to 0·845 times the mean of all the values *v*, and adopt it as sufficiently near to the theoretical 'ϵ.' The probability that, in a given case, $(a_0-a)E^{-1}$ *exceeds*

	$2r$	$3r$	$4r$	$5r$
is	0·18	0 04	0·007	0·0007

respectively.

In these determinations, if the balance lacks a microscopic reading arrangement, it is as well to read from a distance with a telescope, to avoid the parallactic error which we have no right to charge against the balance.

Determination of h.—All that is necessary is to determine the weight value of one degree in the sense of equation (2) for, say, $p=100$, 75, 50, 25, 0 grams, and to calculate the corresponding values h. In a good balance h is so small that (supposing our rule regarding the adjustment of the bob to be followed) the sensibility remains almost constant from $p=0$ to $p=100$ grams. Hence, practically, it suffices to adjust the bob so that at a convenient average charge (where 'average' refers to the most frequently occurring values of p) one demi-degree corresponds to say $\frac{1}{2}$ or $\frac{1}{4}$ of a milligram *exactly*, and then to see what it is at other charges. If there is no sufficient constancy we enter the values E^{-1} found on a system of rectangular co-ordinates in function of the charges p, and draw the nearest curve to the points. This curve (if h were absolutely constant) would be a straight line. In any case it supplies the data for a table of values for E^{-1}. This table, however, must not be relied on in *standard* weighings, because the value h is subject to changes, for this reason amongst others, that the agate of the knives has a different coefficient of expansion from the metal of the beam.

The arm-lengths.—For the determination of the ratio of the arm-lengths, the orthodox method (for a hectogram balance) is to adjust two hectogram-pieces to exact equality, and, after having established equilibrium, to put one into the left and the other into the right pan, &c. But in practice the following method is better. Take any two fairly well adjusted hectograms and viewing them, one as a *standard* representing 100,000, the other as an *object* weighing x milligrams, go through the ordinary operation of weighing once with the object in the left pan and the standard in the right, and once the other way.

Supposing (using S as a symbol for 100,000 milligrams) we find

$$xl' = (S+\delta_1)l'' \quad . \quad . \quad . \quad . \quad \text{I}$$

$$xl'' = (S+\delta_2)l' \quad . \quad . \quad . \quad . \quad \text{II}$$

(where any δ may be negative), we have by division of I by II, and subsequent multiplication with $l'' : l'$,

$$\left(\frac{l'}{l''}\right)^2 = \frac{S+\delta'}{S+\delta_2} = \frac{1+\frac{\delta_1}{S}}{1+\frac{\delta_2}{S}}$$

whence, as a sufficient approximation,

$$\frac{l'}{l''} = 1 + \frac{1}{2}\left(\frac{\delta_1-\delta_2}{S}\right)$$

No maker who has a name to lose would care to send out a precision balance in which $1-\frac{l''}{l'}$ is more than ±0·00005 at the outside, although for any scientific purpose a considerably greater error could be tolerated. The corresponding adjustment indeed, while of the first importance in commercial balances, in precision balances is in a sense irrelevant.

Unequal-armed Lever Balances.

(1) *The steelyard or Roman balance.*—In it only the shorter arm (of the length l) bears a pan; the longer arm, by notches cut into its back, is divided into parts of equal length, l being the unit. The working points or lines of the notches should lie in the plane of the two edges, being so many bearings for the knife-edge forming part of a sliding weight adjusted to P units. The unloaded balance is in its position of rest when the beam stands horizontal. To weigh a body, it is placed in the pan and the sliding weight shifted forwards from notch to notch until (when the weight hangs at the distance nl from the axis of rotation) the beam is again at rest in its horizontal position. We then have for the weight sought

$$xl = nlP \text{ or } x = nP.$$

As fully explained above, the principle of the steelyard is discounted in the modern precision balance for the determination of small differences of weight. In theory there is no objection to its extension to the determination of weights generally, but the technical difficulties to be overcome are great. On an equal-armed balance, whose beam is divided into 100 equal parts (from end to end), all weights from 0·0001 to 100 grams might be determined with three riders weighing half of (100, 1, and 0·01) gram respectively, but the realisation of 101 exact pivots is no small matter. Where relatively high precision is aimed at, it is better to provide only a small number of notches (say 10) and have a set of riders, weighing say 10, 1, 0·1, 0·01 grams respectively. The specific gravity balances of Westphal of Celle, are made on this principle. It strikes us that the steelyard principle might be discounted for the decimal subdivision of weights, thus:

Imagine a precision balance whose two arms measure $10l$ and $11l$ units. 10 grams placed in the pan of the longer arm are balanced by 10+1 grams placed in that of the shorter; hence a 1-gram piece may be adjusted after two exact 10-gram pieces, &c.

The tangent balance has only *one* short arm, from which the pan is suspended; its centre of gravity lies low, so that the *momentum staticum* Ws of the beam assumes a high value, and even a considerable weight placed in the pan produces only a moderate angle of deviation. The needle moves along a circular limb divided so that the readings are proportional to the tangents of the respective angles of deviation, and give the corresponding weights directly. The equation $\Delta = \frac{tg\alpha \cdot Ws}{l}$ (*see* equation (1), above) holds theoretically for any value Δ, but the angular deviation corresponding to 1 gram of additional charge becomes less and less as the charge increases. The tangent balance, though useful for the rough weighing of letters, parcels, &c., is not available for exact gravimetric work.

Compound Lever Balances.

In all these, practical convenience and rapid working are gained at the expense of precision. In the *Robertal balance* the pans are above the system of levers (which as a rule is concealed in a box), so that there is room for bodies of even large dimensions. Our diagram, Fig. 8, is intended to explain only the *principle* of the machine, which in practice assumes an endless variety of forms.

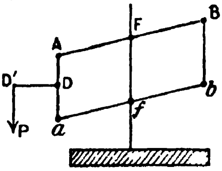

FIG. 8.

The beam consists of two parallel vertical parallelograms of which only the front one is represented in our figure. F and *f* (and F′ and *f′* in the other parallelogram) are fixed pivots, A, B, *a* and *b* (A′, B′, *a′*, *b′*, behind) are movable joints. On each side a horizontal bridge connects a point D on the vertical side A*a* (and a similar point on B*b*) with a corresponding point D′ on the back parallelogram (so that, for instance, A*a*, A′*a′*, DD′ form one piece) and, from the centres of these bridges, vertical rods arise which support the pans. Supposing each pan to be charged with P pounds, the centre of gravity of either of these two equal charges may lie in any of a great many positions about the respective pan, yet the statical effect is the same as if it were concentrated, one in the centre of the one bridge, and the other in the centre of the other; the two charges will balance each other, because, if the centre of gravity of one descends by *h* mm. that of the other rises by *h* mm., so that the work P*h* is the same on both sides. An over-weight added to one of the charges will bring down that side. The bars AB and A′B′ are relatively heavy beams, the lower bars *ab* and *a′b′* are light. Hence it depends chiefly on the distribution of the mass in the beams AB and A′B′ whether the balance (if nearly equally charged) has a definite position of rest: but even if it has, it will never vibrate like an ordinary balance, on account of the great friction in the numerous pivots. If it could only be cured of this defect, the Roberval would be the ideal balance for the counter or ordinary weighings in the laboratory. This problem has been to some extent solved in the torsion balance of Springer, in which the axes are realised in stretched out horizontal bands of elastic steel, which act, so to say, as knives and bearings in one.

The '*torsion balance*' is made[1] in a great variety of forms, but the principle of construction is the same in all. The following description is based upon the examination of what was sold as a high-class pair of counter-scales for loads up to 20 lbs. As shown by Fig. 9, the balance consists of two parallel beams united into a flexible parallelogram by means of three vertical frames, the bond of union in the case of each frame consisting of two horizontal bands of elastic steel, which bridge over certain gaps of the frames, the middle portion of each band being firmly united with the respective beam end at its lower side by means of a screwed-on block of metal. In this instrument the beams measure 290 mm. from end pivot to end pivot, the steel bands are 5·6 mm. broad and 0·49 mm. thick; the length of the working part of a band is 58 mm., 29 on each side of the beam. The middle band lies below the plane of the two end bands by about

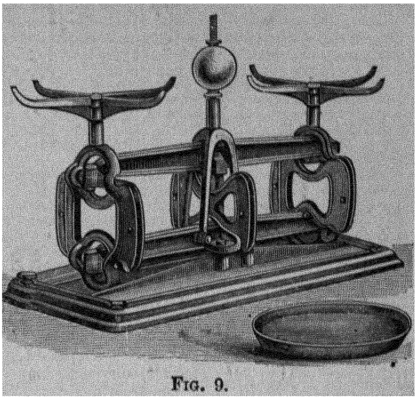

FIG. 9.

2 mm. The central frame, which does service as a pillar, is fixed to the sole of the instrument, the end frames are fixed only to their respective beam ends. Fig. 10, which is drawn to scale,

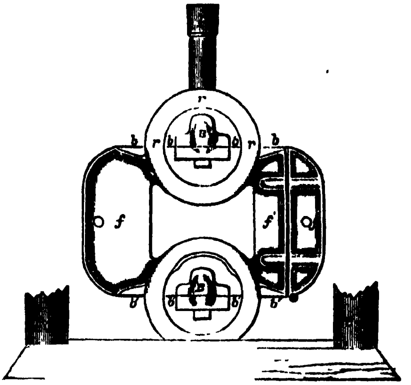

FIG. 10.

represents one of the end frames. The two steel bands of each frame, though independent of each other in their action, are really parts of one continuous band which is wound tightly round the edge of the frame, the ends meeting in B or B′, where they are, we presume, riveted on. To give them the requisite degree of high tension, the frame, of which part of the right side is movable, is stretched laterally (by means of pegs fixed to the two sides of a vice and slipped through the two holes of the frame) and the gap which is thus produced between the two halves of the right side of the frame is made permanent by means of metal plates wedged into it. The central frame is somewhat differently shaped from the lateral ones; the upper ring, *r*, is omitted, to enable the upper beam to pass freely through between the legs of a stool fixed to the lower and terminating in a vertical peg which serves as a needle and carries a globular gravity bob. The bob, which in the case of the balance under consideration weighs 458 grams, *i.e.* more than a pound, can be raised or lowered to enable the sensibility of the instrument to be varied. The system of beams is inclosed within a case of plate-glass; the top plate supports an arch made of a metal tube from which an ivory scale graduated on both sides is suspended vertically so that its lower edge runs through a notch in the upper sharpened end of the needle to enable the vibrations to be read from either side.

---

[1] By the Torsion Balance and Scale Company, 92 Reade Street, New York.

To explain the working of the instrument, let us for a moment substitute for the steel bands so many linear wires, which, though unbendable, offer no resistance to torsional disfigurement. The torsion balance thus modified is in theory identical with the ideally perfect 'Roberval,' and, if the centres of gravity of the beams are in their axes of rotation, the parallelogram will be in a state of indifferent equilibrium at any shape which it may assume. To give it a definite position of rest, we must either shift (let us say one of) the centres of gravity vertically downwards, or else we must endow our ideal wires with torsional elasticity, which, of course, brings us back to the actual instrument. But the torsional elasticity of the steel bands is very considerably more than we want; its effect on the sensibility is the same as if (supposing the upper beam is suspended at its centre of gravity) that of the lower lay at a very considerable depth below its axis of rotation. To give the balance a sufficient degree of sensibility, we must raise the centre of gravity of say, the lower beam, until the stability of the position of rest is reduced to a sufficiently small value. In the actual instrument this is effected by means of the heavy gravity bob above referred to.

The principal advantage claimed for the torsion-balance, in contradistinction to the Roberval balance, is its freedom from friction; and this advantage it undoubtedly possesses, but it is compensated for to a large extent by the unavoidable viscosity in the elastic bands. The instrument described above, when equally charged on both sides, and with the bob sufficiently far down, vibrates like a precision balance of a high order; the position of rest as calculated from a series of couples of successive deviations of the needle, is remarkably constant up to at least a charge of 5 kilos. on each side; but once, when we determined the sensibility at first with no charge, then at a charge of 2 kilos., and lastly for a charge of 5 kilos., and then redetermined the sensibility of the unloaded instrument, we found that it was out of equilibrium to the extent of more than a decigram. We also found that the reading of the balance is not quite independent of the position of the loads on the pans.

The ordinary decimal balance, as used for weighing heavy loads, is a combination of levers as shown in Fig. 11. *a*, *b*, *c*, *d*, *e*, *f*, *g*, *h*, are all joints or pivots; *a* and *h* rest on the fixed framework of the machine and consequently indirectly on the ground, *c* rests on the lever *ab*. In the actual machine *cd* supports the bridge which accommodates the load, while a pan suspended at *f* receives the weights. The pan is so adjusted that it counterpoises the bridge. Suppose the load amounts to P units and its centre of gravity lies vertically above *i*; a portion P_c presses on the knife-edge at *c* and the rest $P_d = P - P_c$ pulls at *d* and with the same force at *g*. Now P_c pulling at *c* is equivalent to a less force ${}_bP_c$ pulling at *b*, and ${}_bP_c \cdot ab = P_c \cdot ac$, whence ${}_bP_c = P_c\frac{ac}{ab}$. But ${}_bP_c$ pulling at *b* or *e* is equivalent to a greater force ${}_gP_c$ pulling at *g* and ${}_gP_c \cdot gh = {}_bP_c \cdot eh$; hence ${}_gP_c = \frac{eh}{gh} \cdot {}_bP_c = \frac{eh}{gh} \cdot \frac{ac}{ab} \cdot P_c$.

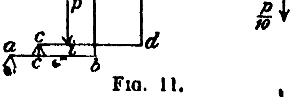

FIG. 11.

The dimensions are so adjusted that $\frac{eh}{gh} = \frac{ab}{ac}$ whence $\frac{eh}{gh} \cdot \frac{ac}{ab} = 1$; hence the joint effect of P_c and P_d at *g* is the same as if they both, *i.e.* P, were suspended at *g*; and if, for instance, *gh* is $\frac{1}{10}$ of *hf*, $\frac{1}{10}$ P units in the pan will balance the P units lying on the bridge. In many balances of this kind the long arm *hf* is divided so that lesser weights can be determined by means of a rider.

ELASTICITY BALANCES.

Imagine an elastic solid body—beam, wire, spiral, &c.—to be held fast in one or more fixed points, and suppose some one other point *a* to be used as a pivot for the suspension of a load of P units. Point *a* will sink until, at a certain depth *h*, the strain developed by the deformation of the working body balances that weight P. As long as the working body is not stretched beyond its limit of perfect elasticity, the length *h*, if not proportional to, is at least a fixed function of P; hence the path of *a* can be graduated, at least empirically, so that each point of the scale corresponds to a fixed number of units of weight. This is the general principle of the multitude of *spring balances*. Sometimes a relatively strong spring is used to effect only a small displacement of *a* even with the highest charge, but this displacement is then multiplied by a system of levers, so that the least difference of weight which the balance is meant to show becomes visible. In a very neat kind of spring-balance, which has become popular, the displacement of *a* is, by means of levers and a toothed wheel, translated into the circular motion of a needle which moves along a divided circular limb like the hands of a clock on their dial.

Jolly constructed a *quasi* precision spring-balance for sp gr. determinations thus:—A long spiral of wire is suspended vertically in front of a vertical millimetre-scale, etched on a strip of plate glass which is silvered behind, so as to avoid the error of parallax. From the lower end of the spiral a light pan is suspended; the index is close above the pan at a convenient point. The instrument has never come into general use, because any second-class precision balance beats it in every sense. A similar remark applies to an ingenious little instrument invented by Ritchie for the determination of minute weights.

Ritchie's balance consists of a very light beam whose axis of rotation passes through its centre of gravity, and which is firmly united with a thin horizontal wire which lies in the axis of rotation. The hind end of the wire is absolutely fixed to the stand; the front end forms the continuation of the axis of a circular pin revolvable within a circular bearing. A needle fixed radially to the pin points to a divided circular limb. The empty balance is so arranged before use that the beam when horizontal is at rest. To determine a small weight (x mgr.), it is placed in, say, the right pan, and the wire turned from the right to the left by turning the pin until after the needle has passed through a degrees (where a may be more than 360°); the beam is again at rest when horizontal. We then have x=const. a. The constant must be determined by experiments with known weights. Sartorius of Gottingen used to apply the Ritchie arrangement to his precision balances for the determination of differences of weight from 10 mgrs. downwards (Bibl. 5), but he has long since given up the notion: at any rate it is no longer to be seen in his price list. A Ritchie balance might perhaps do well for the adjusting of small weights, but a small precision steelyard would work infinitely better.

Sartorius' combination, if provided with a relatively strong wire, might make a handy instrument for the rapid (approximate) determination of weights without the use of any standard mass less than 1 gram.

The Hydrostatic Balance

is a hydrometer provided with a relatively large body and a narrow neck, and so adjusted that it weighs considerably less than its own volume of water. The top end of the neck bears a horizontal table, which serves as a pan, or, what is better, is provided with a horizontal system of cross-bars, from whose ends a pan is suspended by means of wires or chains, below the shelf supporting the vessel containing the floating hydrometer. A certain weight P, placed in the pan, brings down the hydrometer so far that the surface of the water touches a certain mark on the stem. If an unknown weight x requires to be supplemented by standard weights equal to p units, to produce the same effect, $x+p=\mathrm{P}$, or $x=\mathrm{P}-p$. Even for P= let us say 2 kilos., the neck need not be thicker than an ordinary knitting needle, so that the milligram, as a difference of weight, becomes perceptible. Wherever a precision balance has to be extemporised this instrument is useful; but it has no other *raison d'être.* Indeed of all the multitude of machines which the science of mechanics places at our disposal for the measurement of weights, the equal-armed lever-pendulum is the only one which, so far, has worked satisfactorily for precise gravimetric determinations.

A balance based on dynamical principles has been proposed. Imagine a pendulum provided with a shiftable bob above the fulcrum, and carrying a pan attached to the bottom end of the rod by a hook-and-eye. In a given instrument the time of vibration is a function of the distance of the bob from the fulcrum, and of the weight x of the object in the pan, and consequently the weight x is a function of the other variables.

W. D.

On Highly Refined Weighing.

Introductory.—In the late Professor Dittmar's article (*vide supra*), typical forms of the precision and other balances have been considered: the theory of the balance and the conditions necessary for accurate work in general, have also been duly treated. In the present article, it is therefore unnecessary to add more than a consideration of some exceptional, but absolutely indispensable, precautionary measures adopted when we desire to reach that which some may be inclined to term an ultra-degree of refinement of weighing.

This article is based chiefly upon results obtained during two researches, which, for successful issue, demanded more than usual care. The subject was of necessity studied from the severely practical point of view; and few, if any, of the remarks that follow have their foundation in pure theory alone. The following points are severally discussed:—

(1) The Balance Room.
(2) The Balance Table.
(3) The Levelling Screws.
(4) The Scale.
(5) The Illumination of the Scale.
(6) Of possible Variations in the Level of the Bench.
(7) The Telescope and its Carriage.
(8) Of the Necessity for Fatiguing the Beam.
(9) Device for Maintaining Uniformity in the Temperature of the Beam.
(10) Temperature Coefficients of a Balance.
(11) Suppression of Air-Streams about the Pans.
(12) Concerning the Wiping of Glass Vessels.
(13) Of Certain Precautions to be taken in Weighing Glass Vessels.
(14) Determination of the Pressure Coefficients of Glass Globes.
(15) Of the Different Methods for Weighing.
(16) Errors attending the Weighing of Hot Bodies.

(1) *The Balance Room.*—The balance room should be upon the basement: and in selecting it, the choice should fall upon one having a north-easterly aspect: for then comparatively little

direct sunlight can enter the window even during midsummer. A dry, airy cellar is an almost ideal room for a balance that is to be used for highly refined weighing. But in either case, and particularly so in the latter, the variations in the temperature of the air within assume minimum values; this is frequently of great import. For a series of weighings, no weather is so favourable as that which prevails when the sky is overcast and wind absent.

(2) *The Balance Table.*—For work of supreme accuracy, it is imperative that the balance be placed upon a massive pillar of brickwork or stone: and this should rest upon a foundation sufficiently deep to guard against all local vibrations. The flooring should not have direct contact with the pillar; otherwise vibrations may readily pass from the former to the latter, and so to the balance. An excellent plan is to cap the pillar with a rectangular block of slate: this may have a thickness of from 1 to 1·5 inch. The slate should be closely cemented to the main block, and have its upper surface as far as possible truly plane. The slate, freed from all grit and dust, is covered either with a single fold of white linen or with white blotting-paper: and upon this is placed a sheet of thick plate glass, some 2 or 3 inches shorter and narrower than the slate. The paper or linen serves a twofold purpose: first, it acts as a necessary and convenient pad between the glass and slate; and, secondly, it secures for the worker a permanently white surface which renders even small objects sufficiently conspicuous. Near each corner two holes are drilled in the slate, for the reception of wooden pins having rubber covered heads. The positions of these are indicated in Fig. 12. The pins guard against any accidental displacement of the glass.

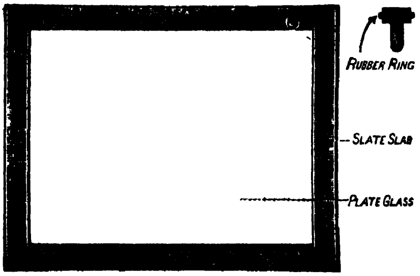

Fig. 12.

(3) *The Levelling Screws.*—With the above described bench, we may with advantage dispense with the brass shoes commonly employed for the levelling screws. When this course is adopted, the screws at their lower ends should terminate in highly polished spherical surfaces of low curvature. At those points where the screws have contact with the glass, a little oil is applied; medicinal paraffin oil is, on account of its non-liability to thicken, admirably suited for the purpose. The base of a balance thus mounted, readily adapts itself to modified conditions resulting from changes in temperature; and inherent stresses and strains are very little if at all affected.

(4) *The Scale.*—In some balances the scale divisions have an excessive length and breadth. Long lines produce an apparent narrowing of the contained spaces; and this increases the difficulty, already sufficiently great, of correctly estimating the turning position of the pointer. Again, a broad line is in general a very considerable fraction of a division; it is not easy to allow for this, and possibly the matter is sometimes overlooked. These two imperfections are reduced to insignificant proportions as follows:—

The slip of ivory is detached from the pillar, and the scale completely removed by lightly rubbing the ivory upon a very fine and large flat file; the slip is then re-polished, and a new scale in millimetres engraved upon it. The engraving tool must be capable of producing the finest of lines, and these are lightly drawn. The divisions, which may have a length of 1 mm., are rendered distinct by the momentary application of an etching pen charged with Indian ink. The ink readily runs along the whole line; occasionally a line may appear a little irregular; but after the ink has dried, any unevenness may be remedied by gently re-polishing with a flat pad. Fine sharp lines may often be secured by a *partial* filing down of the original scale, and the requisite shortness by a *complete* removal of the lower portions of the lines. During the process of shortening a straight-edge is used, not only as a guide for the file, but also as a protector for the portion of the scale to be retained.

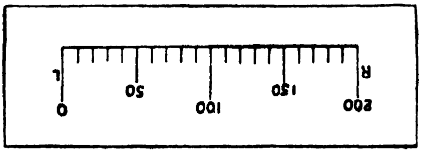

Fig. 13.

As the scale is invariably viewed through a telescope, which inverts the divisions and reverses their order, additional convenience is gained and possible confusion avoided by numbering principal lines as shown in Fig. 13.

(5) *The Illumination of the Scale.*—Weighings should be carried out in the absence of daylight; for unless the light from the window falls upon the balance in a perfectly symmetrical manner, and in general it is difficult to ensure this, the radiant energy absorbed by one part of the instrument will differ in quantity from that absorbed by another; this in itself would be immaterial, provided the ratios of the several quantities remained constant; but direct experimental evidence reveals fluctuations in these, and therefore corresponding variations in the zero or resting-point, R.P., of the beam follow. By using artificial light, we can eliminate this particular source of error. The following device leaves little to be desired:—

A glass globe having a capacity of some 10 or 12 litres, is filled with a dilute solution of potassium chromate and placed upon a shelf erected above the reading telescope. A glass tube, sealed at its lower end and containing an electric lamp, is placed centrally within the liquid: the light is then, by means of a large convex lens, concentrated upon the scale behind the pointer, and upon that alone. Ample illumination is thus secured; further, the light is practically free from heat rays, and owing to its monochromatic nature, the scale as seen through a correctly adjusted telescope is sharply defined. In Fig. 14, the relative positions of the telescope, lamp and lens are shown.

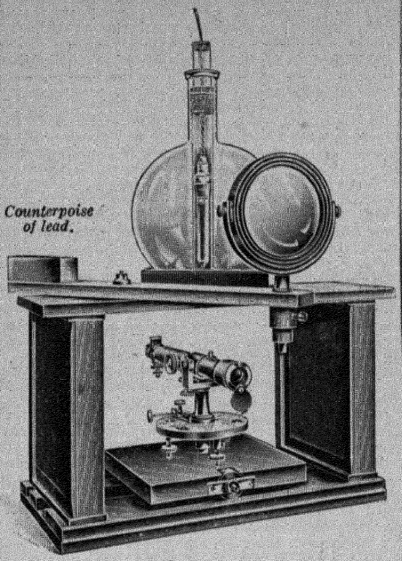

Fig. 14.

(6) *Of possible Variations in the Level of the Bench.*—An error which is readily overlooked, is that originating in variations in the level of the balance table. Observable changes may quickly follow a *sudden* rise or fall in the temperature of the room. Usually of a transitory nature, they are at times particularly noticeable and definite in a bench supported by wall brackets fixed above hot-water pipes. The variations are probably due to minute deformations resulting from inequalities of temperature. In connection with refined weighing, it is obvious that some plan must be adopted for detecting and measuring such variations. We have used with success the following simple form of tiltometer.

At one end of a glass tube T, Fig. 15, having a diameter of 3 cms. and a length of some 3 or 5 cms. greater than that of the balance pointer, a short capillary is formed; the other end is ground so that its containing plane is at right angles to the axis of the tube. Next, a short piece of platinum wire W_1, having a diameter of 0·5 mm., is, by means of gold, joined to one end of another platinum wire W_2, having a diameter of 0·05 mm., and a length some 3 cms. less than that of the tube; the free end of the fine wire is soldered to a small cylindrical weight Y, heavy enough to keep the wire taut; the resultant plumb-line is then introduced into the tube and the thicker wire fused into the capillary at the top. Any error in centring is remedied by a suitable bending of the wire W_1. A short scale, S, mounted upon a half-cylinder of boxwood, is fixed within the tube, so that its distance from the point of suspension of the fine wire equals the length of the balance pointer. The scale consists of 5 very small dots instead of lines; and the spaces they mark off are equal to the corresponding spaces of the scale behind the pointer; they are with advantage numbered and lettered according to the plan shown in Fig. 2. Vibrations of the plumb-line resulting from a necessary or accidental disturbance of the instrument, are quickly damped by oil in the vessel V. The tiltometer is completed by mounting the tube upon a rectangular base of thick plate glass; the width of this base is somewhat less than that of the balance case, but the length is some 3 or 4 inches greater. To the lower surface of the base are attached, by means of Canada balsam, 3 steel balls, and these are so disposed that when the instrument is *in situ*, each ball is in close proximity to a levelling screw of the balance. The position occupied by the tiltometer relatively to that of the balance, is shown in Fig. 16. When correctly adjusted, the scale

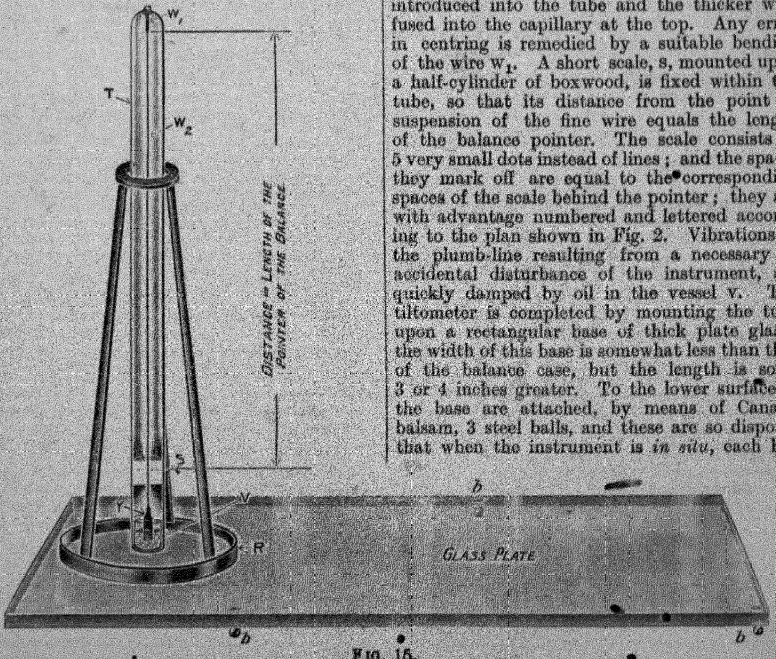

Fig. 15.

of the instrument and that of the balance pointer are in one and the same horizontal line, and they are contained by a vertical plane common to both.

With the tiltometer placed as indicated, it is evident that any vertical movements of the levelling screws resulting from a flexure of the bench, are also imparted, and in the same degree, to the tiltometer. Such movements, provided they are strictly equal, are not detrimental, and they pass undetected; but unequal flexures effect a change in level; and any appreciable change taking place along a line joining the two ends of the balance case, is recorded and may be measured by the tiltometer.

The tiltometer tube is protected by surrounding it with a metal guard, the base of which is a heavy brass ring R; this ring is prevented from being easily moved by smearing its under surface with resin cerate. The tube and its guard have no direct contact. For a series of weighings we proceed as follows:—

The telescope is first brought opposite the tiltometer and the position of the plumb-line determined with the aid of the micrometer. Next, the telescope is moved along until the scale behind the pointer appears in the field of view; the weighing is then carried out with all due precautions. Lastly, the tiltometer is re-observed: if the former and latter readings are identical, and they rarely differ within so short a time, the data for the weighing may be accepted; otherwise the experiment is rejected and a new one undertaken. When carrying out a new weighing at a later hour or on another day, the tiltometer reading may be slightly larger or smaller; but given an accurate knowledge of any such difference δ, the new weighing is easily reduced and made strictly comparable with the first, by the addition of ±δ to the second value obtained for the resting point, R.P., of the beam.

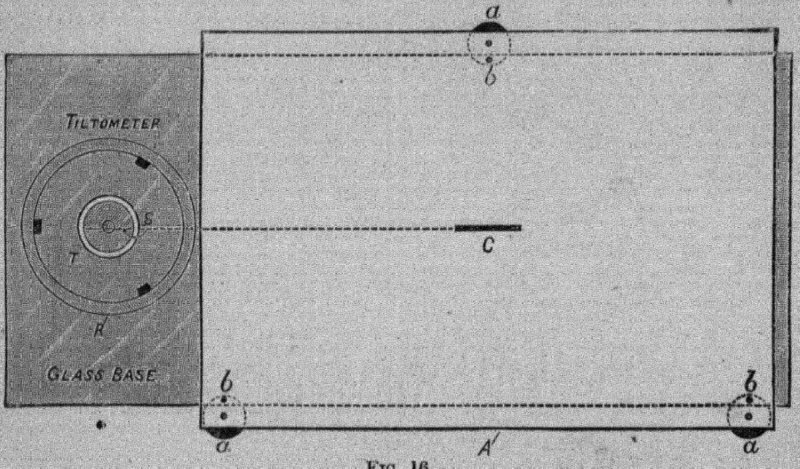

FIG. 16.

(7) *The Telescope and its Carriage.*—For observing the vibrations of the pointer, the best and most convenient plan is probably that in which the telescope is mounted upon a firm bench at a distance of approximately 2 metres from the balance. In order that the pointer as well as the tiltometer of the preceding paragraph may be readily and successively viewed, the telescope is placed upon a carriage having for its guide, a V-groove cut at right angles to the line of vision as shown in Fig. 17. The carriage has three supports; two consist of brass balls, which rest in the groove: one of those B is seen in the figure. The third support is a broad wheel W of boxwood. Easy and smooth movement is ensured by lubricating the groove with tallow. In order that the tiltometer (*vide supra*) may be read with accuracy, the eyepiece of the telescope is fitted with a horizontal micrometer M, graduated to 0·01 mm.

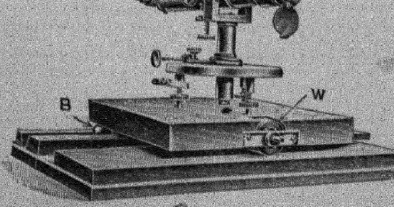

FIG. 17.

(8) *Of the Necessity for Fatiguing the Beam.*—Although from the practical point of view, a balance beam may in itself be perfectly inflexible, it is as yet impossible to so incorporate the knife edges that they and the beam shall constitute one absolutely rigid whole. On releasing a loaded beam, the consequent stresses bring about slight relative movements of the several knife edges and their screws. Such movements frequently affect, although in minute degree only, the ratio of the lengths of the balance arms. The time required for their

completion varies not only with the balance, but also with the load, and it may range from few to many minutes; but, in general, a period of from 10 to 15 minutes suffices. Now, from the above, it will be evident that no weighing can be of definite value, unless the knife edges have already assumed truly normal positions; and in order that they may do so, the balance must be *fatigued*. This simple operation consists in allowing the beam to vibrate, for an appropriate time, after the pans have been loaded and the weights adjusted for weighing; the beam is perfectly fatigued when successive R.P. determinations agree. Having reduced the balance to a normal state, the actual weighing is undertaken; and for this the crank handle is first cautiously turned, so that without in any way relieving the instrument of its load, one of the arrestors is momentarily and very gently made to lift its pan and thus cause the beam to re-oscillate. Several vibrations having passed unrecorded, the usual observations for the determination of the R.P. are carried out. The above remarks concerning fatiguing, are equally applicable in the case of an 'unloaded' balance. In Fig. 18 we have an illustration typical in character and magnitude, of initial knife-edge movements. The curve there shown, and in which successive R.Ps. are graphed against corresponding time intervals, represents the results of an experiment with a highly inflexible beam of the cantilever form. The movements, at first of an oscillatory nature, die away, and finally the R.P. acquires a constant value.

If for any reason the loaded beam is arrested, the balance must again be fatigued before a final weighing is proceeded with. When it is necessary to readjust the position of the rider upon the fatigued beam, the operation may be carried out without detriment, by first slowly raising the pan arrestors until they are in such a position that, although they do not support the loaded pans and so relieve the beam, they reduce the vibrations to a very small amplitude.

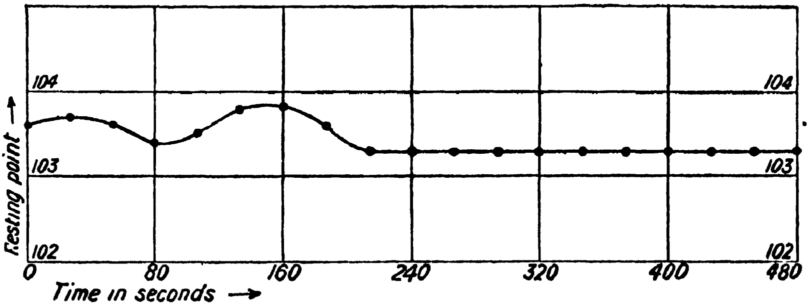

FIG. 18.

(9) *Device for maintaining Uniformity in the Temperature of the Beam.*—If a differential bolometer is arranged within a balance case, so that its two resistance coils are separated by a distance equal, say, to the length of the beam, it is easy to show that small and rapid fluctuations in the temperature of the air are continually taking place, even when the case is closed. On lifting the shutter, the fluctuations become more marked, and during the loading of the pans they are, comparatively speaking, quite violent. A pair of sensitive mercury-in-glass thermometers similarly placed, naturally fail, on account of their sluggishness, to indicate variations in temperature; they show a mean value only. In order that the highest degree of precision may be attained, it is imperative that the temperature of the air enveloping the beam should remain for at least some time, both before and during the process of weighing, strictly uniform. The required uniformity may be ensured by the device illustrated in Fig. 19.

As may be seen, we have here, in addition to the usual balance case, a small inner auxiliary chamber which completely encloses the beam. The base plate *c*, *d*, of this chamber, is of aluminium, having a thickness of 2 mm. or more; it is suitably slotted and perforated for the passage of the pointer and hooks by which the pans are suspended. The ends E, F, are conveniently made of well-seasoned mahogany, having a thickness of 1 cm. The front, back and also the top of the chamber, are of 8–10 mm. thick plate glass. The front of the chamber may be removed and the beam thus rendered accessible, after dropping the holders *h*, *k*. Discs *r*, *s*, *t*, of thin aluminium, are fastened to the pointer and pan hooks a little below the base

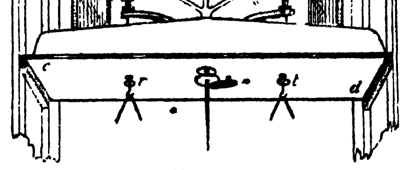

FIG. 19.

plate; these screen the apertures immediately above them. When placed within the auxiliary chamber, a differential bolometer recording variations as small as $\frac{1}{5000}$° C. remains quite unaffected, even during the loading of the pans. The decided advantage held by the protected over the unprotected beam is very well shown in Fig. 20. The groups *a*, *b* are the bolometer records obtained when, using 9 weights, one of the pans was loaded and unloaded six times in succession. During the experiments, the position of the bolometer near the beam remained unchanged.[1]

(10) *Temperature Coefficients of a Balance.*—Other conditions being constant, the R.P. of a beam will, in general, vary simultaneously with the temperature; therefore, unless the balance is thermostatically controlled, we must know with considerable exactitude the *temperature coefficient k* of the instrument. The value of *k* will vary with the balance and also with its load; but for a given balance, the several values of *k* for different loads may be determined as follows:—

Commencing at an early hour, when presumably the temperature of the room is at its lowest, and with the pans as the only load, the beam is released and duly fatigued; the R.P. is then found and the thermometer in close proximity to the beam read. Using hot-water pipes, an electric radiator, or a gas-fire, the temperature of the room is next raised by about 2° C.; a little later the R.P. is re-determined and the thermometer within the balance case read a second time. Proceeding in this way step by step, a total range of temperature of some 10° or 12° C. is covered. Finally, the room is allowed to reassume its original temperature, or approximately so, and a last determination of the R.P. for this series made. If the first and last members of the series are in agreement, the R.P. values for the higher temperatures should be reliable. From the data thus obtained, a temperature coefficient curve is now prepared by plotting the R.P. values against those for the corresponding temperatures; the resultant graph enables us to discover the true R.P. for any temperature falling within the experimental limits and for the particular load employed. (In this case, the so-called zero load.) Extrapolation should never be resorted to; for *k* may at any other temperature assume a distinctly different value; its sign may even be reversed: and so *k*, from being an additive, may become a subtractive quantity. Usually, it will be sufficient if the temperature of the beam is known to 0·05° C. The thermometer is placed horizontally within the auxiliary case.

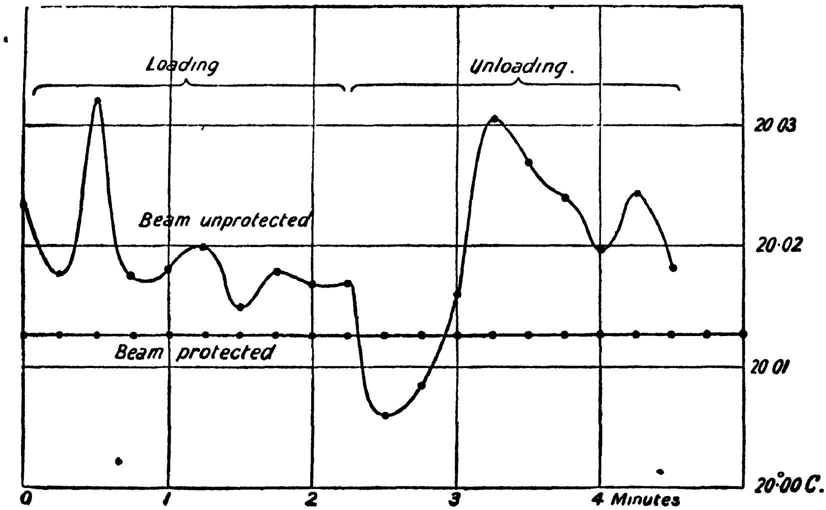

FIG. 20.

With the completion of the above, further operations identical in kind are proceeded with; and unless the balance develops abnormal behaviour, experiments with four additional loads will suffice. For a 200-grm. balance, the several loads may conveniently be 50, 100, 150, and 200 grms. The results obtained with each of these loads are, as before, represented by smoothed graphs, all drawn upon one and the same sheet. Often these graphs are of the same family; with such a group we may, for the given range of temperature, make use of interpolated values for drawing the temperature coefficient curve corresponding to an intermediate load. Finally, the whole series is completed by a re-determination of the R.Ps. for the unloaded pans: the value of all the results is thereby greatly enhanced.

Characteristic curves for *k* for a 200-grm. balance are reproduced in Fig. 21. The two dotted line curves were derived from interpolated values.

---

[1] An excellent plan is to permanently set up a differential bolometer in the immediate vicinity of the beam; the thermometric condition of the enveloping air can then be readily tested at any time.

(11) *The Suppression of Air-streams about the Pans*—Increased accuracy is secured and labour saved, by adopting some plan whereby uniformity in the temperature of the air surrounding the pans is ensured; one that in practice has proved highly efficient is illustrated in Fig. 22.

Each pan, together with its stirrup, is enclosed by a fixed and massive brass cylinder C, having a diameter but little greater than that of the pan. The cylinders extend from the floor of the balance case, where they fit into grooves in thick brass plates PP, to the aluminium plate of the auxiliary chamber; and each is surrounded by a slightly larger cylinder B, which rests upon 3 wheels attached to C; these wheels, of which four lettered W are shown, are placed apart at an angle of 120°. By covering that portion of the fixed cylinder enclosed by B with silk, a smooth and easy movement is imparted to the latter when the handle H is pressed towards the right or left. To render the pans accessible, large rectangular apertures A are cut in the cylinders; these are opened or closed by an appropriate rotation of B. In the figure, the left-hand cylinder is open and the other closed. The interior surfaces of the cylinders are coated with a dead-black lacquer, but the exterior surfaces are polished and left unvarnished. Now, theory and practice alike show that with these conditions, a temperature uniform in the highest degree, and one, moreover, unsusceptible to any but slow variations, is quickly established. But given uniformity in temperature, it follows that within a space so limited and confined, winds or air-streams are non-existent; and therefore the minor irregularities ordinarily arising from convection currents about the pans, are avoided.

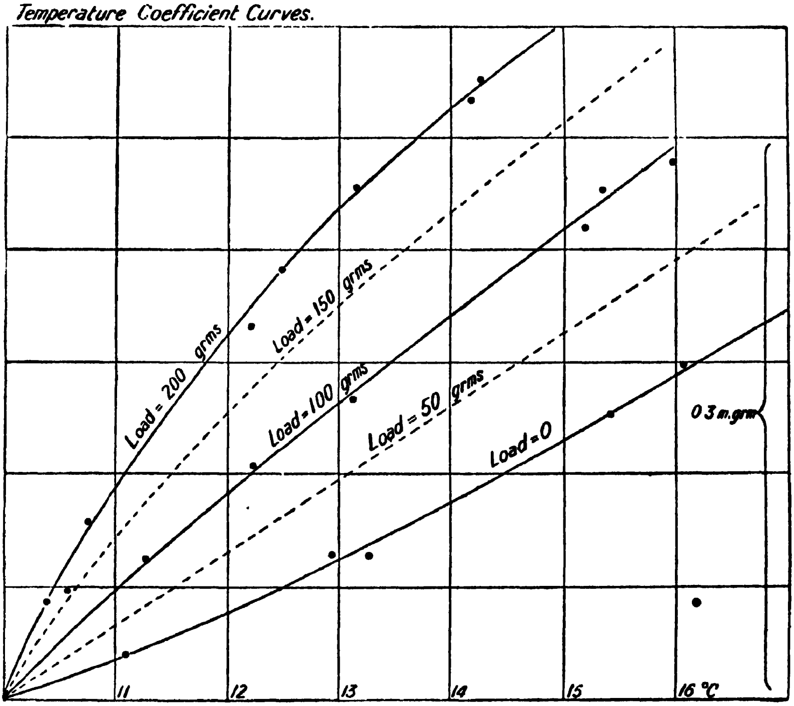

FIG. 21.

(12) *Concerning the Wiping of Glass Vessels.*—For glass vessels that are to be weighed with any degree of refinement, a most careful wiping is an indispensable preliminary; and in making choice of material for the purpose, some discrimination must be shown. Theoretical considerations verified by experiment, lead to the conclusion that in all probability it would be difficult to discover anything superior or equal to silk; this substance possesses a very low heat conductivity; and during use good specimens show a remarkably small tendency for casting off loose filaments. Objection is sometimes taken to the production of electric charges; but from the practical point of view, the ground upon which the objection is based is more imaginary than real.

During the process of wiping, direct contact between the vessel and the hand must be scrupulously avoided; more particularly so if we desire to maintain constancy of temperature. Some four or even more folds of silk should intervene between the hand and the vessel; and if at the same time the hands are thickly gloved, so much the better. The vessel immediately after it has been wiped, should be transferred to the pan of the balance with the aid of a suitable lifter. When the temperature of a globe having a capacity of 200 c.c. is raised by $\frac{1}{10}$° C., the consequent loss in buoyancy results in an apparent increase of weight equal to $\frac{1}{10}$ mg. A slightly warmed vessel reassumes its original temperature with extreme slowness; hence the desirability for guarding against any change in its temperature.

(13) *Of the Precautions to be taken in weighing Glass Vessels.*—In weighing glass vessels, sealed or open, special difficulties are encountered. These chiefly arise from (1) the variableness of the water skin upon the surface; (2) the fluctuating temperature and pressure of the air; and (3) in the case of closed vessels, the inconstancy of volume resulting from changes in the temperature and effective pressure within; the difficulties are still further accentuated when the vessel contains liquid matter, and more particularly so when the contents are solid. For many purposes the errors attendant upon causes (1) and (2) are sufficiently compensated by counterpoising the experimental vessels with others having very similar volumes; but some cases demand additional precautionary measures. Such measures are called for when, from the nature of the investigation, equality of *area* as well as that of volume becomes a prime necessity. Now, although two volumes may, by trial, be adjusted to almost strict equality, to secure at the same time a similar equality of area is a highly difficult problem; and yet, unless conditions are so ordered that a complete absence of moisture is ensured, a difference in the areas of a vessel and its counterpoise may well prove fatal to the object in view. This particular difficulty is surmounted in the following way:—

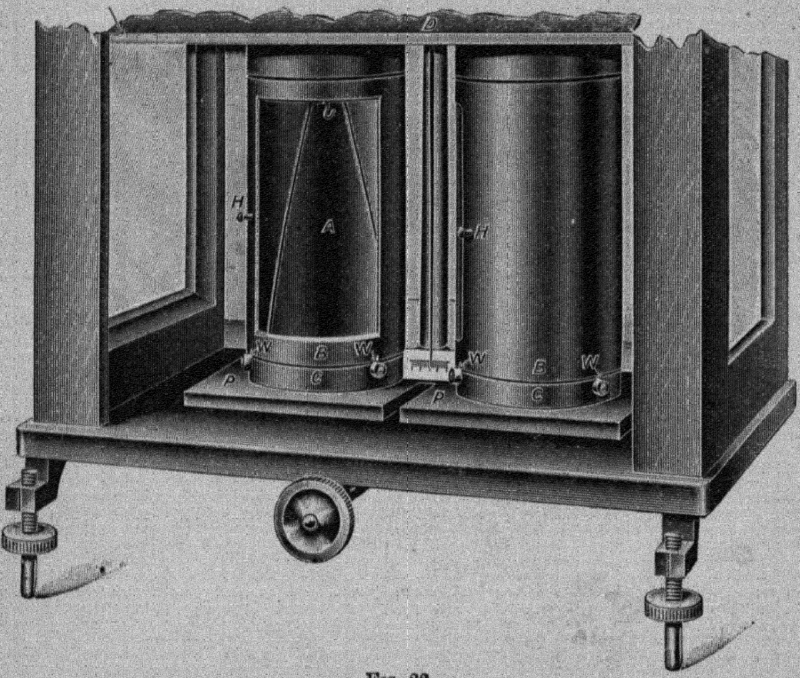

FIG. 22.

A blower is formed by fitting up a large glass jar A, as shown in the self-explanatory Fig. 23. A slow working of the Bunsen water pump *p* is all that is required for keeping the jar full of air, the pressure of which is governed by the length of the tube supporting the bulb R. On leaving the jar by way of the tap *t*, the air is by means of two further taps divided into equal streams; each stream is driven first through a Drecshel wash-bottle, and then through a spiral glass tube, both charged with concentrated sulphuric acid. The stream on emerging from the spiral, enters its own set of 3 purifying tubes; the first half of each set is packed with small fragments of soda-lime, and the second half with similar pieces of calcium chloride. Finally, the air is filtered through glass wool or asbestos, and led, first through the walls of the balance case, and then through the upper ends of the cylinders surrounding the pans. From thence either stream is delivered through a glass jet directed downwards and placed centrally within its cylinder. With the above described apparatus, any two objects (*e.g.* a closed vessel and its counterpoise), whose masses are to be subsequently compared, can be simultaneously subjected to a very perfect washing with air freed from carbon dioxide, moisture, and dust; this washing is allowed to proceed during the fatiguing of the beam. On escaping from the cylinders, the purified air displaces the ordinary air of the balance case; and as it is unnecessary to re-open the shutter before weighing, the operation is carried out within an atmosphere of standard and easily reproducible quality. A great convenience is secured if the air streams can be arrested by taps placed near the balance; these taps are closed just before the object is weighed. The plan here advocated has met with favour in several of the Oxford laboratories, where it has now been used for some years. The method might with advantage be universally substituted for the defective plan so commonly adopted with chemical and physical balances. To do this for any balance, it is but necessary to pass tubes delivering purified air, through the top of the case just above the pans or in a line with the extremities of the beam. The usual method for drying the air within a balance case has several serious objections, which cannot be discussed here.

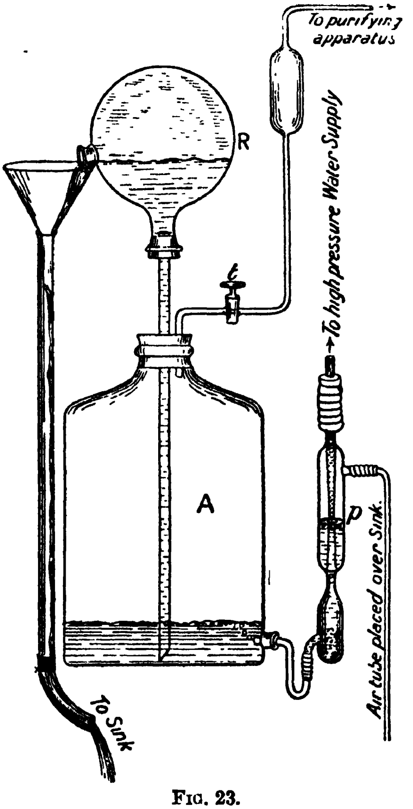

FIG. 23.

(14). *Determination of the Pressure Coefficients of Glass Globes.*—When closed vessels are weighed under different pressures, it is important that the vessel and its counterpoise possess not only similarity of form and volume, but also walls of equal thickness, otherwise compensation may be imperfect and vary with the pressure.

The pressure coefficients of expansion of globular vessels may be compared and accurately measured with the aid of the apparatus indicated in Fig. 24. The taps having been temporarily removed, either globe is introduced into the bell jar A, and its neck passed up through an airtight cork securely fixed in the mouth of the jar; a glass tap, connected with a sealed mercury manometer *m*, is then fused at *d* to the neck of the globe, and the open end of the jar closed by a stout brass plate *p*; the plate may be attached with Faraday cement or marine glue, both of which are insoluble in water and readily soften with heat. Next, through a hole in the cork made for the reception of the tube T, air-free water is introduced until the jar is completely filled; the tube T, also filled with water, is then placed *in situ*, and its fine capillary jet kept immersed in water as shown.

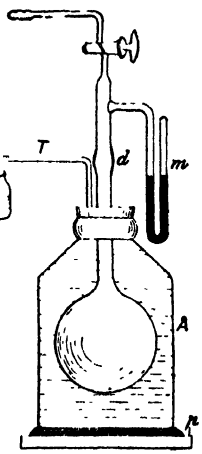

FIG. 24.

In measuring the pressure coefficient, a small weighed bottle is first substituted for that usually kept beneath the jet; air is then forced into the globe until the desired pressure is indicated by the manometer; as the pressure distends the globe, water is ejected into the bottle; this is weighed and the expansion resulting from the pressure calculated. If a series of pressures be applied, their values may subsequently be plotted against the corresponding expansions; from the graph thus obtained expansions for other pressures are readily determined. With slight and obvious modifications contraction coefficients may also be measured.

(15). *Of the Apparent Change in the Weight of a Cooling Body.*—When it is necessary to heat a body before its weight is determined, ample time must be allowed for the subsequent cooling. The time required for a hot body to assume the temperature of the balance case is greater than one would in general suppose. The importance of delaying the weighing until the object has acquired the temperature of the surrounding air is admirably illustrated in the following Fig. 25.

The data for the above graph was obtained as follows: A No. 00 B.P. crucible was heated to bright redness for some time and then removed from the flame. When the crucible was no longer *visibly* hot, it was placed upon the balance and immediately weighed under ordinary conditions; this weighing was followed by others at convenient intervals until 9 weighings in all had been carried out. During the period of half an hour required for the experiment, the weight of the crucible was constantly growing, at first rapidly, and then slowly; and notwithstanding the smallness of the mass, its limited surface and the free cooling in air, the apparent weight of the crucible had not attained a maximum value when the experiment was terminated. The observed changes in the apparent weight result from a summation of various effects of which the following appear to be the chief.

1. An apparent *increase* in weight due to (α) the gradual re-condensation of moisture upon the glazed surface; (β) a slight increase in the length of the arm supporting the object pan; (γ) the re-absorption of air and moisture by the porous mass of the crucible; and (δ) the lessened buoyancy of the heated air immediately enveloping the crucible and balance pan.

2. An apparent *decrease* in weight due to ascending convection currents which tend to lift the object pan.

The lengthening of the balance arm noted in 1 (β) is effected by the heated air rising from the cooling crucible. The re-absorption of air and moisture (1, (β)) by the general mass of the porcelain was rendered possible by the entire absence of glaze upon the bottom of the crucible. When the crucible is completely glazed, the internal condition of the porcelain remains presumably for all practical purposes, strictly constant.

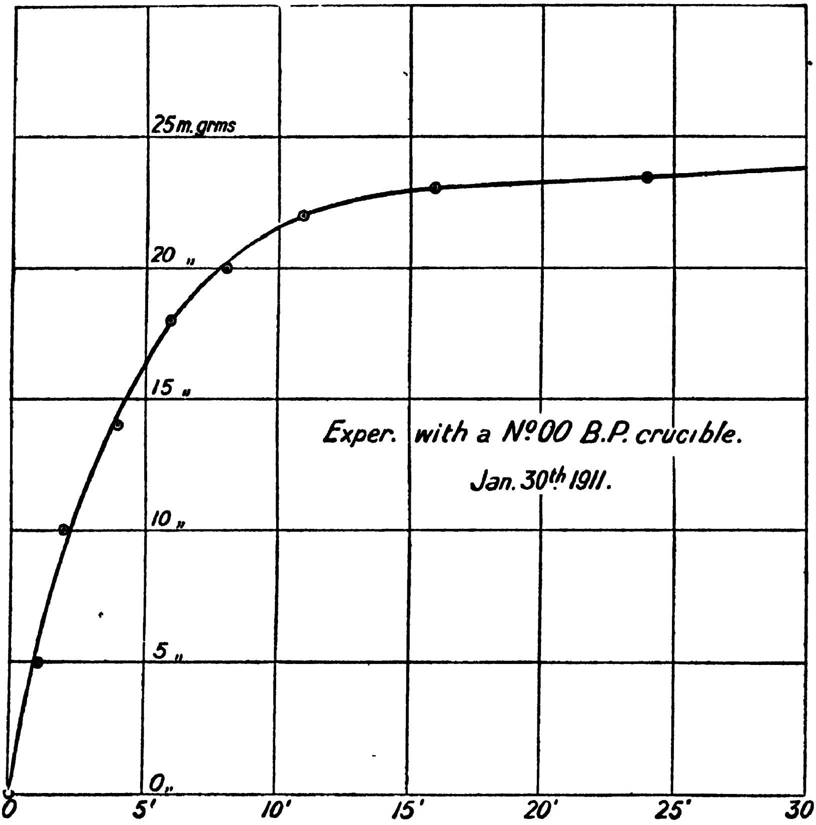

FIG. 25.

(16) *Concerning Ordinary Balance Cases.*—(*a*) With few exceptions the top of the usual balance case consists of a sunk glass panel *a*, *b* (Fig. 26); this is a constructional defect which we remedy in the following way. A strip of velvet *p* about an inch wide is fastened by means of thin glue or seccotine along the four sides and near the edges of the top of the balance case, as shown in the accompanying Fig. 26.

When the glue has hardened, but not before, a piece of plate glass AB, sufficiently large to just overlap the rectangle is placed upon the velvet. The velvet surface not only grips the glass and thus prevents it from being readily disturbed, but also acts as a highly efficient filter and so prevents dust from penetrating to the ordinary panel within. The added panel is easily dusted, and during the cleaning we do not as before incur the risk of forcing dust between the glass and the supporting surfaces and so to the interior of the balance case.

(β) The case of a precision balance should be opened or closed by sliding rather than by hinged doors. When a hinged door is opened the pressure of the air within the case is momentarily lowered; in consequence of this, the external air rushes through the innumerable crevices in the framework, and sweeping before it the erstwhile quiescent dust, charges the space within with floating particles. This fact may be verified by conducting an experiment in bright sunlight; on opening the door the sunbeams at once reveal the incoming dust.

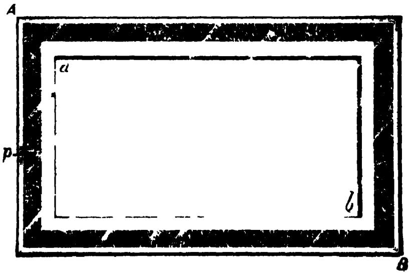

Fig. 26.

(γ) All sliding doors should run with great smoothness, and they should be fitted with counterpoising weights after the manner of ordinary window sashes. Shutters that are arrested by clutches are highly objectionable. During the working of a clutch vibrations are set up, and these are communicated to the balance with detrimental effects.

(17) *Of the Different Methods of Weighing.*—An article on weighing is incomplete unless it contains some allusion to the several methods available for accurate work; but those methods are so well known both in theory and practice that the briefest outline will here suffice. To begin with, we take it as granted that an experimenter seeking for high precision would use the method of vibrations for ascertaining the R.P. of his balance; in the preceding article this matter has been dealt with by the late Prof. Dittmar; and, therefore, further comment would appear uncalled for. Secondly, apart from the common differential method used by chemists and physicists for much of their work, there remain (1) the method of Borda, and (2) that introduced by Gauss.

(1) In Borda's method the object to be weighed is placed in either pan, and then accurately counterpoised by any convenient unknown masses; such masses may consist of indifferent brass weights, lead shots, fine sand, &c. When the adjustment is complete, standard masses are substituted for the object, and these are varied until equilibrium has been re-established. Given unchanging conditions, it is obvious that the total weight of the standard masses equals the sought-for weight of the body. To this method may be opposed the two objections: (α), its tediousness and (β) the impossibility of adjusting two initially different magnitudes to *precise* equality. These objections are so weighty that Borda's method is, comparatively speaking, but seldom used.

(2) Following Gauss and using the method of vibrations, the R.P. is found with the object first in one pan and then in the other; two determinations, d_1, d_2, of the R.P. are thus obtained. Then if S be the sensibility of the balance in mg., the ***difference*** D between the weight of the standard mass employed and that of the object is given by the equation

$$D = \pm \frac{d_1 - d_2}{2} . S \text{ mg.}$$

and the apparent weight of the body is thus determined. The superiority of this method over others is based upon a principle well understood by physicists, that in general it is easier to determine with accuracy by how much two magnitudes differ than to discover the true value of either.

For some further information upon the very important subject of highly refined weighing, the reader may be referred to (1) 'The Limitations of the Balance,' B. Blount, Chem. Soc. Trans. 1917, vol. cxi. 1035, (2) 'Vacuum Balance Cases,' Blount and Woodcock, Chem. Soc. Trans. 1918, vol. cxiii. 81; (3) 'Observations on the Anomalous Behaviour of Delicate Balances,' Manley, Phil. Trans. Series A, vol. ccx. 387-415; (4) 'On the Apparent Change in Weight during Chemical Reaction,' Manley, Phil. Trans. Series A, vol. ccxii. 227-260; (5) 'Observed Variations in the Temperature Coefficients of a Precision Balance,' Manley, Proc. Roy. Soc. A, vol. lxxxvi. 591-600; and (6) 'Dependence of Gravity on Temperature,' Southerns, Proc. Roy. Soc. A, vol. lxxviii. 393. As the above third-named paper contains references to other papers bearing upon the same subject, it is unnecessary to repeat them here.

In concluding this particular branch of an interesting subject, we may state that by availing ourselves of all precautions at present known to us, it has been found possible to attain the accuracy of ± 1 in 2 × 10^8 or thereabouts.

Micro-balances.—For the accurate determination of extremely small masses, instruments known as *micro-balances* are used. These are of two types; the action of the one depends upon torsion, and that of the other upon gravity; but of the two the latter has been the more successfully and highly developed. Nernst and Riesenfeld (Ber. 1903, 36, 2086) described a torsion balance sensitive to 0·0005 mg. with a load of several milligrams (for applications of same, *v.* Jänecke, Zeitsch. anal. Chem. 1904, 43, 547; Brill, Ber. 1905, 38, 140; Brill and Evans, Chem. Soc. Trans. 1908, 93, 1442). The zero of this balance is inconstant, and its sensitiveness varies greatly with the load. Gravity balances have been made by Steele and Grant (Proc. Roy. Soc. 1909, A. 82, 580), and modified by Gray and Ramsay (*ibid.* 1911, A. 84, 536; 1912, A. 86, 270), to carry loads ranging from 1 or 2 mg. to 1 decigram with a sensitiveness of 1×10^{-7} to 4×10^{-9} grm. The zeros of these balances remain constant over long periods of time.

The beam, consisting of thin silica rods fused together to form a framework as shown in Fig. 27, has a length of 10 cms (in Fig. 28 (*a*) a beam having a more rigid type is represented). The quartz knife edge rests upon a highly polished and truly plane quartz surface secured to the top of the brass pillar B

The vibrations of the balance are observed by means of a beam of light introduced through the window C and reflected by a tiny platinised quartz mirror fused to the beam at D; with the mirror in this position, its angular movements are not accompanied by appreciable ones of a translational kind. The reflected light falls upon a vertical mm. scale placed at some convenient distance from the mirror. The three-way tap E allows the interior of the balance case to be put into communication with either the atmosphere or a vacuum pump; the manometer F records the pressure within the case. A fine quartz thread fused to the beam at G supports (i.) a quartz bulb H of known volume V c.c. (either filled with air or vacuous), (ii.) the scale-pan J, and (iii.) a quartz counterpoise K. The whole hangs within the tube L (fitted to the case by the ground glass joint M), and is counterpoised by a solid bead of silica fused to the beam at N. A little uranium oxide inside the case ionises the air and eliminates disturbing electrical effects; and calcium chloride in L keeps the interior dry.

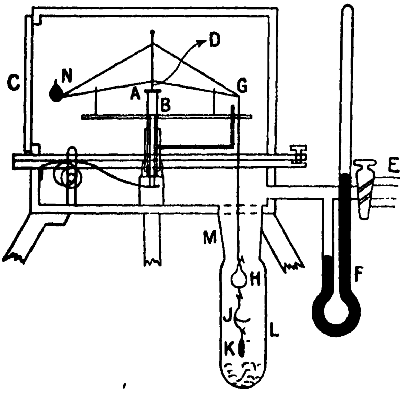

FIG. 27.

To perform a weighing, the pressure in the case is suitably lowered (to P_1 at temp. T_1 abs.), and the position of the reflected spot of light on the scale taken as the zero. The substance is then placed on the pan J, and a new pressure (P_2 at temp. T_2 abs.) determined under which the zero of the balance is recovered. The weight of the substance is then given by the expression (σ_0 = wt. of 1 c.c. air at N.T.P.)

$$\frac{273V\sigma_0}{760}\left(\frac{P_2}{T_2}-\frac{P_1}{T_1}\right)$$

The usual vacuum correction is, of course, necessary. Only weights less than the weight of air that the bulb can hold may be thus determined. To measure greater weights, the counterpoise K is replaced by a lighter one; a series of such counterpoises is required, and the differences between their weights may be measured on the micro-balance itself. It is convenient to make the bead N counterpoise the bulb, scale pan, and a set of weights (Fig. 28 (*b*)) (ranging from 2 to 0·1 mgm. and made from capillary quartz tubing: these are calibrated on the balance). In weighing a substance, weights are removed to obtain a coarse adjustment; the pressure within the case is then altered, thereby making the (variable) buoyancy of the air on the bulb H effect the fine adjustment. The absolute accuracy of the weighings is limited to the accuracy with which V may be determined; their relative accuracy is much greater.

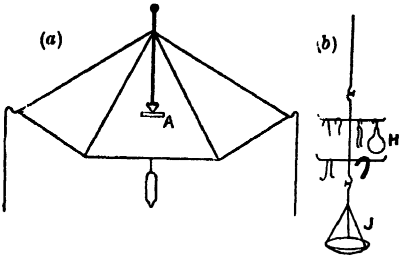

FIG. 28.

In a balance constructed by Steele and Grant, the beam, &c. weighed 0·93 grm., the bulb H had a capacity of 0·422 c.c. and contained $5{\cdot}04\times10^{-4}$ grms. of air; the balance had a period of 33 secs., and was sensivitive to 4×10^{-8} grm.

The micro-balance of Gray and Ramsay has been modified by Hans Pettersson (Göteborgs, Vet. Vitterh. Samf. 1914, 14th series, xvi). In the altered form the central knife edges are dispensed with, and the beam suspended, as shown in Fig 29, by two thin quartz fibres, which are highly attenuated at their points of junction with the horizontal rod. Pettersson also greatly improved the balance case; and for a vacuum-tight cement he uses an alloy having a low fusing-point. Further, the beam arrestment is magnetically controlled through the top of the balance case; in this way, certain sources of error, due to possible air leakage, are avoided.

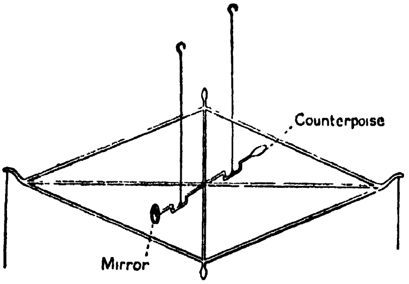

FIG. 29.

R. Strömberg (Annalen, der Physik. 1915, 47, 939), has improved the Pettersson balance, and at the same time increased its sensibility by the substitution of detachable for fixed threads. The form of the Strömberg suspension is shown in Fig. 30, and the complete Pettersson-Strömberg beam and its accessories in Fig. 31. To the axial rod of the balance are attached (1) a tiny screw

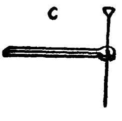

FIG. 30.

, for adjusting the centre of gravity, and (2) a minute plane mirror *m*, for indicating with the aid of reflected light the angular position of the beam. A section of the complete balance is shown in Fig. 32. An instrument of this type when carrying its maximum load of 50 mg., may apparently have a sensibility as high as ·01 μ-mgrm. (1×10^{-11} grm.). The Pettersson-Strömberg balance has been used for testing the validity of Poynting's law at high temperatures, for measuring the volatility of silica at 800° C., and also for the accurate determination of the diamagnetic constants of gaseous hydrogen and nitrogen.

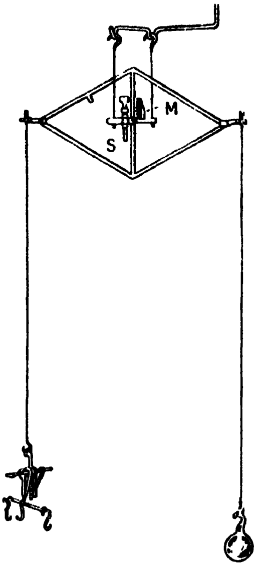

FIG. 31.

A simple form of micro-balance for determining the density of a gas has been described by F. W. Aston (Proc. Roy. Soc. 1914, A. 89, 439). The balance, which is made entirely of quartz, is represented in Fig. 33. The beam consists of two thin rods fused together as shown; the lower end of the shorter rod, *k*, terminates in a knife edge which rests upon a quartz plane. To one end of the beam is fused a bulb *b*, having a capacity of about 0·3 c.c., and to the other the counterpoising rod *r*. The case, made of rectangular pieces of plate glass, is as diminutive as circumstances permit; the cell containing the beam is not more than 3 mm. wide, and its volume is a few c.c. only. A special chamber *c*, which is cemented to the left end of the case, is closed by the stopper *s*, which is pushed in until it just fails to touch the contained bulb. One limb of a T-tube having a capillary bore, gives access to the interior of the balance case; the second limb is fused to a mercury manometer, and the third to a 3-way tap. By means of this tap communication between the balance

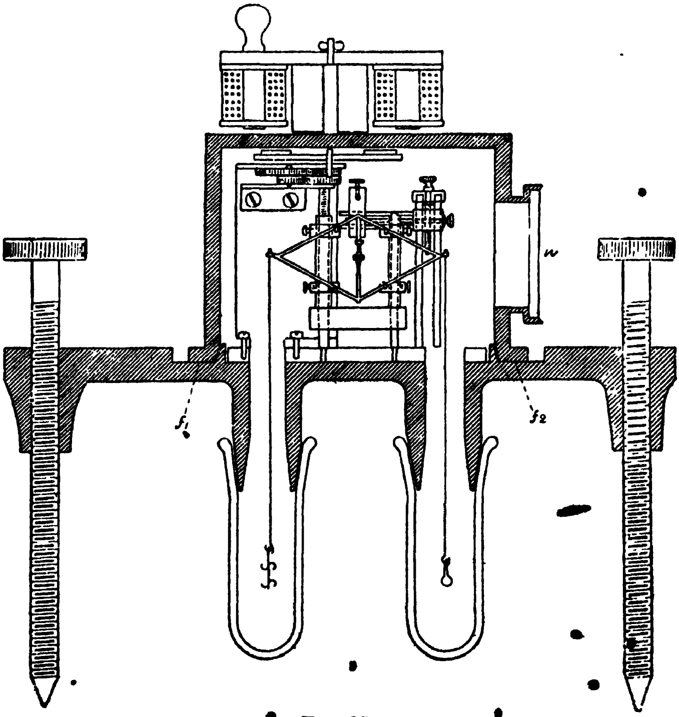

FIG. 32.

and an air-pump or the gas-admission apparatus can be established. With the above described apparatus the density of a gas is usually determined at a pressure of about 100 mm. of mercury Measured at N.T.P., the volume of gas actually required for an experiment is approximately 0·5 c.c. A density determination is carried out as follows: The balance case is first highly

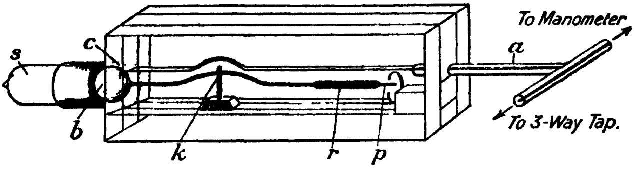

FIG. 33.

exhausted, then the gas of which the density is sought is admitted until the bulb rises and the point *p* of the counterpoise appears in the field of a fixed reading microscope. The pressure is then varied until the beam comes to rest at some convenient but quite arbitrary zero, and the manometer read. Finally, the case is re-exhausted and the experiment repeated with a gas of known density. The ratio of the densities of the two gases is equal to the inverse ratio of the corresponding pressures The determination can be made in a few minutes, and with an accuracy of from 0·1 to 0 01 p.c. For accurate measurements Aston's micro-balance needs, no less than the heavier precision instrument (*vide supra*), a preliminary fatiguing. This operation appears to be best carried out by maintaining for some days a high vacuum within the balance case.

Riesenfeld and Möller (Zeitsch. Electrochem. 1915, 21, 131) describe a form of micro-balance for which they claim a sensibility of $3{\cdot}3 \times 10^{-8}$ grm., when the balance is carrying its maximum load of 5 mg. The beam is a glass capillary tube 13 cms. long; this is supported by a quartz thread attached at a point 3 cms. from one end. A mirror, made from a quarter of a microscope cover glass, is secured to the end of the shorter arm, and from the other end of the beam the pan is suspended. Various ways of supporting the pan are described, but the most successful for high sensitiveness is that obtained by fastening a quartz thread horizontally and at right angles to the end of the arm. From this is hung the quartz thread which carries the pan. The arrestment consists of a clamp of two feathers, placed near the end of the longer arm.

Kramer (Chem. Zeit. 1917, 41, 773) has constructed a micro-balance of the usual type, with a carrying capacity of 1 grm. The length of the beam is 154·4 mm., and the weight 7·825 grm. When the balance is unloaded the sensibility is equal to 48 divisions per 0·1 mg, this decreases to 35 divisions for a load of 100 mg., and to 10 divisions for a load of 1000 mgr. A division equals 0 35 mm

The *micro-assay balance*, known in Germany as a 'Mikro-Chemische Wagen.' is a chemical balance in miniature, it stands as it were midway between the high grade chemical balance of precision and the true micro-balance of Steele and Grant and others. The beam, which may have a carrying capacity of from 1 to 20 grms., is rigid and exceptionally light; some of the more modern beams are also extremely short. First-class instruments have a high sensibility, and when lightly loaded the beam will usually indicate differences in weight ranging, according to the sensibility of the balance, from ·05 to ·005 mg.

Fig. 34 represents a highly sensitive micro-assay balance by Kuhlmann of Hamburg. The beam, which is 7 cms. long, is built to carry a maximum load of 20 grms. in each pan. The sensibility is such that each scale division corresponds to ·01 mg.; and by a special device for reading tenths of a scale division, differences in weight as small as ·001 mg. can be observed.

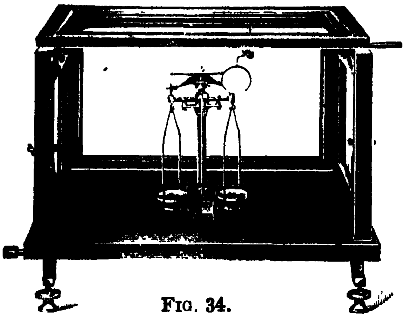

FIG. 34.

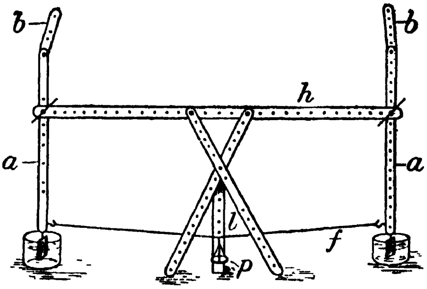

FIG. 35.

It may be unnecessary to add that the remarks and suggestions that have been made in connection with the heavier balance of precision are equally applicable to the assay balance.

A simple form of micro-balance for use in bacteriological laboratories, has been described by Shaxby (Proc. Phys. Soc. of London, 1919, 32, 21. The instrument is for loads varying from 0·005 to 0·5 grm.; its sensibility and 'dead-beat' character are such that weighings may be carried out rapidly and with an accuracy of from one to two parts per thousand. The balance (Fig. 35), constructed of 'Meccano' strips, consists essentially of three parts: (1) a tripod of which the hinder leg *l* terminates in a small flat foot which can be fastened to the table by means of a drawing-pin; (2) a horizontal strip *h* 2 feet long secured to the top of the tripod; and (3) a pair of compound vertical arms each consisting of a 25-hole strip *a* to the upper end of which is bolted a 6-hole strip *b*; each arm is suspended at a point just above its centre of gravity by means of a silk thread *f* passing through a glass tube T (Fig. 36), having rounded edges and a length of ¼ inch; the ends of the thread are held as shown by wire pins *pp*. The required 'dead-beat' action is obtained by immersing the aluminium vanes with which the arms are provided in water (Figs. 35 and 37). The balance is completed by linking the arms together with a fibre *f* (Figs. 35 and 37) of unspun silk from the central point of which is suspended a paper pan *p* for receiving the objects to be weighed. For weighing slips of paper before and after the absorption of a liquid, an aluminium clip *c* (Fig. 38) is substituted for the pan shown in Fig. 35. The balance is adjusted by varying the inclination of the strips *bb* (Fig. 35); and by the same means the tension of the thread and therefore the sensibility of the instrument can be altered. Before use the balance must be calibrated; and this is done by placing in the pan, each in turn, a series of five weights equal to one-fifth, two-fifths, &c., of the maximum load, and noting the resulting depressions of the central point of the fibre *f* with the aid of a vertical mm. scale placed behind it: the requisite precautions are, of course, taken to avoid parallax in reading. Weight values are now plotted against corresponding depressions and a smooth curve termed a *weight curve* drawn. To determine an unknown weight the object is placed in the pan or clip and the resulting depression read: this being known the weight with the aid of the graph can be ascertained. J. J. M.

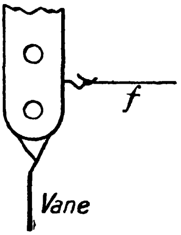

FIG. 37.

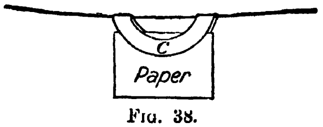

FIG. 38.

BALANOPHORE WAX *v.* WAXES.

BALATA is the product obtained by coagulating the latex of *Mimusops globosa*, Gaertn., a large forest tree, belonging to the natural order Sapotaceæ, which is a native of British, Dutch, and French Guiana, Venezuela, Trinidad, Jamaica, and probably Brazil north of the Amazon. In British Guiana and the West Indies the tree is known as the 'bullet' or 'bully' tree.

In physical properties and chemical composition, balata resembles true guttapercha, for which it is the best natural substitute, and it is of interest in this connection that the tree yielding it belongs to the same order as the trees (*Palaquium* spp.) which furnish guttapercha.

The balata trees are tapped by making a series of incisions in the bark, so arranged that the latex can run down to the base of the trunk, where it is collected in a calabash. The latex is afterwards poured into shallow wooden vessels, which are usually greased or rubbed with soap to prevent the balata from adhering to them, and allowed to stand exposed to the air until it has coagulated spontaneously; a sheet of balata is thus formed, which, when sufficiently hard, is removed from the vessel and hung up to dry. The coagulation of the latex may also be brought about by boiling, in which case the balata is obtained in the form of 'block.' Formerly it was the custom to fell the trees and then to cut rings in the bark in order to obtain the latex, but this practice, which involves the destruction of the trees, is now prevented as far as possible.

The latex of balata trees usually flows freely, and, in favourable circumstances, the yield from a tree 15–20 inches in diameter, tapped to a height of 8 feet, is about 3 pints, representing from 1½ to 2 lb. of dry balata.

Commercial balata may be either grey, pinkish or brown. When immersed in hot water it behaves like guttapercha, becoming soft and plastic, and, on cooling, it slowly hardens again without becoming brittle.

Balata is also similar to guttapercha (*q.v.*) in chemical composition, consisting essentially of a hydrocarbon (*gutta*), of empirical formula $C_{10}H_{16}$, associated with resins; the commercial product also includes varying amounts of insoluble matter (dirt) and moisture. Balata contains a much higher proportion of resins than good guttapercha, and is therefore inferior in quality to the latter; when compared with

guttapercha containing a similar amount of resin, it is found to be a little softer and more flexible.

The composition of Balata is shown by the following typical analyses:—

Description.	Source.	Moisture per cent.	Gutta per cent.	Resin per cent.	Proteid per cent.	Dirt per cent.	Ash per cent.
Specially prepared sheet [1]	British Guiana	1·9	49·7	44·0	3·8	nil	0·6
Block balata [1] . .	Venezuela	1·8	45·7	44·2	3·0	5·3	[1·28]
Commercial specimens [2,3]	Mostly British Guiana	13·8	41·5	34·8	—	9·9	—
Balata [2]	Dutch Guiana	5·3	43·5	36·9	—	14·3	—

The gutta of balata is very tenacious and of excellent quality; it is insoluble in alcohol, acetone, ether, or cold petroleum spirit, but is readily dissolved by chloroform, carbon disulphide, or boiling petroleum spirit. The resins present are similar to those of guttapercha, and consist of (1) a white crystalline resin (*albane*) soluble in hot but insoluble in cold alcohol; and (2) an amorphous yellow resin (*fluavile*) soluble in cold alcohol. An examination of the total resin of balata by Obach showed that it consisted of about 2 parts of albane to 3 parts of fluavile.

Balata is utilised commercially as a substitute for guttapercha. Its chief applications are for the manufacture of belting, in which the balata is interposed between layers of canvas; for insulating purposes; and for the manufacture of the covers of golf balls, after the removal of the greater part of the resin by solvents. It is also employed to a considerable extent for mixing with rubber, and for numerous minor purposes.

The bulk of the commercial supplies of balata are obtained from British and Dutch Guiana and Venezuela. *Cf.* Ter Laag, Caout. et Guttaperclia, 1915, 12, 8610. H. B.

BALLISTITE *v.* EXPLOSIVES.

BALLOON or FLEXIBLE VARNISH *v.* VARNISH.

BALL SODA *v.* SODA MANUFACTURE, art. *Sodium.*

BALM OF COPAIBA *v.* OLEO-RESINS.

BALM OF GILEAD. *Mecca* or *Opobalsam* (*v.* OLEO-RESINS).

BALSAMS. The exudations of plants, whether spontaneous or promoted by incisions made in their stems or roots, consist chiefly of resin, gum, volatile oil, and certain aromatic acids, or mixtures of these. The *resins* are characterised by insolubility in water and solubility in alcohol, the *gums* by solubility in water and insolubility in alcohol, and both by not being volatile without decomposition. In certain exudations the resin is dissolved in volatile oil, forming the class of *oleo-resins* of which the so-called Canada balsam is an instance. Gum arabic is a familiar instance of a gum obtained direct from the plant; mastic is an instance of a resin. The class of *gum-resins* may be represented by myrrh.

Now, amongst these resins and oleo-resins there is a group the members of which are marked by possessing a peculiar fragrant odour and agreeable pungent taste, which is due to the presence of free or combined cinnamic or benzoic acid. These are the *balsams*, and it is convenient to consider them as a class by themselves. The word 'balsam,' it is true, has sometimes been used in a wider sense—indeed, it was originally employed for an oleo-resin resembling the so-called Canada balsam; but it is more convenient to restrict the term to resins or oleo-resins which contain cinnamic or benzoic acid. The balsams have long been familiar to writers on materia medica, some of them being known to Pliny, and even earlier to the Greek physicians. They are favourite constituents of the incense used in the Greek and Roman churches, and while they cannot be said to have an important therapeutic value, they are reputed mild tonics and stimulants and are a common flavouring agent in expectorant medicines. The following are the more important:—

Benzoin. *Gum Benjamin*; *Benzoïnum*, B.P., U.S.P. (*Benzoin*, Fr.; *Benzoëharz*, Ger.). The benzoïn of Java and Sumatra is derived from the thick-stemmed trees of *Styrax Benzoin* (Dryander, Phil. Trans. 1787, 303; Bentl. a. Trim. 169), while the more highly prized Siam benzoïn is probably obtained, according to Royle, from the *Styrax Finlaysoniana* (Wall). The source of Siam benzoïn is, however, still uncertain (Holmes, Pharm. J. [3] 14, 354). The first European writer to mention benzoïn is Batuta, who travelled in the East early in the fourteenth century, and from that time to the present day the drug has been an established article of materia medica. It is largely used for incense and in the preparation of fumigating pastilles, and enters into the well-known Friars' Balsam or compound tincture of benzoïn, a favourite dressing for wounds.

The juice exudes from the trees as the result of incisions, and it is allowed to harden before it is removed. During the first three years of the life of a tree the balsam dries in the form of *tears*. This is called *head* benzoïn, and is the most highly reputed. A less esteemed variety is obtained during the following seven or eight years, which is browner in colour and is called *belly* benzoïn. Lastly, the trees are split, and the commoner *foot* benzoïn is scraped off (*cf.* Flück. a. Hanb. 405).

Benzoïn is obtained as a hard brittle mass, consisting essentially of a mixture of resins together with uncombined benzoic and sometimes cinnamic acids. The resins are entirely soluble in solution of potash and in alcohol, but by their behaviour toward other solvents they have been distinguished as *a-resin*, *β-resin*, &c. (Unverdorben, Pogg. Ann. 8, 397; Kopp, Compt. rend. 19, 1269; Van der Vliet, Annalen, 34, 177). The yield of *benzoic acid* varies from 12 to 20 p.c., being on an average about 14 p.c.

---

[1] Analysed at Imperial Institute.

[2] Analysed by Dr. Obach.

[3] Average figures for nineteen commercial lots representing 50 tons.

To extract it (1) the benzoïn may be mixed with sand and heated in a suitable vessel, over which is placed a receiver to collect the vapours of benzoic acid, which condense in beautiful tufts of acicular crystals: or (2) the benzoïn may be boiled with milk of lime, filtered, and after concentration of the calcium benzoate solution thus obtained, the benzoic acid precipitated by hydrochloric acid: or (3) the free benzoic acid may be extracted by treating the powdered resin with warm carbon disulphide. Lüdy (Arch. Pharm. 231, 43) has shown that the α-, β-, and γ- resins of the earlier investigators are mixtures of the partially hydrolysed cinnamates of the resin alcohols present, the α-resin being the least and the γ- the most hydrolysed. He also finds that benzoïn from Sumatra contains *benzoic acid*, *styrene*, traces of *benzaldehyde* and *benzene*, 1 p.c. of *vanillin*, 1 p.c. of *phenylpropyl cinnamate*, 2–3 p.c. of *cinnamyl cinnamate*, and a mixture of a little *benzoresinol cinnamate* with much *resinotannol cinnamate*, this mixture forming the main constituent of the balsam. In addition, woody impurities occur to the extent of 14–17 p.c., also free *cinnamic acid*, but to a less extent than free benzoic acid. By hydrolysis of the mixture of benzoresinol and resinotannol cinnamates the two alcohols are obtained, *benzoresinol* $C_{16}H_{26}O_2$, consisting of white crystals, and *resinotannol* $C_{18}H_{20}O_4$, a brown amorphous powder.

Siamese benzoïn also examined by Lüdy (Arch. Pharm. 231, 461) differs from Sumatra benzoïn by containing no cinnamic acid either free or combined, the main constituent being a mixture of a little benzoresinol benzoate with much *siaresinotannol benzoate*. The total amount of benzoic acid from both esters was 38·2 p.c. The alcohols obtained by the hydrolysis of the resin are present in the proportion of about 1 : 11. The benzoresinol is identical with that obtained from Sumatra benzoïn and crystallises in white prisms; m.p. 272°. *Siaresinotannol* $C_{12}H_{14}O_3$ is a brown powder very similar to resinotannol obtained from benzoïn of Sumatra. To distinguish between Sumatra and Siam benzoïn, 0·5 grm. is slowly heated to 40° C. with 10 c.c. potassium permanganate solution, when the Sumatra variety gives the odour of benzaldehyde (U.S.P.).

Benzoïn, with the exception of woody fragments always present in the cake variety, should dissolve in five times its weight of alcohol, and this solution should give with water a milky emulsion having an acid reaction; not less than 75 p.c. of Sumatra and 90 p.c. of Siam benzoïn should be soluble in alcohol. Adulteration with resin may be detected by warming with petroleum benzine or carbon disulphide, washing the benzin solution with sodium bicarbonate and then with water, and finally shaking with copper acetate solution: a green colour indicates the presence of resin.

Peru. *Balsamum Peruvianum*, B.P.; U.S.P. (*Baume de Pérou*, Fr.; *Perubalsam*, Ger.)

A dark molasses-like liquid obtained in the State of Salvador in Central America from trees of *Myroxylon Pereiræ* (Klotzsch). Description, *v.* Bentl. a. Trim. 83. Balsam of Peru was probably introduced into Europe soon after the Spanish conquest of Guatemala in 1524 (Flück. a. Hanb. 206). The bark is bruised and scorched late in the autumn, and the exudation excited by this means is collected (Flück. a. Hanb. 207; Dorat, Amer. J. Pharm. [3] 8, 302; Hanbury, Pharm. J. [3] 5, 241, 315).

Balsam of Peru sinks in water, in which it is insoluble. It has a sp.gr. of 1·140 to 1·158 (1·130–1·160 at 25°, U.S.P.). It is soluble in absolute alcohol, chloroform, acetone, and glacial acetic acid. Examined by Kraut (Annalen, 152, 129) and Kachler (Ber. 2, 512), the chief constituent of Peru balsam was supposed to be *cinnameïn*, benzyl cinnamate

$$C_6H_5{\cdot}CH:CH{\cdot}COOC_7H_7$$

Kachler's analysis of Peru balsam is:—cinnamic acid 46 p.c., benzyl alcohol 20 p.c., resin 32 p.c. *Cf.* Attfield (J. 1863, 557); Delafontaine (Z. 1869, 156) finds in addition to benzyl cinnamate, *cinnamyl cinnamate* or *styracin*. Trog. (Arch. Pharm. 232, 70) by suitable treatment has divided Peru balsam into two constituents, an oil and a resin. The liquid portion, known as cinnameïn to the earlier investigators, consists of benzyl benzoate with a small quantity of benzyl cinnamate and forms from 56 to 60 p.c. of the balsam; cinnamic acid and vanillin are present in very small proportions. The resin when hydrolysed yields cinnamic acid and a small proportion of benzoic acid and *peruresinotannol*, a resin alcohol of the formula $C_{18}H_{20}O_5$. The balsam has also been examined by Thoms (Arch. Pharm. 237, 271).

The B.P. demands that at least 57 p.c. shall remain in ethereal solution after shaking with *N*/2 NaOH solution; this portion, termed cinnameïn, must have a saponification value of not less than 235. The U.S.P. requires an acid number 56 to 84 and 50 to 56 p.c. of cinnameïn, extracted by ether from 4·5 p.c. NaOH solution; the saponification value of the cinnameïn must be 235-238.

A useful test is that 1 grm. balsam should give a clear solution with 3 grms. chloral hydrate in 2 c.c. water. Among the adulterants used have been copaiba, gurjun colophony, Canada turpentine, storax, tolu alcohol, &c. The presence of turpentine may be detected by warming 1 grm. balsam with 5 c.c. purified petroleum benzine on a water-bath; the petroleum extract on evaporation should yield no smell of turpentine and give neither green nor blue colouration with a drop of nitric acid, showing absence of resin (U.S.P.). On shaking the balsam with water, a diminution in its volume will occur if alcohol has been added; the specific gravity also gives information as to the probable presence of alcohol.

(For other modes of testing, *v.* Hirschsohn (Pharm. Zeit. 16, 81); Flückiger (Pharm. J. [3] 12, 45); Schlickum (Arch. Pharm. [3] 20, 498); MacEwan (Pharm. J. [3] 15, 236); Andrée (Arch. Pharm. [3] 22, 561); Denner (J. Pharm. Chim. [5] 18, 259). Testing of balsams, resins, and gum-resins: Pharm. J. [3] 17, 547.)

A *White Peru Balsam* is sometimes prepared in Salvador by expression from the fruit of the *Myroxylon Pereiræ*. It is a golden yellow semi-fluid granular crystalline mass containing a crystalline resin, *myroxocarpin* $C_{24}H_{34}O_3$, together with *styrolene*, *styracin*, and *cinnamic acid* (Stenhouse, Annalen, 77, 306; Pereira, Annalen, 77, 309; Scharling, Annalen, 97, 70; Harrison a. Malsch, J. 1875, 856). (For more recent investigations, *see* Germann (Arch. Pharm. 234, 641); Biltz (Chem. Zeit. 26, 436); Thoms a. Biltz (Chem. Zentr. 1904, ii. 1047); Hellström (Arch. Pharm. 243, 218). For other varieties of Peru balsam, *v.* Flück. a. Hanb. 210.)

Storax, *Liquid Storax*; *Balsamum Styracis*; *Styrax praeparatus,* B.P.; *Styrax,* U.S.P. (*Styrax Liquide,* Fr.; *Flüssiger Storax,* Ger.)

Storax balsam is derived from trees of *Liquidambar orientalis* (Miller), which are natives of Asia Minor (*cf.* Bentl. a. Trim. 107). This liquid storax is nearly related to another harder resin—the exudation of the *Styrax officinale* (Linn.). Both have been known since the later Greek period, but the latter is now no longer an article of commerce. Storax has been identified in the resins obtained from embalmed Egyptian mummies dating back about 3000 years (Tschirch and Reuter, Arch. Pharm. 250, 170). To obtain the storax the outer bark of the tree is removed, and the inner bark is collected and boiled in water. The balsam melts and rises to the surface and is skimmed off.

Liquid storax is heavier than water, about the consistence of honey, and of a greyish-brown colour. It always contains a little water, which imparts to it a greyish opacity. When this is removed, by long standing or by heat, the resin becomes quite transparent. Dried in this way it is soluble in alcohol, ether, carbon disulphide, and volatile oils; but not in light petroleum. The odour of storax is agreeably balsamic and the taste aromatic and pungent. Examined with a microscope crystals may be detected which have been identified, the feathery spicular crystals as styracin, and the rectangular tables and short prisms as cinnamic acid.

Storax contains 10 p.c. to 20 p.c. of water, 13 p.c. to 18 p.c. of woody and inorganic impurities, leaving 56 p.c. to 71 p.c. of matter soluble in alcohol, which consists chiefly of styrene, metastyrene, cinnamic acid, styracin, and a large proportion of resin (Flück. a. Hanb. 275). The alcohol-soluble part constitutes the *styrax praeparatus* of the B.P.

Styrene or phenylethylene $C_6H_5 \cdot CH : CH_2$ is obtained as a colourless mobile liquid by distilling storax with water (Bonastre, J. Pharm. Chim. 16, 88; Simon, Annalen, 31, 267). The solid polymeride of styrene, *metastyrene,* is also said to exist in storax. *Cinnamic acid* to the extent of 6 p.c. to 12 p.c. is obtained by boiling the balsam with sodium carbonate solution, which extracts it as a sodium salt from which the free acid is liberated by mineral acids.

Styracin or *cinnamyl cinnamate*

$$C_6H_5 \cdot CH : CH \cdot COOC_9H_9$$

was originally discovered in storax by Bonastre. It may be obtained, after removal of the styrene and cinnamic acid by treatment of the residue with ether, alcohol, or light petroleum in the form of a liquid, which with difficulty assumes a solid crystalline form, the crystals melting at 44° (Simon, Annalen, 31, 273; Toel, Annalen, 70, 1; Miller, Annalen, 188, 200). Styracin is readily converted by alkali into cinnamyl alcohol and cinnamate. *Benzyl alcohol* has been detected as a constituent of storax by Laubenheimer (Annalen, 164, 289). A good bibliography will be found in W. von Miller's memoir on the Chemical Compounds contained in Liquid Storax (Annalen, 188, 184), in which the author describes as present, in addition to the constituents already mentioned, *phenylpropyl cinnamate*, *ethyl cinnamate*, *ethyl vanillin*, large quantities of two alcoholic compounds, *α*- and *β-storesin*, and their cinnamic esters, a *sodium compound of storesin* and a *resin*. Dieterich showed that Miller's ethyl vanillin was really vanillin (Pharm. Centralhalle, 1896, No. 28). According to v. Itallie (Chem. Zentr. 1901, ii. 856), a good specimen of storax contains about 2·4 p.c. of substances insoluble in ether, 23·1 p.c. of free cinnamic acid, 14 p.c. of water, 22·5 p.c. of aromatic esters, 2 p.c. of styrene and vanillin, and 36 p.c. of resin. The total proportion of cinnamic acid is about 43 p.c.; the combined acid occurring partly in the resin and partly in the aromatic esters.

The B.P. demands an acid value between 60 and 90, and an ester value between 100 and 146; the U.S.P. an acid value of 56–85 and a saponification value of 170–230. Storax is sometimes adulterated with turpentine. To detect this Hager dissolves the balsam in a little warm alcohol, and shakes this solution with light petroleum. The light petroleum on evaporation leaves a residue in which the terebinthinous odour is concentrated, and may be readily detected. Further, the residue so obtained, in the case of genuine storax, is colourless with a bluish opalescence, and represents 45–55 p.c. of the original balsam; but if turpentine be present the percentage is larger, and the residue has a yellowish colour (Ph. Centh. 15, 163).

Closely allied to liquid storax are the exudations from the *Styrax officinale* (Linn.), *Liquidambar styraciflua* (Linn.), a native of North America, the balsam of which was examined by Flückiger and v. Miller (Arch. Pharm. [3] 20, 646, a. 648). It is obtained in the form of a sticky grey mass containing white crystalline portions mixed with fragments of wood and bark. Its composition does not differ essentially from that of Asiatic Storax (*v.* Itallie). *Liquidambar formosana* (Hance); and *Altingia excelsa* (Noronha) (*cf.* Flück. a. Hanb. 276; Tschirch a. v. Itallie, Arch. Pharm. 239, 541).

Tolu. *Balsamum tolutanum,* B.P.; U.S.P. (*Baume de tolu,* Fr.; *Tolubalsam,* Ger.)

Monardes, in his book published in 1574, describing the products of the West Indies, is the first to mention balsam of tolu. Soon afterwards it was introduced into England. Tolu is the product of the trees of *Myroxylon toluiferum* (H. B. a. K.), natives of Venezuela and New Granada, and probably also of Ecuador and Brazil. Considerable amounts are exported by Bolivia. (For botanical characters, *v.* Bentl. a. Trim. 84.) V-shaped incisions are made, and the concreted juice from time to time collected. This draining of the trees goes on for eight months of the year (Weir, Journ. R. Hort. Soc., May, 1864).

Balsam of tolu is a viscid resin or plastic solid, which on exposure hardens and is brittle in cold weather. It has an agreeable odour suggestive of vanilla, and has a decided aromatic taste. Crystals of cinnamic acid may be seen in tolu when thin layers are examined. It is soluble in alcohol (1 in 1), glacial acetic acid (1 in 1), chloroform (2 in 1), benzene (1 in 3), acetone, also in caustic potash. Carbon disulphide dissolves it partially, removing chiefly cinnamic acid. Balsam of tolu consists for the most part of an *amorphous resin* similar to that left by carbon disulphide in the case of Peru balsam. This resin on hydrolysis yields *tolu-resinotannol* $C_{17}H_{18}O_5$, a lower homologue of peruresinotannol, a dark brown powder decomposing at 100° without melting. It gives colour reactions with ferric chloride and potassium dichromate, and precipitates with lead acetate and gelatin (Oberländer, Arch. Pharm. 232, 559). Treatment with water extracts from balsam of tolu *cinnamic acid* (Carles, J. Pharm. Chim. 19, 112), and according to Busse (Ber. 9, 830) it contains also *benzoic acid*, and both *benzyl benzoate* and *cinnamate*. Distilled with water, small quantities of a peculiar hydrocarbon pass over which has been called *tolene*. The yield, according to Deville, is 2 p.c. (Ann. Chim. Phys. [3] 3, 152). Tolene has the formula $C_{10}H_{16}$. Its sp.gr. at 10° is 0·858 (Kopp), and it boils at 170°, according to Deville and Scharling, or at 154°–160° (Kopp). Deville found tolene to have a vapour density of 5·1. This hydrocarbon does not appear to have been further studied or to be known in any other chemical relation.

Colophony present as an adulteration in tolu may be detected by extracting 1 grm. with 25 c.c. of carbon disulphide and filtering; on evaporation the residue, dissolved in glacial acetic acid, does not become green on adding a few drops of sulphuric acid. The carbon disulphide, or light petroleum extract, filtered and shaken with 0·1 p.c. copper acetate, does not become green (Hirschsohn, Chem. Zentr. 1895, ii. 694). Added colophony is also detected by the saponification number of the residue left on evaporation of the carbon disulphide. If the residue falls below 25 p.c. the addition of exhausted balsam may be suspected. When turpentine has been added, sulphuric acid produces a black instead of the normal cherry-red colour. The U.S.P. demands saponification value 154–220 and acid value 112–168 for tolu balsam; the B.P. requires 107·4–147·2 for acid value, and a saponification number of 107–202.

Xanthorrhœa Balsams. A number of balsamic resins are obtained from the xanthorrhœas or grass trees of Australia. Seven species of these, the *arborea*, *australis*, *Hastile*, *media*, *minor*, *bracteata*, and *Pumilio* were described as early as 1810 by Brown (Prodromus Novæ Hollandiæ). The first two are arborescent trees, the third and fourth have short stems, and the last three are stemless. Hirschsohn (Pharm. Zeit. 16, 81) distinguishes three xanthorrhœa balsamic exudates; but of these only two are important, the *yellow* or *acaroid balsam* and the *red balsam* (Pereira, Mat. Med. 3rd ed. 1099).

Acaroid Balsam, *Acaroid Resin*, *Resina Acaroides*, *Resin of Botany Bay*. This balsam was first mentioned by Governor Phillips in 1789 (Voyage to Botany Bay). It exudes spontaneously from the *Xanthorrhœa Hastile* and, according to some writers, from the *X. arborea*. It has a yellow colour resembling gamboge, and when heated evolves a balsamic odour. It is used in the preparation of sealing-wax and lacquers and japanner's gold-size. Rudling found for the yellow resin an acid value of 65–90, a saponification value of 100–150, and an iodine value of 175–176 (Chem. Rev. Fett. v. Harz. Ind. 1903, 10, 51). It may be identified by heating with nitric acid, dissolving the cold residue in alcohol and adding 10 drops of 5 p.c. ferric chloride solution. A brownish-black colour and turbid appearance denotes the presence of acaroid resin (Rebs, Lack. und. Farb. Ind. 1908, No. 11). Its chief constituents are *resin*, a trace of *volatile oil*, and *cinnamic*, *benzoic*, and *para-coumaric acids*, also *para-hydroxybenzaldehyde* and probably vanillin (Bamberger, Monatsh. 14, 333). The resin consists of *xanthoresinotannol* $C_{43}H_{46}O_{10}$, chiefly in form of *para-coumarate* (Hildebrand, Arch. Pharm. 234, 698). (For properties of xanthorrhœa resin oil, *see* Schimmel and Co. (Chem. Zentr. 1898, i. 258); Haensel (Chem. Zeit, 1908, i. 1837).) By distilling acaroid balsam, Stenhouse obtained a light neutral oil containing *benzene* and *cinnamene*, and by treatment with nitric acid the same observer finds acaroid balsam to give so large a yield of *picric acid* that he recommends it as a convenient source of that compound. As much as 13 p.c. of *parahydroxybenzoic acid* is formed when acaroid balsam is fused with potash. Amongst the other products of this reaction, are *resorcinol*, *pyrocatechol*, and a *double compound of para-hydroxybenzoic and protocatechuic acids* $C_{14}H_{12}O_7,2H_2O$, which has been likewise obtained from benzoin (Hlasiwetz and Barth, J. 1866, 630).

Red Acaroid Balsam. Grass-tree Gum. Black-boy Gum. A red balsamic resin resembling dragon's blood, and obtained chiefly from *Xanthorrhœa australis*. When heated it evolves a balsamic odour. This resin does not contain cinnamic or benzoic acid, it contains a small quantity of *para-hydroxybenzaldehyde*, and consists mainly of *erythroresinotannol* $C_{40}H_{40}O_{10}$, chiefly as *para*-coumarate (Bamberger, Hildebrand). Its solution in alcohol stains a deep mahogany colour. A red acaroid balsam is also obtained from the Bahamas, which is lighter in colour than the Australian variety. It is similar in composition to the latter, except that it contains cinnamic acid. Grass-tree resins are used in the preparation of spirit lacquers, varnishes, sealing-wax, &c. During the European War considerable quantities of picric acid were made from the different varieties of *xanthorrhœa* resins.

BAMBARA FAT *v.* Bassia oils.

BAMBOO. The ash of the shoots of these grasses (*Bambusa arundinacea* (Willd), *Gigantochloa verticillata* (Munro), &c.) contains from 30 to 40 p.c. of potash (K_2O), and constitutes a good source of potash. The fibres of the shoots supply an excellent paper-making material, and have been used for this purpose by the Chinese from time immemorial (Romanis, Chem. News, 45, 158; 46, 51; Nature, 18, 50).

BAMBOOI FAT or **BAMBUK BUTTER** *v.* Bassia oils.

BANANA. The fruit of *Musa sapientium*, a plant growing freely in tropical countries. When ripe the pulp is rich in sucrose and invert sugar, but in the unripe condition contains much starch, and is extensively used for the preparation of banana flour in the Indian Archipelago, Brazil, the west coast of Africa, and the Pacific Islands.

Analyses by Leuscher (Zeitsch. öffentl. Chem. 1902, 8, 125) of (1) green husks, (2) ripe husks, (3) unripe fruit (pulp), (4) ripe fruit (pulp), and (5) banana-meal, are as follows:—

	(1)	(2)	(3)	(4)	(5)
Water . .	70·0	70·0	70·5	67·1	15·0
Crude protein .	2·0	2·9	3·9	5·0	7·0
Crude fat .	4·5	4·1	0·1	0·2	0·3
Crude fibre .	9·9	8·6	0·4	0·3	5·9[1]
N-free extract .	8·3	10·4	—	—	70·0
Starch . .	—	—	19·1	—	
Dextrin . .	—	—	2·6	1·0	
Tannin . .	—	—	2·2	0·1	
Sucrose . .	—	—	—	15·8	
Invert sugar .	—	—	—	9·7	
Ash . .	5·3	3·9	1·1	0·9	1·8

Only the quite green fruit, containing mere traces of sugar, can be used for preparing the meal.

• Ripe bananas contain *invertase* (Mirran, Chem. Zeit. 1894, 17, 1283). American analyses show much less protein in ripe bananas than is given in Leuscher's figures, the average being only 1·3 p.c. (Bulletin 28, U.S. Dept. of Agriculture, 1899).

The pulp appears to contain small quantities of amyl acetate, to which its characteristic aroma is due.

For a study of the relative amounts of sucrose, invert sugar and starch present in the fruit dried at temperatures between 40° and 105°, *see* Waterman (Chem. Weekblad, 1915, 12, 552). For a study of the changes in composition of ripening bananas, *see* Gore (J. Agric. Research, 1914, 3, 187).

The stalks and skins of bananas are rich in potash, and have been suggested as worth collecting for manurial purposes (Ellis, Jour. Soc. Chem. Ind. 1916, 456 and 521). The following figures were quoted:—

	Stalks.	Skins.
Moisture . . .	91·6 p.c.	88·2 p.c.
Dry matter . .	8·4 „	11·8 „
Ash, in original .	2·4 „	1·8 „
Potash, in original .	1·1 „	1·0 „
Ash, in dry matter .	29·9 „	15·0 „
Potash, in dry matter .	13·7 „	9·0 „
Potash in ash . .	45·9 „	57·2 „

It is estimated that the bananas imported into this country per annum (about 9,000,000 bunches) include, on the average, about 16,000 tons of stalks and 60,000 tons of skins, containing about 160 tons and 600 tons of potash, respectively.

BANDROWSKI'S BASE. Tetra-amino-diphenyl-*p*-azophenylene.

BAPTISIN *v.* GLUCOSIDES.

BAPTITOXINE *v.* CYTISINE.

BARBALOIN *v.* GLUCOSIDES.

BARBATIC ACID. *Barbatic acid* $C_{19}H_{20}O_7$ was first isolated from the lichen *Usnea barbata* by Stenhouse and Groves (Chem. Soc. Trans. 1880, 37, 405), in which it occurs in conjunction with usnic acid. Zopf (Annalen, 1897, 297, 271) found barbatic acid in the *Usnea longissima*, in the *Electora ochrole uca* (*ibid.* 1899, 306, 282), and in the *Usnea dasypoga* (*ibid.* 1902, 324, 39); Hesse (J. pr. Chem. 1898, ii. 57, 232) describes its presence in the *Usnea longissima*, *Usnea barbata*, and *Usnea ceratina*. Hesse (*l.c.* originally considered that barbatic acid had the composition $C_{22}H_{24}O_8$, and described potassium barium and copper salts and an ethyl ester, m.p. 132°, which apparently established this formula, but in a later paper (J. pr. Chem. 1903. ii. 68, 1) he adopted Stenhouse and Groves' formula, $C_{19}H_{20}O_7$. The *sodium salt*

$$C_{19}H_{19}O_7Na, 2H_2O$$

crystallises in straight-sided leaflets (*cf.* also Zopf, 1902, 789). The action of acetic anhydride on barbatic acid leads to the formation of a compound which is probably the lactone of acetylbarbatic acid; this melts at 250° and on recrystallisation from acetic anhydride yields *acetylbarbatic acid* $C_{19}H_{19}(C_2H_3O)O_7$, m.p. 172°. By the hydrolysis of barbatic acid with aqueous alkalis *betorcinol* and *rhizoninic acid* are formed. Barbatic acid crystallises in colourless needles, m.p. 184° (Hesse, J. pr. Chem., 1906 (2), 73, 113). A. G. P.

BARBERRY. Barberry or berberry, *Berberis vulgaris*, is a compact bush which attains to a height of from 8 to 10 feet, and is found wild in Great Britain and throughout most parts of Europe and North America. The colouring matter present is *berberine*, and this, though occurring mainly in the bark, is also present in the stem and root of the plant.

Until recently a concentrated commercial extract of this material, known as 'Barberry extract,' was to be found on the market, and employed for dyeing silk and leather. It does not appear to have been at any time extensively used for these purposes, and is now apparently obsolete.

Barberry is, however, interesting, in that it contains the only natural basic dyestuff at present known, and may, in fact, be applied to fabrics in the same way as the artificial basic colouring matters. Silk and wool, for instance, may be dyed yellow by means of a faintly acidulated decoction of the material, preferably at from 50° to 60°, whereas for cotton, a tannin antimony mordant is necessary.

For the isolation of berberine the procedure is simple, and consists merely in extracting the ground dyestuff with boiling water containing a slight excess of lead acetate. The concentrated extract is mixed with hydrochloric acid when, on cooling, crystals of berberine hydrochloride separate. Berberine hydrochloride, $C_{20}H_{18}O_4NCl$,[1] when pure, crystallises in long silky needles which possess an intense yellow colour and are soluble in hot water and alcohol. The most reliable of the earlier analyses of berberine are those given by Perrins (Annalen, Supp. 2, 176), who suggested the formula $C_{20}H_{17}NO_4$, but it is now known that berberine has the composition $C_{20}H_{19}NO_5$. The base

---

[1] Including tannin and colouring matter.

[1] The substance commonly known as *berberine hydrochloride* is, in fact, not a hydrochloride, but a quaternary chloride containing the grouping given below, and should be named *berberinium chloride* (W. H. Perkin, Chem. Soc. Trans. 1918, 113 503)—

The old names for this and the other salts described are, however, retained in this article.

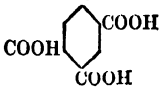
berberine (or berberinal) is best obtained by adding strong caustic soda to the aqueous solution of the sulphate and extracting the product with ether, from which it separates in yellow needles and melts at 144° (Gadamer, Archiv. der Pharm. 1905, 243, 34). Berberine is a strong base, yielding well-defined crystalline salts of a deep yellow colour, of which the following may be given as examples:—

Berberine nitrate $C_{20}H_{18}NO_4{\cdot}NO_3$, *Berberine hydrochloride*, $C_{20}H_{18}NO_4Cl$, *Berberine hydriodide* $C_{20}H_{18}NO_4I$, and *Berberine platinichloride* $(C_{20}H_{18}NO_4)_2PtCl_6$.

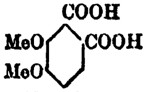
The most important of the early work on berberine is that of Hlasiwetz and Gilm (Jahres. 1864, 407), who by reducing the base with zinc and sulphuric acid prepared *tetrahydroberberine* $C_{20}H_{21}NO_4$, and by fusion with alkali obtained the acids $C_9H_8O_5$ and $C_8H_8O_5$, the second of which was termed *berberinic acid*. Perkin (Chem. Soc. Trans. 1889, 55, 89), who subsequently examined this latter compound and found that its properties agreed in all respects with those given by Hlasiwetz and Gilm, has shown that it possesses the constitution of a *homocatechol carboxylic acid*.

Interesting also is the fact that by the alkali fusion of berberine, or by distilling it with lime, Bernheimer and Bödecker isolated an oily base which they regarded as quinoline, but which is now known to be *iso-quinoline*.

The most valuable results, however, have been afforded by a study of the oxidation products of berberine hydrochloride. Weidel, who employed nitric acid for this purpose, obtained *berberonic acid*, $C_8H_5NO_6$, which he rightly regarded as a pyridine tricarboxylic acid, and this has been more recently shown to consist of the 2 : 4 : 5 compound—



whereas Schmid and Schilbach (Arch. Pharm. [3], 25, 164) by the action of permanganate obtained some quantity of *hemipinic acid*—



Subsequently, W. H. Perkin, junr. (Chem. Soc. Trans. 1889, 55, 75; 1890, 57, 991; 1910, 97, 323) published a series of elaborate researches on this subject, and it is almost entirely to these that our present knowledge of berberine is due. By adopting special precautions and by the employment of a very large quantity of material, this author succeeded in obtaining from berberine hydrochloride by the action of permanganate, numerous important compounds, the study of which gave the clue to its constitution. The operations employed are of too involved a nature to be dealt with in detail here, but a general idea of the methods employed can be gathered from the scheme given below, drawn up by the investigator himself (*l.c.* 1890).

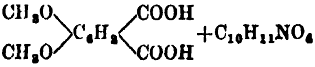
Among the oxidation products of berberine, anhydroberberilic acid and berberal have proved to be the most important, and these only will be discussed here in detail.

Anhydroberberilic acid $C_{20}H_{17}NO_8$, as its name denotes, is an anhydro derivative of berberilic acid, into the sodium salt of which it is readily transformed by the gentle action of sodium hydroxide solution—

$$C_{20}H_{17}NO_8+2NaOH=C_{20}H_{17}NO_9Na_2+H_2O$$

Berberilic acid, $C_{20}H_{19}NO_9$, though only slowly attacked by alkalis, is readily hydrolysed by boiling dilute sulphuric acid, and Perkin thus obtained hemipinic acid and a basic compound $C_{10}H_{11}NO_4$—

$C_{20}H_{19}NO_9+H_2O=$



$$\begin{matrix}CH_3O\\CH_3O\end{matrix}\!\!>\!C_6H_2\!<\!\!\begin{matrix}COOH\\COOH\end{matrix}+C_{10}H_{11}NO_4$$

This latter substance proved to consist of *a-aminoethylpiperonyl-carboxylic acid*—

BERBERINE HYDROCHLORIDE IS OXIDIZED WITH POTASSIUM PERMANGANATE, THE PRODUCT TREATED WITH SULPHUROUS ANHYDRIDE AND FILTERED.

<table>

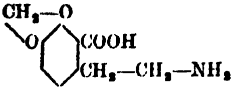
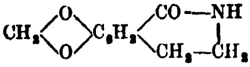
</table>

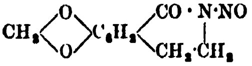


and the main facts which lead to the determination of its constitution are as follows :—

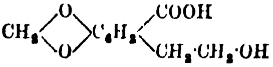
When boiled with water, it readily loses the elements of water with production of the anhydride—



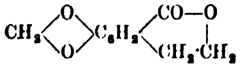
which reacts with nitrous acid to give the nitroso derivative—



and this compound with dilute caustic soda evolves nitrogen with the production of *ω-hydroxyethylpiperonyl-carboxylic acid*—



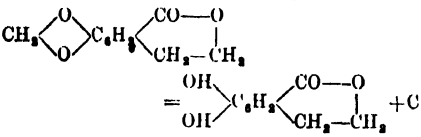
The anhydride—



readily obtained from this latter by merely boiling with water, when fused with alkali yields *catechol* and *protocatechuic acid*—

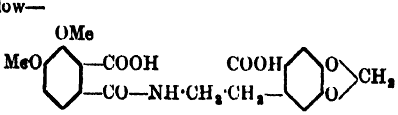
$$\begin{matrix}OH\\OH\end{matrix}\!>C_6H_3{\cdot}COOH$$

and by the action of hydrochloric acid at 170°–175° is converted with loss of carbon, a reaction characteristic of piperonal derivatives, into *hydroxyethylcatechol-carboxylic anhydride*—

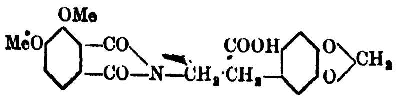


As the result of these experiments, there could be little doubt that berberilic acid (1) and its anhydride (2) possess the constitutions given below—

(1)

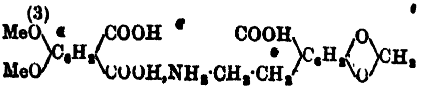


(2)



and that these are correct was subsequently established by the observation that the hemipinate of ω-aminoethylpiperonyl-carboxylic acid (3) on heating is transformed into anhydroberberilic acid—

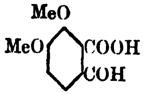
(3)



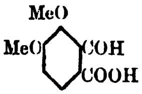
Berberal. As in the case of berberilic acid, the constitution of berberal has been established mainly by a study of the products of its hydrolysis. By the action of alcoholic potash it yields ω-aminoethylpiperonyl-carboxylic acid and an acid $C_{10}H_{10}O_5$, and thus resembles berberilic acid which under similar conditions gives hemipinic acid in the place of this latter.

The acid $C_{10}H_{10}O_5$ on examination proved to be constituted similarly to opianic acid (1), and was, therefore, termed *pseudo-opianic acid* (2)—

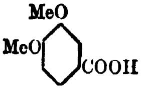
(1)



(2)

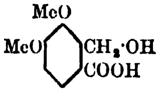


Thus by the action of caustic potash solution it gave veratric acid—

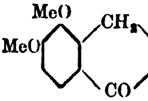


and when reduced formed the unstable acid (3) which readily passed into *pseudomeconine*—

(3)



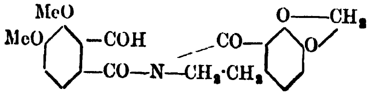
(4)



Perkin now found that whereas pseudo-opianic acid and ω-aminoethylpiperonyl-carboxylic acid on heating together give first the salt of the base, that this subsequently by elimination of water passes into berberal—

$$C_{10}H_{10}O_5 + C_{10}H_9NO_3 = C_{20}H_{17}NO_7 + H_2O$$

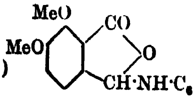
Apparently, therefore, berberal could be represented as follows :—



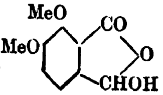
and this formula was at first adopted.

Liebermann, however (Ber. 1896, 29, 175), subsequently pointed out that when opianic acid reacts with aniline to form anilinoopianic acid (1) the latter behaves as a derivative of hydroxyphthalide (2)—

(1)

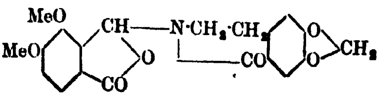


(2)

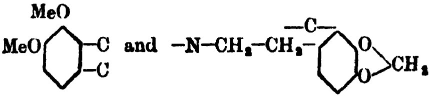


and it is now generally accepted that in the condensations of opianic acid with basic substances, it is always the carbon atom of the aldehyde group which becomes attached to the nitrogen in the final product.

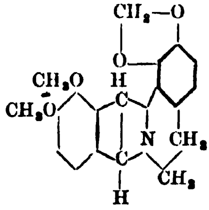
As a result of this later work, Perkin and Robinson have modified the original expression for berberal as follows :—



An examination of the formulæ both of berberilic acid and of berberal, led Perkin in 1890 to the consideration that in berberine the following groups of atoms are present—



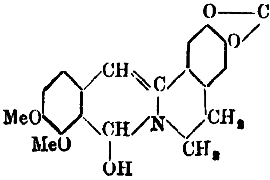
and that, in order to construct a formula for this alkaloid, these require to be united with the addition of but one atom of hydrogen. As a result the following constitution was assigned to this alkaloid—



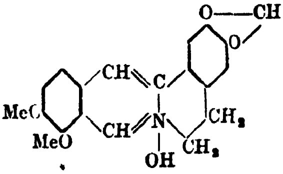
this structure being based upon the older formula of berberine, $C_{20}H_{17}NO_4$, which at that time was considered to be correct.

Subsequently Perkin and Robinson pointed out that the methylenedioxy-group in Perkin's original formula had been incorrectly placed, as was evident from an examination of the structure of ω-aminoethylpiperonyl-carboxylic acid (*cf.* also Freund and Beck, Ber. 1904, 37, 4673). Moreover, as a result of the newer views of the former authors as to the constitution of berberal (*l.c.*) the position of the methoxy groups in the old berberine formula required modification. It is now considered that berberine has the formula $C_{20}H_{19}O_5N$, and is represented by formula (1), and that for the purpose of salt formation it undergoes change into the modification called berberinium hydroxide (2), from which the salts are obtained by the replacement of the OH group by the acid radical—

(1)

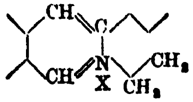


(2)



The reasons for this assumption (W. H. Perkin, jun., Chem. Soc. Trans. 1918, 113, 503) are based on the similarity between berberine and cotarnine, but are too complex to enter into in this article, and for their understanding the literature must be consulted (*cf.* Robinson and Robinson, Trans. 1917, 111, 958).

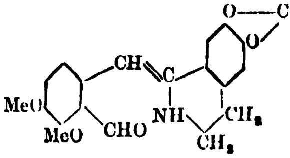
Interesting is the fact that though the salts of berberine are derived from the hydroxyl formula and contain the grouping—



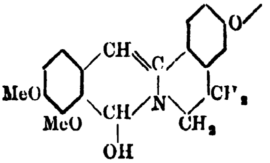
(where X=Cl, HSO_4, NO_3, &c.), the alkaloid itself exists as a different modification.

When berberine sulphate is treated with barium hydroxide (Gadamer), a strongly alkaline liquid is produced which possibly contains the hydroxy modification of berberine (berberinium hydroxide), but if to this solution excess of sodium hydroxide is added, the yellow modification known as *berberinal* is obtained. The constitution assigned to this substance by Gadamer was—

(1)



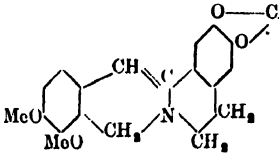
but its most probable structure is that represented by the formula—



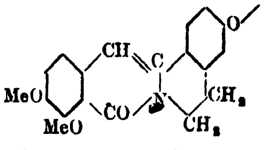
(*cp.* Tinkler, Chem. Soc. Trans. 1911, 99, 1345).

When treated with excess of alkali, berberinal yields dihydroberberine (1) with simultaneous formation of oxyberberine (2), owing, according to Gadamer, to the conversion of the COH group into $CH_2(OH)$ and COOH in the manner characteristic of aromatic aldehydes—

(1)



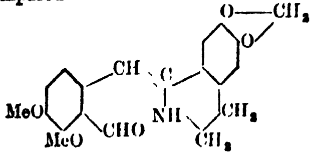
(2)



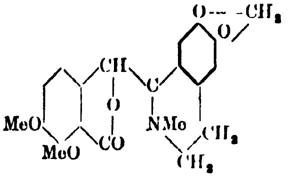
The latter compound was first obtained by Perkin as an oxidation product of berberine.

On the other hand, Faltis (Monatsh. 1910, 31, 557) considers the reaction of berberinal with alkali to be similar to that which takes place between quinoline methiodide under the same conditions and that the products of the reaction are oxyberberine and tetrahydroberberine (*cf.* Dekker, 1903, 1205 and 2568). It has, however, been shown conclusively that Faltis' view is incorrect (W. H. Perkin, private communication).

Berberine is closely allied to hydrastine, which occurs along with it in *hydrastis canadensis*, and the relationship between these compounds is clearly evident, if the formula of Gadamer for berberinal and that of hydrastine (*see* above) are compared—



Berberinal.



Hydrastine.

In 1911 Pictet and Gams (Ber. 1911, 44, 2480) were successful in effecting the synthesis of berberine by the following series of reactions. Homopiperonylamine,

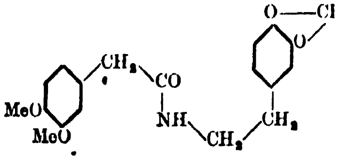
$$CH_2 : O_2 : C_6H_3{\cdot}CH_2{\cdot}CH_2{\cdot}NH_2$$

by condensation with the chloride of homo veratric acid,

$$(CH_3O)_2C_6H_3{\cdot}CH_2{\cdot}COCl,$$

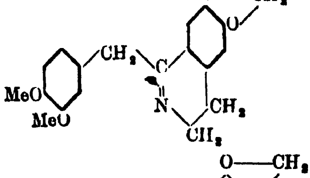
yields *homo-veratroyl-homopiperonylamine* (1) —

(1)

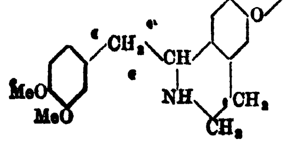


and this compound on treatment with phosphorus pentoxide in the presence of boiling xylene is transformed into the dihydro-quinoline base (2). By reduction with tin and hydrochloric acid this passes into *veratroyl-methylene-dioxy-tetrahydro-iso-quinoline* (*veratryl norhydrohydrastinine*) (3)—

(2)

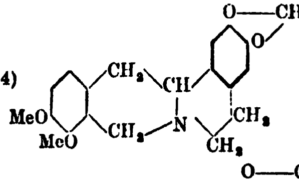


(3)

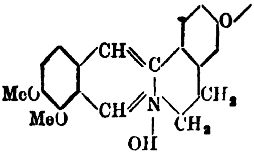


which on treatment with methylal, $CH_2(OCH_3)_2$, gives *tetrahydroberberine* (4), a compound originally prepared by Hlasiwetz and Gilm, and subsequently examined by Perkin and others. This by the action of mild oxidising agents such as iodine or mercuric acetate is readily transformed into berberine (5)—

(4)



(5)



For the synthesis of oxyberberine the paper of Pictet and Spengler (Ber. 1911, 44, 2036) must be consulted.

Numerous plants contain berberine, and though most of these have been or are used medicinally, their employment for dyeing has apparently been of rare occurrence. The following list embodies most of these :—

Berberis aquifolium (Gordin, Arch.. Pharm. 1902, 240, 146), *B. aetnensis* (Perkin, Chem. Soc. Trans. 1897, 71, 1198), *Cossinium fenestratum* and *Xanthorrisa aquifolia* (Perrins, Annalen, 83, 276), *Hydrastis canadensis* (Mahla, Amer. Chem. J. [2], 33, 843), *Coptis aceta* and *C. trifolia, Chelidonium majus* and *Stylophorum diphyllum* (Schlotterbeck, Amer. J. Pharm. 1902, 74, 584), *Evodia meliæfolia* and *Toddalia aculeata* (Perkin and Hummel, Chem. Soc. Trans. 67, 414), *Xanthoxylum clava Herculis* (Chevallier and Pelletan, Journ. de Chim. Médicale, 1826, 2, 314), yellow Assam wood or 'Woodumpar' (Crookes' Dyeing and Calico Printing), *Coelocline polycarpa* (Stenhouse, Annalen, 66, 384 ; 69, 40), *Archangelisa lemnis-cata* (Becc.) and *Mahonia nepalensis* (D.C.), (Brooks' Philippine Journ. of Science, 1910, v. 442).

For the commercial preparation of berberine the *Hydrastis canadensis*, which contains about 4 p.c. of the alkaloid, forms the best available material. A. G. P.

BARBITAL and **BARBITONE.** *See* VERONAL, PYRIMIDINES and SYNTHETIC DRUGS.

BARBITURIC ACID *v.* MALONYL CARBAMIDE.

BARILLA or **BARILLOR.** (Fr. *Barille.*) Commercial name of an impure soda obtained from the ashes of the *Salsola Soda* (Linn.), formerly grown specially in Spain, Sicily, Sardinia, the Canary Islands, and the Levant. The seed was sown at the end of the year, and the plants were ready for cutting in September of the following year ; they were usually burnt during October. A hole capable of holding one or two tons of soda was dug in the ground and covered over with an iron grating ; the dried plants, mixed with canes, were heaped on this and set on fire. The heat was sufficient to melt the ash, which ran down and collected in the hole. More

material was supplied to the fire till the hole was full of fused soda; it was then covered with earth and left to cool, after which the porous mass was broken out and was ready for shipment. Contained about 20 p.c. alkali, together with chlorides and sulphates of sodium, calcium and aluminium and very little sulphur. Formerly much used for making soda soap; little, if at all, used now.

Kelp is sometimes called British Barilla.

BARIUM. Symbol, Ba. At. wt. 137·37.

The name 'barote' (from βαρύς, heavy) was given to the earth contained in heavy-spar (*terra ponderosa*) by Guyton de Morveau in 1779, and was afterwards altered to 'baryta' by Lavoisier; the name itself, therefore, is indicative of the great density of its compounds. Barium occurs principally as the sulphate, *barytes* or *heavy-spar* $BaSO_4$, and is generally found associated with metallic ores containing sulphur. Dieulafait (Ann. Chim. Phys. [5] 15, 530) has shown that all primary rocks contain barium in sufficient quantity to be easily detected. Barium also occurs in nature as *witherite* $BaCO_3$, *barytocelestite* $(BaSrCa)SO_4$, *barytocalcite* $(BaCa)CO_3$, *alstonite* $(BaCa)CO_3$, and in certain varieties of the ores of manganese; also in certain silicates, as *brewsterite* $H_4(SrBa)Al_2Si_6O_{18},3H_2O$, *harmotome* $H_2(K_2Ba)Al_2Si_5O_{15}\cdot 4H_2O$, and *hyalophane* or *baryta-felspar* $K_2Ba\cdot 2Al_2Si_8O_{24}$, and frequently in mineral waters. Barium is also frequently found in calcium and strontium minerals, replacing a portion of those elements with which it is isomorphous.

It is never found native. Its oxide, baryta BaO, was first recognised as a peculiar earth distinct from lime by Scheele in 1774.

Preparation.—Davy (Phil. Trans. 1808, 354) electrolysed a moist paste of a barium salt, using a cathode of mercury. He thereby obtained a poor amalgam which on distillation yielded a silver-white solid that he believed to be metallic barium, but which in reality was only a rich amalgam as shown by Donath (Ber. 12, 745).

Bunsen (Pogg. Ann. 91, 619) slightly modified Davy's process, heating the amalgam in a charcoal boat in a current of hydrogen, obtaining a tumefied mass which was probably a mixture of hydride and carbide. Guntz has also shown that Kern's method (Chem. News, 31, 243) of heating the iodide with sodium yields a sub-iodide which decomposes water.

Clarke (Ann. Phil. 17, 419) exposed baryta to the action of the oxy-hydrogen blow-pipe flame on charcoal and obtained metallic-looking globules probably of barium carbide.

Matthiessen (Annalen, 93, 277) electrolysed the fused chloride and obtained metallic-looking globules which were probably sub-chloride.

Maquenne (Bull. Soc. chim. (3) 7, 368) heated the amalgam *in vacuo*, but owing to decrepitation of the substance and rupture of the tube he was unable to obtain satisfactory results.

Guntz (Bull. Soc. chim. [3] 29, 483), by studying the same process, was finally able to distil off all the mercury without decrepitation or bursting of the tube. After many experiments, he finally adopted the following method: An amalgam containing 3 p.c. of barium was prepared according to Davy's original process, and 5 to 6 kilos of it were distilled in an atmosphere of hydrogen under reduced pressure to such a point as to obtain an amalgam having a close grain and not readily oxidisable, containing about 10 p.c. barium. About half a kilo. of it was then placed in an iron boat contained in a large porcelain tube. Over the boat was placed a nickel spiral to prevent spurting and loss. The tube was then heated very slowly by an electric current circuit so as to arrive at a dull red heat in about four hours, a vacuum being maintained in the tube. The amalgam slowly loses mercury without change of form, and towards 900° it suddenly liquefies, when the current is turned off to avoid ebullition and loss. The amalgam so obtained, containing about 65 p.c. barium, has a coarsely faceted crystalline structure, and quickly oxidises in air. For the last operation it is placed in a nickel boat contained in a porcelain tube lined with nickel foil. The latter is necessary, as when the barium distils towards the end of the operation its corrosive action on the glass causes rupture. The tube is maintained at 900° for two or three hours under diminished pressure, keeping the ends of the tube suitably cooled; then at 950° for one hour during which time there is a considerable loss of barium. The barium so obtained is kept in an atmosphere of dry carbon dioxide. A sample obtained by distilling half the barium had the composition Ba 98·35, Hg 0·83, Fe 0·40. In repeated experiments Guntz failed to obtain barium much purer than 98 p.c. He, however, found in his later experiments that by preparation of the hydride a much purer metal could be obtained (Compt. rend. 141, 1240). The method is a modification of the earlier experiment. After the preparation of the metal in the above way pure dry hydrogen is allowed to enter the tube, maintained at 900°. It is then heated to 1200°, just below the fusion point of the hydride; by this means every trace of mercury can be removed. The hydride contained in a nickel boat is then placed in the nickel-lined tube, heated in a vacuum at 1200°, whereby the hydride is completely decomposed and the volatilised barium is condensed on a polished steel tube cooled by circulating water placed inside where the vapours are being liberated. The metal so obtained assayed 99·5 p.c. barium and was free from hydrogen.

A very convenient laboratory method for preparing small quantities of barium, also due to Guntz, is to heat barium oxide with one-tenth its weight of metallic aluminium at 1200° in a vacuum. The metal condenses in the cooler part of the tube and assays as much as 98·8 p.c. barium.

Matignon (Compt. rend. 150, 1378) has obtained barium by heating the oxide (3 mols.) with silicon (1 atom.) in a vacuum, in a steel tube, at 1200°. The metal distils off and condenses in the cooler part of the tube, the reaction being—

$$3BaO+Si=BaSiO_3+2Ba-37 \text{ cals.}$$

The silicon can be replaced by ferro-silicon containing 95 p.c. silicon.

The preparation of the metal by electrolysis of the fused oxide or chloride does not appear to be attended with success; sub-salts are formed, and the current passes without further action (Z. Electroch. 9, 291).

Properties.—Barium when absolutely pure is a silver-white metal with a density of 3·78. It is slightly harder than lead. It melts at about 850° and commences to volatilise at 950°. Barium oxidises rapidly in air, yielding principally the monoxide; the powder easily takes fire spontaneously. Guntz states that molten barium attacked all the metals he tried, iron and nickel being the most resistant. Barium decomposes water and alcohol in the cold, yielding in the latter case barium ethoxide.

Oxides of barium. Three oxides of barium are known—barium suboxide Ba_2O, barium oxide or baryta BaO, and barium peroxide BaO_2.

Barium suboxide Ba_2O is obtained, according to Guntz (Compt. rend. 143, 339), by heating the protoxide with magnesium or barium to a temperature of 1100°. It is a black mass which decomposes water.

Barium oxide, protoxide, monoxide, or baryta, BaO, is the oxide formed when the metal burns in air. It is more readily obtained by heating (1) the nitrate or (2) the carbonate of barium.

(1) Barium nitrate heated progressively, fuses, then decomposes with the liberation of nitric fumes and much frothing leaving a porous mass of barium oxide.

(2) The carbonate may also be converted into barium oxide by exposing it to the strongest heat of a forge fire; but the last traces of carbonic acid are only expelled with difficulty. However, at an ordinary white heat, this may be accomplished by mixing the carbonate with one-tenth of its weight of lampblack or charcoal and making into a thick paste with oil or tar, carbonic oxide being evolved, thus:

$$BaCO_3+C=BaO+2CO.$$

The mixture should be heated in an earthen crucible lined with lampblack and fitted with a tight cover; on the large scale witherite is thus converted into baryta for use in separating crystallised sugar from molasses. In a second baryta-manufacturing process a mixture of the carbonates of barium and calcium is ignited in a current of aqueous vapour.

(3) On the small scale, baryta may be easily obtained by heating barium iodate, which readily gives up all its iodine, together with five-sixths of its oxygen, without fusing or frothing:

$$Ba(IO_3)_2=BaO+I_2O_5.$$

Barium oxide as prepared by the above methods is generally a greyish-white friable mass of specific gravity 4·7–5·5. Brügelmann (Annalen, [2] 4, 277), by heating barium nitrate in a porcelain flask, obtained minute crystals of BaO belonging to the regular system, of sp.gr. 5·722. He found later that by heating the oxide in a clay or graphite crucible he obtained needles belonging to the hexagonal system sp.gr. 5·32, but if heated in a platinum crucible the oxide is obtained in cubic forms, sp.gr. 5·74. It is therefore dimorphous (Zeitsch. anal. Chem. 29, 127). It is only just melted even by the heat of the oxyhydrogen blowpipe; but in the electric furnace it may be readily liquefied and volatilised. The liquid on cooling yields a crystalline mass (Moissan, Ann. Chim. Phys. [7] 4, 139); it is a non-conductor of electricity, but in presence of mercury may be electrolysed into barium and oxygen. BaO is strongly alkaline, caustic, and poisonous. Fluorine attacks it in the cold, liberating oxygen, the mass becoming incandescent. Dry chlorine has little or no action on the perfectly anhydrous baryta. It is deoxidised by potassium at a red heat, and slakes with water, forming barium hydrate $Ba(OH)_2$ with such energy that the whole mass becomes incandescent provided the amount of water be not too large. It rapidly absorbs moisture from the air. It unites with methyl and ethyl alcohols, forming the compounds $BaO,2CH_4O$ and $BaO,2C_2H_6O$. Heated in the vapour of carbon disulphide, it forms barium carbonate and barium sulphide:

$$3BaO+CS_2=BaCO_3+2BaS.$$

It dissolves readily in dilute nitric and hydrochloric acids, but with most other acids forms insoluble salts. When vapour of sulphuric anhydride is passed over it, heated to low redness in a glass tube, formation of barium sulphate $BaSO_4$ occurs with incandescence.

Barium peroxide or dioxide BaO_2 is formed when anhydrous baryta is heated to a dull red heat in a stream of oxygen or of air freed from carbonic acid. Barium hydroxide may be similarly converted into the peroxide, but less readily, as it fuses below the temperature of absorption of oxygen; but the absorption may be rendered rapid by mixing the hydroxide with lime or magnesia which prevents fusion and keeps the mass porous. Peroxide of barium may also be obtained by sprinkling red-hot baryta with four times its weight of powdered potassium chlorate in successive small portions; the potassium chloride simultaneously formed may be washed out with water, leaving the peroxide in the form of a hydrate.

The peroxide obtained by these means is not pure, being contaminated with a little unconverted barium oxide, iron, silica, and other substances derived from the preparing vessels. In order to purify it the finely powdered crude product is gradually added to an excess of dilute hydrochloric acid, avoiding any considerable rise of temperature; the crude substance dissolves, forming barium chloride and peroxide of hydrogen. The solution is filtered from insoluble matters and treated with baryta water until the silica and ferric oxide, together with a little hydrated barium peroxide, regenerated by action of the peroxide of hydrogen upon the barium hydroxide, are precipitated. The liquid is again filtered and then supersaturated with baryta. By this means the whole of the peroxide of hydrogen regenerates barium peroxide, which is precipitated in minute prisms or laminæ of the hydrate $BaO_2,8H_2O$, in which condition the peroxide is best preserved, and is a suitable form for use in the preparation of peroxide of hydrogen. On drying at 130° or at ordinary temperatures *in vacuo* it is converted into pure anhydrous barium peroxide.

The preparation of barium peroxide in the wet way always yields the octohydrate when more than one molecule of baryta is present per molecule of H_2O_2. Above 60° it is formed, whatever the composition of the solution. Below 40° the di-peroxyhydrate $BaO_2,2H_2O_2$ is obtained from solutions containing much H_2O_2. A compound BaO_2,H_2O_2 may be obtained between 30° and 60° (Zeitsch. Anorg. Chem. 89, 405).

Barium peroxide is a grey, impalpable powder, slightly more fusible than the monoxide. The temperature of dissociation depends upon the pressure. According to Le Chatelier (Compt. rend. 115, 654), the figures are as follows:—

Temp. C.°	520	555	650	670	720	735	750	775	785	790
Press. mm.	20	25	65	80	210	260	340	510	620	670

These pressures vary according to the degree of decomposition being highest at the commencement of the operation. Brin's method of preparing oxygen depends upon the above physical factors. The spongy protoxide of barium prepared as indicated above is placed in thin beds in iron retorts heated by special furnaces. The temperature is maintained as constant as possible between 500° and 600°. Air which has been freed from moisture and carbon dioxide by passing first over quicklime and then over caustic soda is forced by pumps through the retorts whereby the BaO is converted to BaO_2. The residual nitrogen is allowed to escape into the atmosphere. When the peroxidation is complete a set of valves places the retorts in connection with the exhaust pumps, the reduction of pressure causing liberation of oxygen. The first portions are allowed to escape until the pressure measures 65 cm. mercury, another set of valves then comes into play and automatically connects the retorts with the gasometer. The oxygen obtained is 97 to 98 p.c. pure. Barium peroxide is used in the preparation of hydrogen peroxide or dissolved in accidulated water as a bleaching agent.

Peroxide of barium is decomposed by sulphuretted hydrogen at ordinary temperatures, and when heated in a current of carbonic oxide it becomes white hot. It becomes incandescent when heated in sulphur dioxide. When treated with strong sulphuric acid at a temperature exceeding 70°, oxygen is given off; at lower temperatures the oxygen is mixed with ozone. When the peroxide is mixed with acidulated water in presence of oxide of silver, peroxide of manganese, or peroxide of lead, oxygen is evolved both from the peroxide of barium and from the other oxide. A small quantity of a silver compound is capable of decomposing a large quantity of barium peroxide, but iodine decomposes an exactly equivalent quantity:

$$BaO_2+I_2=BaI_2+O_2.$$

The amount of active oxygen in BaO_2 may be determined by adding a known quantity of the peroxide to pure hydrochloric acid, then potassium iodide free from iodate together with excess of bicarbonate of soda, and titrating the liberated iodine with a standard solution of sodium thiosulphate. It may also be estimated by titrating an acidulated solution with standard potassium permanganate (Bertrand, Bull. Soc. chim. [2] 33, 148).

Barium hydroxide, *Hydrate of Baryta*, or *Caustic Baryta* $Ba(OH)_2$ or $BaO{\cdot}H_2O$, is formed, with great evolution of heat, when water is added to anhydrous baryta (barium oxide):

$$BaO+H_2O=Ba(OH)_2.$$

A hot concentrated solution of equivalent quantities of barium nitrate and sodium or potassium hydroxide deposits, on cooling, crystals of barium hydroxide. Soda is usually employed, of sp.gr. 1·10–1·15, and the crystals obtained are freed from mother liquor by draining, or better, by means of a centrifugal machine.

Commercial caustic baryta is prepared on the large scale by igniting the native sulphate or heavy spar with coal or charcoal, whereby an impure barium sulphide is obtained, and heating this is earthenware retorts into which a current of moist carbonic acid is passed, thus converting it into carbonate:

$$BaS+CO_2+H_2O=BaCO_3+H_2S.$$

Superheated steam is then passed over the heated carbonate, when the following decomposition takes place:—

$$BaCO_3+H_2O=Ba(OH)_2+CO_2.$$

According to R. Heintz (Chem. Zeit. 1901, 199), only the carbonate is used to any extent. The calcination is conducted in specially constructed furnaces lined with basic material and heated with producer gas. The product contains 95 p.c. BaO. The same author reviews the methods that have been suggested for the manufacture of baryta from barytes, and considers them too costly for the production of a cheap commercial oxide.

Marino (Gazz. chim. ital. 43, 416) has shown that the reduction of barium sulphate to sulphide is effected by reducing gases, especially water gas, more readily than with the use of coal, the reduction occurring at 525°–540°. In practice 600°–625° is used, and a yield of 95–98 p.c. was obtained in an experimental furnace. Baryta is then prepared by the electrolysis of a solution of barium sulphide by Brochet and Ransome's process, a diaphragm of high resistence being employed in all cases. The best results are obtained with copper electrodes and a solution containing 20 p.c. of BaS. The barium hydrate at the anode increases as long as the concentration does not fall below 5 p.c., and in concentrated solutions, at 70°–80° amounts, after 24 hours, to 13 grms. per litre. Formation is due to interaction of hydroxyl ions with the BaS.

Caustic baryta crystallises from water in large, transparent, colourless, quadratic prisms capped by pyramids. The crystals $Ba(OH)_2,8H_2O$ are isomorphous with the corresponding strontium compound. They dissolve in 20 parts of water at 15°, and in 2 parts of boiling water. The aqueous solution known as baryta water is highly caustic and of strong alkaline reaction, rapidly becoming covered with a film of carbonate owing to absorption of atmospheric carbonic acid; hence it is frequently used in the determination of the amount of carbonic acid contained in the air. On exposure to air the crystals fall to a white powder, with loss of seven molecules of water. De Forcrand (Compt. rend. 103, 59) isolated the hydrate $Ba(OH)_2,H_2O$ by allowing the compound $BaO,2CH_3O+2H_2O$ to evaporate over sulphuric acid *in vacuo*. H. Lescœur (Compt. rend. 96, 1578) shows that at 100° $Ba(OH)_2,H_2O$ has a tension of dissociation of 45 mm., and that this hydrate is completely converted to $Ba(OH)_2$ when heated to 100° *in vacuo*. Lescœur also proves that the dissociation tension of $Ba(OH)_2,8H_2O$ is 213 mm. at 75°, so that at this temperature all three hydrates of BaO may exist simultaneously.

$Ba(OH)_2$, when heated alone, is only reduced to baryta above a red heat; if not heated above redness, it re-forms, on cooling, a crystalline mass of $Ba(OH)_2$, but when heated in a current of air it takes up oxygen and is converted into peroxide of barium with loss of water; when heated in a current of carbonic acid it also loses water and is converted into barium carbonate:

$$Ba(OH)_2+O=BaO_2+H_2O.$$
$$Ba(OH)_2+CO_2=BaCO_3+H_2O.$$

Baryta has until recently been used in the processes of sugar-refining, inasmuch as it forms the compound $C_{12}H_{22}O_{11}BaO$ with cane-sugar, which, when treated with carbonic acid gas, is decomposed into insoluble barium carbonate and sugar, hence affording a means of separating the pure sugar from the molasses; but as strontium hydrate acts in a similar manner, and is not poisonous, it has been substituted for baryta in sugar-refining.

Hydrated barium peroxide. Schöne has shown (Ber. 13, 803) that only one hydrate of BaO_2 exists, containing 8 molecules of water, $BaO_2,8H_2O$. This hydrate is precipitated in crystalline scales when peroxide of hydrogen is added to concentrated solutions of barium hydroxide. It is slightly soluble in cold water, but decomposes in boiling water, forming $Ba(OH)_2$ and evolving oxygen.

Barium subchloride BaCl is obtained (Guntz, Bull. Soc. chim. [3] 29, 490) when equal amounts of $BaCl_2$ and Ba are heated together *in vacuo* at 850°. The fragments of $BaCl_2$ absorb the molten barium without change, and are microcrystalline. The material so obtained is not pure. It decomposes water. By using Na, a definite compound NaClBaCl can be obtained. BaCl appears to be formed when electrolysing fused $BaCl_2$.

Barium chloride $BaCl_2$. Crystallised (*terra ponderosa salita*) $BaCl_2,2H_2O$. Barium chloride may be prepared either from witherite, the native carbonate, or from heavy-spar, the native sulphate. The witherite is dissolved in dilute hydrochloric acid and the solution allowed to stand some time in contact with excess of the carbonate, which is added to precipitate iron and other foreign metals present in the mineral; the rapidity of precipitation is much increased by the addition of a little baryta water. The filtered liquid is then neutralised with hydrochloric acid, and the salt crystallised out and purified by recrystallisation.

From the native sulphate barium chloride may be prepared in two ways:

(1) By heating the sulphate in a crucible with powdered coal and decomposing a filtered solution in water of the barium sulphide formed with hydrochloric acid: $BaS+2HCl=BaCl_2+H_2S$.

Excess of hydrochloric acid is added, and the liquid boiled till free from sulphuretted hydrogen; it is then filtered, cooled, and evaporated to the crystallising point.

(2) By heating a mixture of 100 parts finely powdered heavy-spar, 40 parts of charcoal, 20 parts of limestone, and 50 parts of calcium chloride to a red heat in a reverberatory furnace, by which barium chloride and calcium sulphide are formed. The mass is lixiviated with water, when the barium chloride is dissolved out, leaving an insoluble calcium oxysulphide formed by the union of the sulphide with the oxide of calcium produced by ignition of the limestone.

Commercial barium chloride generally contains small quantities of strontium and calcium chlorides, together with traces of the chlorides of iron, aluminium, copper, and lead. Washing the crystals with alcohol removes both the strontium and calcium chlorides, whilst calcium chloride may also be removed by digesting with barium carbonate suspended in water, when the calcium chloride becomes converted to carbonate, or more rapidly by adding baryta water and passing carbonic acid gas into the liquid. Digestion with barium carbonate also precipitates the sesquioxides of iron and alumina. Lead and copper may best be removed by the addition of a little barium sulphide.

Barium chloride may be recovered from mixtures of chlorides of the alkalis and alkaline earths by treating the concentrated liquor with a hot saturated solution of salt, when on cooling a mixture of barium and sodium chlorides crystallises out; by treating a cold saturated solution of this mixture with twice its volume of hydrochloric acid, barium chloride is precipitated (Dingl. poly. J. 250, 91).

Barium chloride crystallises from aqueous solution with two molecules of water $BaCl_2,2H_2O$ in transparent, colourless, rhombic tables; sp.gr. 2·66–3·05. The crystals decrepitate when heated. They have an unpleasant, bitter, sharply saline taste, exciting nausea, and are very poisonous.

One hundred parts of water at 0° dissolve 32·62 parts of anhydrous barium chloride, and 0·2711 part for every degree above 0°; 100 parts of water at 15·6° dissolves 43·5, and at 105·5° 78 parts of the crystallised chloride. One part of crystallised barium chloride at 18·1° dissolves in 2·257 parts of water to form a solution of sp.gr. 1·28251 (Karsten). A solution saturated at 8° has a sp.gr. of 1·270 (Anthon).

Barium chloride is almost insoluble in strong hydrochloric acid, so that it is precipitated from its solutions by hydrochloric acid, and a few drops of the acid reduces the solubility considerably. Hot absolute alcohol dissolves only $\frac{1}{400}$ part of the crystals; but according to Fresenius, 1 part of the salt dissolves in 8108 parts of alcohol of 99·3 p.c. at 14°, and in 4857 parts of the same alcohol at its boiling point.

The crystals are not efflorescent, but give up the whole of their water at 100°, leaving a white mass of the anhydrous salt, which melts at a red heat, forming a translucent mass on cooling; the crystals are optically biaxial and positive. Specific gravity of the anhydrous chloride is given by various observers as 3·70 to 4·15. Hans Winter (Diss. Leipzig. 1913, 1) gives the following constants, m.p. 958°, sp.gr. 3·789. When heated in a current of steam it evolves hydrochloric acid below its fusing point.

Calcium and barium chlorides form the double salt $CaCl_2BaCl_2$ (m.p. 631°), but no mixed crystals. Barium and strontium chlorides form a complete series of regular (β) mixed crystals, which on cooling are transformed to (α) crystals (monoclinic). The two series correspond with the α and β forms of $BaCl_2$, which coexist in equilibrium at 922°. The freezing-point curve shows a minimum at 847°, at which point 30 mols. p.c. $BaCl_2$ are present. The double chlorides $2KCl,SrCl_2$ and $2KCl,BaCl_2$ are isomorphous and rhombic.

A concentrated solution of barium chloride is decomposed by sodium or potassium nitrate, forming barium nitrate and a chloride of the alkali-metal. With glycocol $CH_2(NH_2)\cdot COOH$ it forms a crystalline compound, and also acts upon blood as a preventive of putrefaction and coagulation.

Barium chloride is extensively used as a reagent, especially for the detection and estimation of sulphuric acid. It is also used for the preparation of artificial sulphate or 'permanent white,' and for preventing the incrustation of steam boilers by decomposing the gypsum of hard waters.

Barium oxychloride. André (Compt. rend. 93, 58) obtained an oxychloride of barium by adding 60 grams of $Ba(OH)_2$ to 200 grams of crystallised barium chloride, and boiling the mixture with 500 grams of water, filtering, and allowing to cool, when nacreous lamellæ, to which he ascribed the formula $BaCl_2\cdot BaO,5H_2O$, separated out (Compt. rend. 98, 572). Beckmann (J. pr. Chem. [2] 27, 126) also obtained nacreous plates by similar means to which he gave the formula $BaCl(OH),2H_2O$. These plates lose $\frac{4}{5}$ths of their water at 120° and the remaining fifth at the fusing-point by prolonged heating in a stream of hydrogen. This oxychloride is readily decomposed by water or alcohol.

Barium chlorite $Ba(ClO_2)_2$ may be obtained absolutely free from chloride by the action of a mixture of chlorine dioxide and carbon dioxide free from chlorine on barium peroxide suspended in hydrogen peroxide. The decomposition of barium chlorite takes place according to the equation—

$$Ba(ClO_2)_2=BaCl_2+2O_2+48{\cdot}6 \text{ cals.}$$

From this follows the equation—

$$Ba+Cl_2+2O_2=Ba(ClO_2)_2(\text{solid})+148 \text{ cals.}$$

and

$$BaCl_2+2O_2=Ba(ClO_2)_2-48{\cdot}6 \text{ cals.}$$
$$Ba(ClO_2)_2+O_2=Ba(ClO_3)_2+22{\cdot}8 \text{ cals.}$$
$$Ba(ClO_3)_2+O_2=Ba(ClO_4)_2+30{\cdot}2 \text{ cals.}$$

Consequently in compounds containing chlorine in different degrees of oxidation the formation is the less endothermic and the more exothermic the higher the degree of oxidation (Gazz. chim. ital. 45, 161).

Barium chlorate $Ba(ClO_3)_2$. Dry $Ba(OH)_2$ does not absorb chlorine, but in presence of water it rapidly takes it up, forming first hypochlorite and chloride, the former of which breaks up into chlorate and chloride

$$6BaO+6Cl_2=5BaCl_2+Ba(ClO_3)_2$$

(Konigel-Wiesberg, Ber. 12, 346).

As it is difficult to separate from the chloride, the chlorate is best prepared by neutralising a solution of chloric acid with barium carbonate and evaporating to the crystallising point. It crystallises in colourless monoclinic prisms with 1 molecule of water, soluble in 4 parts of cold and less than 1 part of boiling water.

Barium chlorate is also slightly soluble in alcohol, and the alcoholic solution burns with a green flame.

If strongly heated fused barium chlorate be plunged into a jar of coal gas, a brilliant combustion of the carbon and hydrogen contained in the coal gas occurs at the expense of the oxygen of the chlorate.

Barium perchlorate $Ba(ClO_4)_2,4H_2O$ is readily formed by neutralising perchloric acid with barium hydrate or carbonate. It crystallises from the solution in long deliquescent prisms very soluble in water.

Barium bromide $BaBr_2$. Crystallised

$$BaBr_2,2H_2O.$$

This salt is prepared by saturating baryta water or barium carbonate or sulphide with hydrobromic acid; or by decomposing the sulphide with free bromine, sulphur being precipitated.

The most convenient method is to bring together under water 12·5 parts of bromine and 1 part of amorphous phosphorus, by which a solution of hydrobromic and phosphoric acids is formed, which is neutralised with barium carbonate rendered alkaline by baryta water. The insoluble barium phosphate may then be filtered off and the bromide obtained by evaporation and crystallisation.

Barium bromide is very soluble in water, and crystallises with difficulty; it is isomorphous with the chloride, but unlike the latter salt is soluble in strong alcohol. It loses one molecule of water at 75°, and the second at 120° (Beckmann, J. pr. Chem. [2] 27, 126), m.p. of anhydrous salt 847°.

Barium oxybromides. Two oxybromides have been prepared by Beckmann (*l.c.*)

$BaBr(OH),2H_2O$ resembles the corresponding oxychloride. $BaBr(OH),3H_2O$ was obtained by adding alcohol to mixed solutions of $BaBr_2$ and $Ba(OH)_2$.

Barium iodide BaI_2. Anhydrous, sp.gr. 4·917, it forms several hydrates with 7,6,2,1 molecules of water. Barium iodide is formed when hydriodic acid gas is passed over baryta at a red heat, a violent action occurring attended with incandescence. It is generally prepared by mixing barium monosulphide with a saturated solution of iodine in alcohol as long as sulphur is precipitated; the filtrate is then boiled rapidly to near dryness, redissolved in a little water and again evaporated, this time to dryness, preventing the access of air as much as possible by performing the operation in a glass bolt head. On redissolving the mass in hot water and allowing to cool, slender needles separate out of the composition $BaI_2,7H_2O$ (Croft, Gazz. chim. ital. 1856, 125; Thomsen, Ber. 10, 1343).

These crystals are very deliquescent and readily soluble in alcohol. They lose 6 molecules of water at 125°, and the remainder at 150° (Beckmann, J. pr. Chem. [2] 27, 126). They decompose slowly at ordinary temperatures, and quickly when warmed, giving off violet vapours of iodine. Commercial barium iodide crystallises at the ordinary temperature in large hexagonal prisms, apparently isomorphous with $SnCl_2,6H_2O$. They melt in their water of crystallisation at 25·7° (Centr. Min. 1918, 105).

The double iodide of barium and mercury has a sp.gr of 3·588 higher than that of Thoulet's solution, and may be of use for petrographical purposes (Rohrbach, Jahrb. Min. 1883, 2, Mem. 186).

Barium oxyiodide. Beckmann (J. pr. Chem. [2] 27, 126) prepared an oxyiodide of barium of the formula $BaI(OH),4H_2O$ which crystallises in short thick needles.

Barium iodate $Ba(IO_3)_2$ is largely used for the preparation of iodic acid, and is obtained as a white granular precipitate by adding potassium iodate to barium chloride.

It is soluble in 3000 parts of cold and 600 parts of boiling water. It dissolves in hot nitric acid, and crystallises out on cooling in bright, glittering, monoclinic prisms isomorphous with the chlorate. Hydrochloric acid dissolves it with evolution of chlorine.

Barium periodate. By passing iodine vapour in a current of dry air over heated oxide of barium a basic periodate of the formula $Ba_5I_2O_{12}$ or $Ba(IO_4)_2 \cdot 4BaO$ is formed. The same basic periodate is formed when barium iodate is heated to a high temperature:

$$5Ba(IO_3)_2 = Ba_5I_2O_{12} + 4I_2 + 9O_2$$

or on heating barium iodide in a current of air until no more iodine is given off:

$$5BaI_2 + 6O_2 = Ba_5I_2O_{12} + 4I_2.$$

Hence Sugiura and Cross (J. Chem. Soc. 1879, 118) conclude that $Ba_5I_2O_{12}$ is the most stable combination of barium, iodine, and oxygen.

Barium fluoride BaF_2 (m.p. 1289°), is obtained by neutralising hydrofluoric acid with barium hydroxide or recently precipitated carbonate; or by precipitating a solution of barium nitrate with sodium or potassium fluoride. It forms a white, granular, crystalline powder, sparingly soluble in water, but readily soluble in nitric, hydrochloric, or hydrofluoric acids. It crystallises in the cubic system.

It combines with fluorides of silicon and boron, forming the compounds $BaF_2 \cdot 2SiF_4$ barium silicofluoride and $BaF_2 \cdot 2BF_3$. The former is precipitated by adding hydrofluosilicic acid to soluble barium salts as a crystalline precipitate totally insoluble in alcohol, and serves as a means of separating barium from strontium and calcium, which are not precipitated by hydrofluosilicic acid.

Barium fluoride forms a crystalline compound with the chloride of barium $BaCl_2 \cdot BaF_2$ when a solution of barium chloride is mixed with one of sodium or potassium fluoride; this double compound is more stable than the fluoride itself, and remains as a granular mass on evaporation of the solution. The crystals are tetragonal in habit, and optically negative, m.p. 1008°, sp.gr., 5·931.

Barium carbide BaC_2 was first obtained by Maquenne (Ann. Chim. Phys. (6) 28, 259) by heating a mixture of the carbonate and carbon with magnesium or by the action of carbon on the amalgam in an atmosphere of hydrogen at a red heat. Moissan (Compt. rend. 118, 683) obtained it in a pure crystalline condition by heating a mixture of the carbonate or the oxide with carbon in an electric furnace. Its specific gravity is 3·75, and it possesses properties similar to CaC_2, but is more fusible.

Barium carbonate $BaCO_3$. The native carbonate was first noticed to occur at Leadhills in Scotland, in 1783, by Withering, and hence received the name *witherite*. It is found in many places in England, specially fine crystals being met with at Fallowfield in Northumberland: it is also found in Silesia, Hungary, Styria, Russia, South America. Witherite crystallises in the rhombic system isomorphous with aragonite. It occurs also in globular, tuberose, and botryoidal forms; more frequently massive. Sp.gr. 4·29–4·35; hardness 3–3·75.

Knop (Landw. Versuchs-Stat. 17, 65) found 0·02 p.c. of barium carbonate in Nile mud from Minich and Achmin; and Dworzack (Landw. Versuchs-Stat. 17, 65) found baryta in the ash of the wheat grown thereon. *Alstonite* $(BaCa)CO_3$ contains barium and calcium in varying proportions, and is isomorphous with witherite. *Baryto-calcite* $BaCO_3 + CaCO_3$ crystallises in the monoclinic system.

Boeke (Jahrb. Min. 9–10) shows by heating barium carbonate under pressure of carbon-dioxide, that it undergoes two reversible transformations. At 811° the ψ form (witherite, orthorhombic and pseudo-hexagonal) passes to the β form (hexagonal), and at 982° to the α form (cubic), m.p. about 1740°. The system barium carbonate-calcium carbonate (represented by the minerals alstonite and barytocalcite) give iso-dimorphous mixed crystals with a eutectic at 1139° and 52½ mol. p.c. $CaCO_3$. Up to 30 mol. p.c. $CaCO_3$ the orthorhombic alstonite is the stable form, but with more calcium carbonate, this is replaced by trigonal baryto-calcite. Monoclinic baryto-calcite is not present in the fusions.

Barium carbonate is rapidly formed when baryta, hydrated or anhydrous, is exposed to the atmosphere. When BaO is heated in CO_2 it absorbs the gas, becoming incandescent; the basic carbonate being formed (Raoult, Compt. rend. 92, 1, 110).

It is readily prepared by precipitating aqueous solutions of the nitrate or chloride with ammonium carbonate, filtering, and washing with hot water; or by igniting a mixture of 10 parts powdered heavy-spar, 2 parts charcoal, and 5 parts pearl ash (potassium carbonate). Potassium sulphide and barium carbonate are obtained and may be separated by water. The impure carbonate thus produced may be used to prepare other salts of barium, but these salts will contain iron.

Artificial barium carbonate is a dense soft white powder, poisonous, and hence used for destroying rats. It is very sparingly soluble in water, slightly soluble in water containing carbonic acid, owing to the formation of an acid carbonate which is stable only in solution. It dissolves readily in ammonium chloride, nitrate, and succinate, and when boiled with ammonium chloride is totally decomposed, forming ammonnium carbonate and barium chloride.

The solubility of $BaCO_3$ in water has been determined by Missenberger (Zeitschr. physikal. Chem. 88, 257), and also in water containing small quantities of sodium hydroxide, which represses the hydrolysis and so furnishes a lower and more accurate value for the solubility. The minimum solubility is found in aqueous solutions containing $1 \cdot 25 \times 10^{-5}$ mols. of sodium hydroxide. The following values were obtained (1) for pure water at 13°, $1 \cdot 62 \times 10^{-3}$; 18°, $1 \cdot 72 \times 10^{-3}$; 22°, $1 \cdot 83 \times 10^{-3}$; 27°, $1 \cdot 96 \times 10^{-3}$; 33°, $2 \cdot 14 \times 10^{-3}$; 37°, $2 \cdot 28 \times 10^{-3}$ mols. per litre, and (2) true values calculated from experimental results in faintly alkaline solutions at 14°, $4 \cdot 32 \times 10^{-4}$; 18°, $4 \cdot 57 \times 10^{-4}$; 23°, $4 \cdot 89 \times 10^{-4}$; 27°, $5 \cdot 22 \times 10^{-4}$; 32°, $5 \cdot 69 \times 10^{-4}$; 38°, $6 \cdot 27 \times 10^{-4}$ gram mol. per litre.

It is not decomposed at a strong red heat, but at 1361° it fuses with loss of carbon dioxide; the tension of CO_2 emitted at 1100° is 20 mm.; at 1600° dissociation is complete. The decomposition is much more easily effected in presence of carbon, being complete at 1450°. It is decomposed by steam at a red heat, and very easily if mixed with an equal weight of chalk or slaked lime.

The artificial carbonate is of considerable use in chemical analysis.

Barium nitride Ba_3N_2. Maquenne (Bull. Soc. chim. [3] 7, 368) obtained this compound by passing nitrogen into a tube containing a 25 p.c. amalgam at a red heat. Guntz and Mentrel (*ibid.* (3) 29, 581) obtained it by heating barium ammonium at 430°. So obtained it is a light porous material of a canary-yellow colour. It decomposes water in the cold, giving ammonia and $Ba(OH)_2$.

The pure nitride and hydride are readily obtained by heating the metal in the respective gases. When the nitride is heated in a current of hydrogen a compound having the formula $Ba_3N_2H_4$ is formed, but the product is impure since the compound reacts even at relatively low temperatures with hydrogen according to the equation

$$Ba_3N_2H_4+H_2=3BaH_2+N_2$$

When hydrogen is passed over the heated impure nitride ammonia is formed. BaH_2 which is thereby produced is readily transformed back to the nitride by the action of nitrogen, so that a process is given for the fixation of nitrogen (Monatsh. 34, 1685).

Barium ammonium is formed by the action of ammonia gas on barium or barium amalgam below 28°; but it is best prepared by dissolving barium in dry liquid ammonia at −50°, when it forms a dark-blue oily liquid immiscible with the liquid ammonia. The compound is somewhat indefinite, but a body having the formula $Ba(NH_3)_6$ appears to exist.

Barium amide $Ba(NH_2)_2$ is obtained by heating barium ammonium to 60° or by passing ammonia over barium at 280° C.

When a barium salt and excess of potassamide are allowed to interact in liquid ammonia solution a white insoluble precipitate of potassium ammonobariate $BaNK,2NH_3$, or $Ba(NH_2)_2,KNH_2$, is produced. The strontium and calcium salts may be prepared in the same way (J. Amer. Chem. Soc. 37, 2295).

Barium nitrite $Ba(NO_2)_2,H_2O$ is prepared by heating the nitrate, dissolving in water, and precipitating any baryta formed by passing a stream of carbon dioxide through the solution, adding alcohol to the filtrate to precipitate the unreduced nitrate, and evaporating to the crystallising point. Or by passing nitrous vapours into baryta water, evaporating to dryness, digesting in a small quantity of water (not sufficient to dissolve the nitrate) and crystallising. It is most readily prepared pure by adding barium chloride to a boiling solution of silver nitrite, filtering off the silver chloride, and evaporating.

It is permanent in the air, readily soluble in water or alcohol, and crystallises in colourless prisms, either needle-shaped or, according to Fischer, thick short prisms of 71½°.

Barium nitrate $Ba(NO_3)_2$. A native barium nitrate has been discovered in Chile in the form of colourless octahedra, occasionally twinned like spinel (Groth, Jahrb. Min. 1883, 1, Ref. 14).

Barium nitrate is prepared on the large scale either by dissolving the native carbonate (witherite) or the crude sulphide in dilute nitric acid, or by mixing hot saturated solutions of barium chloride and sodium nitrate. On cooling, the larger portion of the barium nitrate crystallises out, and the evaporation of the mother liquors yields the remaining portion.

Barium nitrate crystallises in lustrous, colourless, regular octahedra, frequently modified by faces of the cube, of sp.gr. 3·2. The crystals are permanent in the air, decrepitating when heated, and melting at 595·53° (Carnelley 597°). At a red heat the salt decomposes, evolving oxygen, nitrogen, and nitrogen peroxide, and leaving a residue of pure baryta. It detonates slightly with combustible bodies, and decomposes with a yellowish light when thrown upon the fire. It is largely used in pyrotechny for giving green-coloured lights, especially for the preparation of green fire; and for the manufacture of *saxifragin*, an explosive mixture of 76 parts of barium nitrate, 2 parts of nitre, and 22 parts of charcoal.

It dissolves in water, producing a slight depression of temperature; 100 parts of water dissolve 5·2 parts of barium nitrate at 0°, 9·2 at 20°, 17·1 at 50°, and 32·2 at 100°. It is less soluble in dilute nitric acid; hence a second crop of crystals may be obtained from cooled saturated solutions on addition of a little nitric acid. It is quite insoluble in concentrated nitric acid and in alcohol.

Hirzel (Zeitsch. f. Pharm. 1854, 49) obtained a hydrate $Ba(NO_3)_2,2H_2O$ from a solution cooled below 12°. Berry (Chem. News, 44, 190), by saturating the same water with barium and strontium nitrates, introducing a crystal of $Sr(NO_3)_2,4H_2O$, and evaporating over sulphuric acid *in vacuo*, obtained crystals containing 17 p.c. of a hydrated barium nitrate isomorphous with the strontium compound. On account of the great electro affinity of nitrion (nitrate ion), the formation of double nitrates is found to occur in few cases, and with one exception (the double nitrate of barium and potassium) are formed only when one of the metals has a valency greater than 2. The unexpected formation of the double nitrate of potassium and barium was first observed by Wallbridge (Amer. Chem. J. 30, 154), whose analysis showed it to be anhydrous and to have the formula $2KNO_3,Ba(NO_3)_2$. Foote showed (Amer. Chem. J. 32, 251) that the double salt can form at 25° under a moderately wide range of conditions, as, for example, from solutions containing 15 to 27 p.c. KNO_3, and from 6 to 2 p.c. $Ba(NO_3)_2$. The salt cannot be recrystallised. Only one well-defined basic nitrate $Ba_2N_2O_7$ is known, and this forms several hydrates.

Barium monosulphide BaS is obtained in a pure state by passing sulphuretted hydrogen over heated baryta as long as water is formed. Veley (Chem. Soc. Trans. 1886, 369) prepared pure crystals of the hydrate of barium hydroxide $Ba(OH)_2,8H_2O$, and heated them at 80° in a current of hydrogen until they attained the constant composition $Ba(OH)_2,H_2O$, when a stream of sulphuretted hydrogen was passed over them, yielding pure BaS and water:

$$Ba(OH)_2,H_2O+H_2S=BaS+3H_2O$$

It may also be prepared by passing carbon disulphide over red-hot baryta, or by reducing powdered barium sulphate in a stream of hydrogen.

On the manufacturing scale it is prepared by roasting 100 parts of heavy-spar with 20 parts of coal slack or charcoal. If charcoal is used, a thorough mixture must be effected, as the reaction is otherwise very imperfect, owing to the non-fusibility of the mass. If the slack of bituminous coal is used, the 'caking' supplies a carbonaceous material which readily permeates the mass and ensures complete reduction. The admixture of resin, oil, or sawdust is also advantageous, and the asphalt of gasworks is a capital reducing material, as the hydrogen contained in it prevents the formation of polysulphides of barium. The mass thus obtained contains excess of carbon and some undecomposed sulphate, but the barium sulphide may be extracted by treating with hot water.

Another method is to heat a mixture of 100 parts heavy-spar, 200 of common salt, and 15 parts charcoal powder in a reverberatory furnace, the salt being added to assist fusion.

Barium sulphide forms a white mass of hepatic odour and alkaline taste, soluble in water, forming a mixture of hydrate and sulphydrate:

$$2BaS+2H_2O=Ba(SH)_2+Ba(OH)_2$$

When exposed to the air it becomes converted into carbonate with evolution of sulphuretted hydrogen, owing to absorption of moisture and carbonic acid. When heated to redness in presence of aqueous vapour, it is converted into barium sulphate with elimination of hydrogen. It is decomposed by hydrochloric and nitric acids with formation of the chloride and nitrate and elimination of sulphuretted hydrogen. Chlorine, bromine, and iodine decompose it with formation of chloride, bromide, and iodide, and deposition of sulphur.

The phosphorescent material known as 'Bolognian phosphorus' is a sulphide of barium obtained by heating 5 parts of precipitated barium sulphate with 1 part of powdered charcoal over a gas flame for half an hour, and then heating for ten minutes over the blowpipe; it must be sealed up while still hot in glass tubes. After exposure to the sun's rays, or to any light rich in ultra-violet rays such as that emitted by burning magnesium wire or the electric arc, it phosphoresces in the dark with a brilliant orange-coloured light. Sulphides of barium, strontium, and calcium are now manufactured for the preparation of luminous paints which are used for coating clock-faces, match-boxes, &c Their surfaces are protected from moisture by a thin coating of varnish. Good Bolognian stones are obtained (J. pr. Chem. ii. 82, 193) from a mixture of strontium carbonate (20 grams), sulphur (3 grams), lithium carbonate (0·5 gram), thorium nitrate (1 c.c. of 0·5 p.c. alcoholic solution), or barium carbonate may be substituted for strontium carbonate and (0·3 gram) rubidium carbonate instead of thorium nitrate. The phosphorescence is more intense if one half of the alkaline earth carbonate is replaced by the corresponding hydroxide. Stones exceeding any others previously made in the intensity and duration of the phosphorescence have been prepared by the ignition for ¾ hour in a Rössler furnace of the following mixture: calcium oxide (10 grams), strontium carbonate (10 grams), barium carbonate (10 grams), magnesium oxide (10 grams), sulphur (6 grams), potassium sulphate (1 gram), sodium sulphate (1 gram), lithium carbonate (2 grams), starch (2 grams), bismuth nitrate (2 c.c. of 0·5 p.c. solution), and thallium sulphate (2 c.c. of 0·5 p.c. solution). The stones exhibit a pale blue phosphorescence. When the ignition is prolonged to two hours the phosphorescence is very intense and greenish-yellow. After three hours' ignition the stones are no longer luminous. The finest green phosphorescence is produced by ignition for ¾ hour of the following mixture: calcium oxide (10 grams), strontium oxide (10 grams), sulphur (3 grams), potassium sulphate (0·5 gram), sodium sulphate (0·5 gram), lithium carbonate (1 gram), starch (1 gram), bismuth nitrate (1 c.c.), rubidium nitrate (1 c.c. 0·5 p.c. solution). Barium sulphide is now largely used in the manufacture of lithophone by adding it dissolved in water to a solution of zinc sulphate. Mutual precipitation takes place, and the white powder formed, consisting of zinc sulphide and barium sulphate, is used as a rubber filler and pigment.

When a solution of 5 parts of barium sulphide is boiled with 1 part of sulphur, and the solution evaporated over sulphuric acid *in vacuo*, colourless six-sided transparent tables of $BaS,6H_2O$ are deposited, which are decomposed by a small quantity of water, forming barium hydrosulphide which dissolves, and barium hydroxide which remains behind.

Barium hydrosulphide $Ba(SH)_2$ is formed by saturating a warm solution of barium hydroxide or sulphide with sulphuretted hydrogen, evaporating apart from the air and cooling, when crystals of baryta and yellow prisms separate out. The mother liquor is mixed with alcohol, filtered from the sulphur and barium thiosulphate formed, and cooled to −10°, when colourless transparent four-sided prisms are obtained. The crystals contain water, which they lose on heating, becoming white. Exposure to air decomposes the crystals, with efflorescence, into barium thiosulphate and sulphate. Heated in a retort, they lose their water of crystallisation without fusing, evolving sulphuretted hydrogen as the temperature approaches redness, and leaving a yellow mass of barium monosulphide, which becomes white on cooling. It is insoluble in alcohol.

Veley (Chem. Soc. Trans. 1886, 369) finds that the composition of crystals of barium sulphydrate is $Ba(SH)_2,4H_2O$.

Barium trisulphide BaS_3 is formed as a greenish-yellow mass when 2 parts of barium sulphide are fused with 1 part of sulphur, the excess of sulphur being distilled off below 360°. It melts at 400° with loss of sulphur and formation of a black liquid. On boiling for some time with water it dissolves to a red liquid which deposits on cooling crystals of the hydrated mono- and tetrasulphides of barium.

Barium tetrasulphide BaS_4. When 7 parts of barium sulphide are boiled in water with 4 parts of sulphur, pale-red rhombic prisms are deposited, soluble in water to a red-coloured liquid from which alcohol precipitates it as an orange-coloured crystalline powder.

Veley (Chem. Soc. Trans 1886, 369) obtains it by dissolving sulphur in a warm saturated solution of barium hydrosulphide; the crystals which separate out have the composition $BaS_4,2H_2O$.

When a mixture of 2 parts of barium hydroxide, 1 part of sulphur, and 25 parts of water is boiled, a deep brown liquid is obtained, which on cooling becomes orange-red in colour. If this solution is evaporated rapidly until a crust is formed on the surface, on cooling the liquid deposits voluminous red prisms of barium tetrasulphide $BaS_4{\cdot}H_2O$ mixed with sulphur and barium thiosulphate. The orange-red liquid contains sulphur and barium in the proportion corresponding with the pentasulphide, which appears to exist in solution, but decomposes during evaporation (Compt. rend. 63, 390).

Barium pentasulphide BaS_5 is obtained in solution by boiling an aqueous solution of the monosulphide with sulphur. On evaporation of the caustic alkaline yellow solution, crystals of barium tetrasulphide and sulphur are obtained: $BaS_5 = BaS_4 + S$.

Barium sulphocarbonate $BaCS_3$ is deposited as a canary-yellow crystalline powder when a solution of barium sulphide is added to carbon disulphide (Thenard, Compt. rend. 79, 673). On the large scale 90 p.c. yield may be obtained, and Dumas suggested its use against the phylloxera in wine districts. Thenard was of opinion that this barium salt would be injurious to the soil, and proposed to convert it into the potassium salt by adding potassium sulphate to its solution.

Barium sulphite $BaSO_3$ is obtained as a white crystalline precipitate by adding potassium or sodium sulphite to a soluble barium salt. Is soluble in a warm solution of sulphurous acid, and crystallises out on cooling in six-sided prisms. When heated in closed vessels it is converted into a mixture of sulphide and sulphate, but heated in air the sulphate is the sole product. Birnbaum and Wittich (Ber. 13, 651) state that BaO unites slowly with SO_2 at 200°, but more rapidly at 230°, forming $BaSO_3$.

Barium sulphate $BaSO_4$ occurs in nature as *barytes*, or heavy-spar, forming fine tabular crystals belonging to the rhombic system. It is a very common mineral in metalliferous veins, and is more particularly associated with lead, silver, and cobalt ores. Clowes (Chem. News, 52, 194) states that the beds of the new red sandstone near Nottingham are permeated by minute crystals of heavy-spar, which acts as a cementing material.

Crystals of artificial barytes, identical in form and properties with native heavy-spar, may be obtained by fusing certain metallic chlorides, such as those of manganese, sodium, potassium, or even barium itself, gradually dissolving barium sulphate in the fused mass, very slowly cooling, and afterwards extracting the soluble chlorides with water. By this means Gorgeu (Compt. rend. 96, 1734) prepared crystals much larger than those obtained by the older process of fusing potassium sulphate with barium chloride. The sp.gr. of the mineral and of the artificial crystals varies from 4·3 to 4·7.

Barium sulphate has been formed by Spring (Bull. Soc. chim. 46, 299) by subjecting an intimate mixture of molecular proportions of sodium sulphate and barium carbonate to great pressure. It is precipitated as a heavy white amorphous powder of sp.gr. 4·0–4·5, when sulphuric acid or a soluble sulphate is added to the solution of a barium salt; this precipitate is nearly insoluble in water (1 pt. in 232,588 pts.), very slightly soluble in dilute acids, more so in strong acids. Concentrated sulphuric acid does not attack anhydrous baryta, but pyrosulphuric acid attacks it so violently that the mass becomes incandescent, and forms barium sulphate. For heat of combinations of Ba and SO_4 ions see Bull. Soc. chim. 1918 (iv.), 23, 13. When freshly precipitated, it is readily soluble in concentrated sulphuric acid at 100°, the solution depositing on cooling lustrous prisms of the *acid barium sulphate* $BaH_2(SO_4)_2$. If the acid solution be exposed to the air, moisture is taken up, and silky needles of a salt having the composition $BaH_2(SO_4)_2$, $2H_2O$ are deposited. Both these acid salts are decomposed by water, yielding sulphuric acid and the neutral salt.

Barium sulphate is also soluble to a perceptible extent in ammonium and potassium nitrates. Hydrobromic acid solution containing 40 p.c. HBr dissolves it to the extent of 1 in 2500 parts acid (Haslam, Chem. News, 53, 87; Karaoglanow. Zeitsch. anal. Chem. 1917, 56, 225).

Barium sulphate is partially decomposed by boiling with a concentrated solution of a fixed alkaline carbonate into alkaline sulphate and barium carbonate, but the reaction is much more complete when the sulphate and alkaline carbonate are fused together. It is reduced to sulphide by ignition with charcoal or organic matter, also by ignition in a stream of coal gas or of hydrogen mixed with vapour of carbon disulphide.

Powdered heavy-spar is used to adulterate white lead, but has not sufficient body to form a pigment by itself; the amorphous sulphate is prepared on the large scale by precipitation of a solution of barium chloride of sp gr. 1·19 by one of sulphuric acid of sp.gr. 1·245, and is used as a pigment under the name of 'permanent white' or 'blanc fixe.'

Barium sodium sulphate $BaNa_2(SO_4)_2$ is formed as an opaque hard mass of pearly lustre by fusing together equivalent quantities of the sulphates of sodium and barium (Berthier).

Barium disulphate BaS_2O_7. If precipitated, barium sulphate be dissolved in fuming sulphuric acid, and the solution heated to 150°, on cooling a glistening deposit of granular crystals of the disulphate is obtained. Decomposition of these crystals occurs at a low red heat without previous fusion.

Barium dithionate $BaS_2O_6,2H_2O$. Prepared by adding barium sulphide to the manganese salt formed on passing sulphur dioxide through finely divided manganese dioxide suspended in water:

$$MnS_2O_6 + BaS = MnS + BaS_2O_6.$$

On allowing the solution to evaporate in a warm place, glittering monoclinic crystals of the salt are deposited of the composition BaS_2O_6,

$2H_2O$. According to Sénarmont and Rammelsberg, the crystals are rhombic. According to V. Lang (Sitz. B. [2] 45, 27), they are monoclinic.

The crystals are soluble in 4 parts of water at 18° and in 1·1 parts at 100°. When the dry salt is heated, it breaks up into sulphur dioxide and barium sulphate. The same decomposition occurs on boiling with hydrochloric acid, but the solution of the dithionate itself in water may be boiled without decomposition.

A tetrahydrate $BaS_2O_6,4H_2O$ may also be obtained by spontaneous evaporation in distinct shining monoclinic crystals, which effloresce on exposure to air.

Barium thiosulphate

$$BaS_2O_3,H_2O \text{ or } BaH_2(SO_2)_2$$

is obtained as a white crystalline precipitate when the sodium salt $Na_2S_2O_3$ is added to barium acetate; it loses its water of crystallisation at 215°. The anhydrous salt, when heated to redness, gives off sulphur and leaves a residue of barium sulphide, sulphite, and sulphate:

$$6BaS_2O_3 = BaS + 2BaSO_3 + 3BaSO_4 + 6S.$$

Barium selenide $BaSe$ is formed by heating barium selenite to redness in a stream of hydrogen. It is decomposed by water into barium hydroxide and a higher selenide, which is decomposed by acids with evolution of H_2Se and precipitation of selenium.

Barium selenate $BaSeO_4$ resembles the sulphate in being insoluble in water, but differs from it in being decomposed by hydrochloric acid into selenite, which dissolves in the hydrochloric acid.

Barium chromate $BaCrO_4$ is precipitated as a yellow crystalline powder when potassium chromate or bichromate is added to the solution of a barium salt. The salt may be obtained in green rhombic crystals isomorphous with $BaSO_4$ by heating two equivalents of $BaCl_2$ with one equivalent of potassium chromate and one of sodium chromate, and allowing the mixture to cool; the chlorides may be boiled out with water, leaving the right rhombic prisms of $BaCrO_4$, of sp.gr. 4·6. They are insoluble in water, but are easily soluble in hydrochloric and nitric acids, and are decomposed by sulphuric acid into $BaSO_4$ and CrO_3 (Bourgeois, Compt. rend. 88, 382).

The precipitated chromate is used as a pigment under the name of 'lemon yellow' or 'yellow ultramarine.' When strong sulphuric acid is added to the dry pigment, great heat is developed, and it is coloured deep red from liberation of CrO_3. If it be now ground in a mortar and heated to bright redness, the chromic acid is reduced to chromic oxide, and a fine green pigment is obtained (Douglas, Chem. News, 40, 59).

Barium dichromate $BaCr_2O_7$ is obtained by dissolving barium chromate in hot concentrated chromic acid. On cooling, red crystals of the composition $BaCr_2O_7,2H_2O$ are deposited, which lose their water at 100°, and are decomposed by water into the normal chromate and chromic anhydride (Preis and Rayman, Ber. 13, 340).

Barium manganate $BaMnO_4$ is formed when manganese dioxide is heated with barium carbonate or nitrate as an emerald-green powder consisting of microscopic four-sided prisms or six-sided plates, insoluble in water but decomposed by acids. This salt is now used in plac of the poisonous Scheele's green.

Barium permanganate $BaMn_2O_8$ is prepared by passing carbonic acid gas through water containing barium manganate in suspension after filtering off the barium carbonate the red solution is rapidly evaporated. Or it may be obtained by the action of barium chloride or silver permanganate.

Or potassium permanganate may be decomposed by slight excess of hydrofluosilicic acid the mixture kept cool, and, after separation o the precipitated potassium silicofluoride, the supernatant solution decanted and saturated in the cold with barium hydroxide. After separation of the insoluble barium silicofluoride, the solution is evaporated until the barium permanganate separates out on cooling (Rousseau and Bruneau Compt. rend. 98, 229).

It forms large orthorhombic octahedra, deep red and almost black, with a violet reflection.

It is used for the preparation of permanganic acid and of the ammonium salt.

Rousseau and Saglier (Compt. rend. 99, 139 find that on heating two grams of barium manganate with ten grams of barium chloride for four hours to 1500°, and extracting with water and dilute acid, a residue of small opaque bluish-black crystals of *barium manganite* $BaMnO_3$ remains; sp.gr. 5·85; readily soluble in hydrochloric acid with evolution of chlorine The manganite is also formed when mixtures o manganese chloride and barium oxychloride are heated below 1000° or above 1100°. Between these temperatures the product is barium dimanganite $BaO{\cdot}2MnO_2$, which crystallises in brilliant black lamellæ. At 1500° the manganite is reconverted to manganate.

Barium phosphide Ba_3P_2. When vapour o phosphorus is passed over red-hot baryta, a brownish-red mixture of barium phosphide and phosphate is obtained commonly known as 'phosphuret of baryta.' It is decomposed by water, forming a solution of hypophosphite o barium and evolving a mixture of free hydrogen and spontaneously inflammable phosphoretted hydrogen.

Jaboin (Compt. rend. 129, 762) prepared the phosphide by heating 100 parts of barium phosphate with 16 parts of lamp black in an electric furnace. The product so obtained has a crystalline structure. It decomposes water yielding PH_3 and $Ba(OH)_2$.

Barium monometaphosphate is obtained as a white powder by evaporating a solution o barium carbonate in excess of metaphosphoric acid and heating the residue to 316°. Its formula is not known with certainty.

Barium dimetaphosphate $Ba(PO_3)_2,2H_2O$ is formed as a crystalline sparingly soluble precipitate when barium chloride is added to a solution of the corresponding ammonium or sodium salt

Barium trimetaphosphate $Ba_3P_6O_{18},6H_2O$ apparently a polymeric form of the last salt, is produced when a solution of 1 part of the corresponding sodium salt in 10 to 15 parts of water is mixed with a nearly saturated solution o 3 parts barium chloride. On standing, the salt separates in monoclinic prisms, which give off two-thirds of their water at 100°, and the rest at a higher temperature.

Barium hexametaphosphate is obtained as a gelatinous precipitate by precipitating the corresponding sodium salt with barium chloride.

Monobarium orthophosphate $BaH_4(PO_4)_2$ is prepared by evaporating a solution of the di- or tri-barium salt in aqueous phosphoric acid. It forms colourless crystals—triclinic according to Erlenmeyer, with acid reaction; soluble without decomposition in a small quantity of water, but decomposed by excess of water into free phosphoric acid and the neutral salt.

Joly (Compt. rend. 98, 1274) states that as the total weight of salt brought in contact with the same quantity of water increases in arithmetical progression, the weight which is dissolved without decomposition decreases in geometrical progression; but as soon as half the original salt has been decomposed a diacid salt is formed $BaO{\cdot}2P_2O_5+xH_2O$, the proportion of which increases as the acidity of the liquid increases, and eventually exists alone in solution.

Dibarium orthophosphate $Ba_2H_2(PO_4)_2$ or $BaHPO_4$ is obtained as a white, scaly, crystalline precipitate when hydrogen disodium phosphate is added to a neutral solution of a barium salt. It is soluble in 20,570 parts of water at 20°, somewhat more soluble in water containing barium or sodium chloride or ammoniacal salts. From the solution in nitric or hydrochloric acid excess of ammonia precipitates the tribarium salt or a salt intermediate between the two. Thus, according to Wackenroder, a solution of $BaHPO_4$ in nitric acid yields, on addition of ammonia, a precipitate of barium phosphato-nitrate $4BaHPO_4{\cdot}Ba(NO_3)_2$, which leaves, on heating, a mixture of di- and tri-barium phosphates.

By precipitating a solution of dibarium phosphate with alcohol, a salt intermediate between the mono- and di-salts is obtained:

$$BaH_4(PO_4)_2{\cdot}2BaHPO_4,3H_2O.$$

If a mixture of potassium silicate and baryta water is boiled, and afterwards mixed with a solution of potassium silicate containing a quantity of potassium phosphate, on cooling, cubical crystals of the composition $BaKPO_4,10H_2O$ separate out. $BaNaPO_4,10H_2O$ was similarly obtained in regular tetrahedrons (De Schulten, Compt. rend. 96, 706).

Tribarium orthophosphate, or neutral phosphate of barium, $Ba_3(PO_4)_2{\cdot}H_2O$ is prepared by adding hydrogen disodium phosphate to a solution of barium chloride rendered strongly alkaline by ammonia, and separates as a heavy granular powder. It parts with a portion only of its water at 200°.

If a saturated solution of tribarium phosphate in hydrochloric acid is evaporated, on cooling, crystals of barium chloride are deposited, more and more monobarium phosphate being left in solution, and if more hydrochloric acid is added, all the barium may be crystallised out as barium chloride, and pure phosphoric acid remains.

If the solution of tribarium phosphate in hydrochloric acid is boiled, shining needles form in the liquid, and on adding sufficient water to redissolve them, well-defined crystals of a phosphato-chloride $4BaH_4(PO_4)_2{\cdot}BaCl_2$ are deposited on standing (Erlenmeyer, J. 1857, 147).

According to Ludwig, a solution of dibarium phosphate in hydrochloric acid also yields, on addition of ammonia, a phosphato-chloride containing $3Ba_5H_2P_4O_{16}{\cdot}BaCl_2{\cdot}3H_2O$.

A salt intermediate between the di- and tri-phosphates, containing $Ba_3(PO_4)_2{\cdot}2BaHPO_4$ or $Ba_5H_2P_4O_{16}$, is formed when a solution of the dibarium phosphate in hydrochloric acid is mixed with a quantity of ammonia just sufficient to precipitate it.

Barium pyrophosphate $Ba_2P_2O_7$. Pyrophosphoric acid does not precipitate barium salts, but with baryta water gives a precipitate of barium pyrophosphate. Barium salts, however, give with sodium pyrophosphate a white amorphous precipitate of barium pyrophosphate, soluble in aqueous pyrophosphoric and sulphurous acids; more soluble in hydrochloric or nitric acid, but not perceptibly soluble in water containing ammonium chloride or in acetic acid.

Monobarium arsenate $BaH_4(AsO_4)_2$ is obtained by adding baryta water to aqueous arsenic acid until a precipitate begins to form, or by dissolving the dibarium salt in aqueous arsenic acid and leaving the solution to crystallise.

Dibarium arsenate

$$2BaHAsO_4,H_2O \text{ or } BaHAsO_4,H_2O$$

according to Berzelius, is obtained when a solution of the disodium salt is added to excess of barium chloride. It gives up its water at a red heat, and in contact with water is decomposed into the tribarium salt, which is precipitated, and the monobarium salt, which dissolves.

Tribarium arsenate $Ba_3(AsO_4)_2$ is obtained as a white sparingly soluble powder by precipitating aqueous arsenic acid with baryta water, or better, by gradually dropping trisodium arsenate into barium chloride.

Barium ortho-thioarsenate $Ba_3(AsS_4)_2$ is obtained together with $Ba(AsS_3)_2$ by the action of hydrogen sulphide on a solution of $BaHAsO_4$. The barium thioarsenate is precipitated by adding alcohol. Arsenic pentasulphide prepared by the action of a rapid stream of hydrogen sulphide on a solution of arsenic acid and hydrochloric acid, reacts with a freshly prepared solution of $Ba(SH)_2$ according to the equation

$$3Ba(SH)_2+As_2S_5=Ba_3As_2S_8+3H_2S$$

After evaporation transparent yellow needles of $Ba_3As_2S_8,6H_2O$ separate (Zeitsch. anorg. Chem 70, 86). A solution reacts with potassium chloride yielding potassium barium ortho-thioarsenate $BaKAsS_4,6H_2O$, which may also be prepared direct by adding KCl to a solution of $Ba(SH)_2$ saturated with As_2S_5.

Barium silicate. Solutions of baryta, when kept in glass bottles for any length of time, deposit transparent rhombic crystals of the composition $BaSiO_3,7H_2O$. These crystals lose their water a little above 100°, and become turquoise-blue: they are decomposed by boiling water (Le Chatelier, Compt. rend. 92, 931); Cossa and Lavalle (Zeitsch. f. Chem. 11, 399).

According to Le Chatelier, they may be readily obtained in a few days, by suspending calcined silica in baryta water, when the sides become covered with crystals.

Barium disilicate $BaSi_2O_5$ has been prepared synthetically. It crystallises in the orthorhombic system. The colourless six-sided plates which form in optical glass rich in barium have been identified with this compound.

Barium titanate. When equivalent quantities of titanic anhydride and barium carbonate are fused at a bright red heat for an hour with excess of barium chloride, and the product extracted with very dilute hydrochloric acid, a residue of yellow microscopic crystals resembling cubes and octahedra of the composition

$$2BaO\ 3TIO_2$$

and of sp.gr. 5·91 remains undissolved. These crystals are found on examination by polarised light to consist of aggregations of rhombic lamellæ.

Reactions of the compounds of barium. When heated on a thin platinum wire in the inner blowpipe flame, or when brought into any non-luminous flame, barium compounds impart a yellowish-green colour to the outer flame. When viewed through the spectroscope two green lines Baα and Baβ come out most intensely; Baγ, though not so marked, is also a characteristic line. Besides these, there are numerous lines in the red and yellow and one broad indistinct line in the blue, close to Fraunhofer's F. Bunsen found that $\frac{1}{1000}$ of a milligram of barium salt may be detected spectroscopically. Silicates of barium give this reaction on moistening with strong hydrochloric acid.

The hydrate, sulphide, chloride, bromide, iodide, nitrate, and many organic salts of barium are soluble in water, and all are poisonous. The majority of the remaining salts are soluble in hydrochloric and nitric acids, whilst the sulphate and silicofluoride are insoluble in all acids.

Alkaline carbonates precipitate white barium carbonate, soluble in most acids, hence ammonium carbonate is used to precipitate it (along with the carbonates of strontium and calcium) in qualitative analysis.

Potassium and sodium hydroxides, free from carbonates and sulphates, give a voluminous precipitate of barium hydroxide $Ba(OH)_2$ with concentrated solutions soluble in more water. Ammonia gives no precipitate.

Sulphuric acid, as well as all soluble sulphates, throws down barium sulphate from all solutions of barium salts. Pickering (Chem. News, 40, 223) states that the smallest quantity of barium which can be detected is 1 part in 833,000 parts of water. The presence of an alkaline citrate greatly interferes with the precipitation. Strontium sulphate (which is more soluble) forms a delicate test for barium.

Phosphate, arsenate, borate, and iodate of sodium also give precipitates soluble in acids.

Ammonium oxalate gives, from moderately dilute solutions, a white pulverulent precipitate of barium oxalate.

Potassium chromate precipitates bright lemon-yellow barium chromate, soluble in nitric, hydrochloric or chromic acid, insoluble in dilute acetic acid.

Hydrofluosilicic acid gives a colourless crystalline precipitate of barium silicofluoride; this reaction will detect 1 part of the chloride in 3800 parts water. The precipitate is nearly insoluble in nitric and hydrochloric acids, more insoluble in alcohol.

Barium is readily distinguished from lead (which also forms a sulphate insoluble in water) by the fact that sulphuretted hydrogen gives a black precipitate of lead sulphide with soluble lead salts.

Soluble barium salts are at once distinguished from those of strontium and calcium by the fact that they are immediately precipitated by a solution of calcium sulphate, which only gives a precipitate with strontium salts on standing. The hydrofluosilicic acid reaction is also of use in separating barium from the other two metals. Barium chloride is insoluble in alcohol, whilst the chlorides of strontium and calcium are soluble, and the nitrates of barium and strontium are insoluble, in alcohol, whilst calcium nitrate is soluble. From these facts a scheme of separation is readily derived, the precipitated carbonates of barium, strontium, and calcium being converted into chlorides, and the chlorides of strontium and calcium dissolved out by alcohol, leaving a residue of chloride of barium. The strontium and calcium may then be separated by converting their reprecipitated carbonates to nitrates and dissolving out the calcium nitrate (*v.* ANALYSIS).

Estimation of barium. When no other alkaline metal is present, barium may be estimated as sulphate. A solution of the chlorides slightly acidified with hydrochloric acid is best. Sulphuric acid is added cautiously to the hot solution in slight excess. The precipitate is allowed to settle in a warm place for some hours before filtering.

For precautions and effect of salts, see work of Karooglanow (Zeitsch. anal. Chem. or Abstrs. J. Chem. Soc. for 1917). For details of volumetric estimation of barium by separation as chromate and titration of liberated iodine, on addition of KI to HCl solution, see Analyst, 43, 287.

In its organic salts barium may be estimated as carbonate by heating in a platinum crucible and subsequent moistening of the residue with a concentrated solution of ammonium carbonate, evaporation, gentle ignition, and weighing.

Where strontium and calcium are present, after the separation of the other elements, the alkaline earths are precipitated by ammonia and ammonium carbonate. This precipitate is then dissolved in acetic acid, and the barium twice precipitated as chromate, in which form it may be weighed or dissolved in hydrochloric acid, then precipitated, and weighed as sulphate.

G. S. B.

BARK BREAD. A kind of bread which was formerly made by the peasants in various parts of Norway from the inner bark of *Pinus sylvestris* (Linn.).

BARKLYITE *v.* CORUNDUM.

BARLEY. Two species are in common cultivation—*Hordeum distichum*, two-rowed, and *H. vulgare*, six-rowed. Many varieties are known, differing in size and shape of ear and grain. The two-rowed varieties are chiefly grown as spring-sown crops, while the six-rowed varieties are often sown in the autumn.

The grain resembles in composition that of other cereals, but contains less gluten than wheat; moreover, the gluten of barley is not so tenacious as that of wheat: consequently, barley meal does not yield a satisfactory bread.

Barley is chiefly grown for cattle-feeding and for malt production. For the latter purpose, a grain containing but little nitrogenous matter is preferred, so that too lavish nitrogenous manuring must be avoided in the production of malting barley.

The following are analyses of typical average barley as given by 1, Warington; 2–5, Kellner (German); 6, Wiley (of American barley).

The table represents the composition of barley expressed in the usual manner. The item 'nitrogenous substances' is simply the total nitrogen ×6·25. Of the total nitrogen, a small portion—probably about $\frac{1}{100}$—is present in non-albuminoid form.

	1 English	2 Medium	3 Large gr'nd	4 Flat gr'nd	5 Feeding	6 American
Water . .	14·3	14·3	14·3	14·3	14·3	10·85
Nitrogenous substances	10·6 [1]	9·4	8·7	10·2	12·0	11·00
Fat . . .	2·1	2·1	1·8	2·5	2·4	2·25
Soluble carbohydrates .	66·0	67·8	70·2	63·7	63 7	69·55
Fibre . . .	4·5	3·9	2·7	6·5	5·0	3·85
Ash . . .	2·5	2·5	2·3	2·8	2·6	2·50

According to Osborne (18th Ann. Rep. Conn. Expt. St.), the proteids in barley are: (1) Soluble: leucosine 0·30 p.c., hordein 4·0 p.c., edestine and proteose 1·95 p.c.; (2) insoluble proteids 4·50 p.c. The soluble proteids just mentioned contain an average of 17·6 p.c. of nitrogen, so that the factor to convert nitrogen into proteids in barley should be much less than 6·25, probably about 5·7. Consequently, the amount of proteids in barley should be about 1 p.c. less and that of carbohydrates (since they are determined by difference) 1 p.c. more than the values given in the tables.

Under the heading 'soluble carbohydrates' are included: pentosans 6·5 p.c. (Bull. 13, U.S. Dept. of Agric. 1898); cane sugar 0·8–1·6 p.c. (O'Sullivan, J. Chem. Soc. 1886, 49, 58); 1·3 p.c. (Banister, Chem. News, 1885, 298); 0·2 p.c. (Bull. 13, *l.c.*); small quantities of reducing sugars (O'Sullivan); dextrine and raffinose (O'Sullivan). The remainder is chiefly made up of starch and cellulose, though gum 2·8 p.c. (Muntz, Compt. rend. 102, 681) and amylan 2–4 p.c. (O'Sullivan, J. Chem. Soc. 41, 24) have also been found.

Barley contains diastase even before germination (when its amount is enormously increased). Brown and Morris (J. Chem. Soc. 1890, 505) recognise two kinds of diastase—of secretion, as formed in germination, which rapidly corrodes starch granules, and of displacement—present in the ungerminated grain - which slowly diminishes the volume of starch granules without visibly corroding them.

The ash of barley, neglecting the CO_2, has the average composition:

—	K_2O	Na_2O	CaO	MgO	Fe_2O_3	P_2O_5	SO_3	Cl	SiO_2
[2] Mean, 28 American samples	24·15	6·42	2·44	8·23	0·33	35·47	0 22	0·56	22·30
[2] „ 19 Canadian „	26·76	9·36	4·27	7·87	0·35	24·63	0·71	0·47	20·69
„ Wolff's analyses .	20·15	2·35	2·60	8 62	0·97	34·68	1·69	0·93	27·54

For a full yield of barley the soil must be well supplied with plant food, including combined nitrogen, but such a crop, though excellent from the farmer's point of view and valuable for feeding purposes, is rarely suited to the maltster's requirement. Good malting barley should be as rich as possible in starch and low in albuminoids. Between 8 and 9 p.c. of nitrogenous matter is usually regarded as the most desirable proportion in malting barley. If grown in hot, dry countries, *e.g.* Southern Russia, it is usually richer in nitrogen. The best malting barleys are grown on light soils not too rich in nitrogen, and in temperate climates (*v.* BREWING).

Owing to the injurious effect of too lavish a supply of nitrogen upon the malting properties of barley, it is by many considered best to take the barley crop after wheat, rather than after roots, though the latter procedure is often adopted in Ireland.

Pearl barley is barley deprived of its husk. American analyses give as its average composition: Water, 10·8 p.c.; protein, 9·3 p.c.; fat, 1·0 p.c.; carbohydrates, 77·6 p.c.; ash, 1·3 p.c.

According to Wolff's analyses, the ash of the barley kernel amounts to 2·13 p.c., and 100 parts of the ash contain:

K_2O	Na_2O	CaO	MgO	Fe_2O_3	P_2O_5	SO_3	SiO_2
28·5	1·8	3·1	12·0	1·9	47·1	2·9	3·6

Barley straw is much more affected in composition than the grain by the richness or poverty of the soil, and by the conditions under which it is grown. If the ripening of the grain has been fully completed, the straw is robbed of its nitrogenous matter and phosphates to a much greater extent than when the seed has not been fully matured. Thus the straw of a crop cut before it is fully ripe possesses much higher feeding value than usual.

According to Kellner, the following represents the average composition of barley straw:—

	Water	Protein	Ether extract	Soluble carbohydrates	Fibre	Ash
Summer barley	14·3	3·5	1·4	35·9	39·5	5·4
Winter barley	14·3	3·2	1·4	33·5	42·0	5·6

The ash of barley straw (Wolff) contains:

K_2O	Na_2O	CaO	MgO	Fe_2O_3	P_2O_5	SO_3	SiO_2	Cl
23·3	3·5	7·2	2·6	1·1	4·2	3·9	51·0	3·2

Barley straw consists largely of cellulose, and pentosans and lignose. The amount of pentosans has been estimated at about 25 p.c. The 'crude protein' given in the above table is probably nearly all true albuminoids, since direct experiments showed about 91 p.c. of the total nitrogen to be present as albuminoids. The lowest portions of the stems are least nutritious, while the uppermost leaves and top of the stem are the most digestible and richest in protein.

When barley precedes clover, as is often the case in England, the barley straw is enriched by including a portion of young clover plants. Under such circumstances, the product is of much higher feeding value, and contains more protein (up to 6 or 7 p.c.), and soluble carbohydrates (38 or 39 p.c.), and less crude fibre.

---

[1] Of which 10·2 p.c. are albuminoids.

[2] Composite samples from the World's Columbian Exposition (Wiley, Bull. 13, U.S. Dept. of Agric.).

H. I.

BARRESWIL'S or FEHLING'S SOLUTION. It has long been known that a mixture of verdigris, honey, and vinegar, when boiled together to form an ointment, changes in colour from green to red.

Vogel (Schweigger's Journ. 13, 162) proved that the precipitate formed consisted of cuprous oxide, and later Buchner attempted to explain the part played by the sugar in the change. Trommer first used alkaline copper sulphate solution as a qualitative reagent for sugars, and succeeded in detecting one part of grape sugar in a million parts of water, and also in differentiating between different kinds of sugars (Annalen, 1841, 39, 360).

Alkaline copper solution was first applied to volumetric analysis by Barreswil (J. Pharm. Chim. 1844, [3] 6, 301), who added potassium tartrate to the solution, and the method of titration was worked out by H. Fehling (Annalen, 1849, 72, 106; 1858, 106, 75).

Various formulæ have been suggested for the preparation of Barreswil's solution by Bödekerr, Soxhlet, Meissl, Herzfeld, Allihn, Kjeldahl, &c. (Bruhns, Zeitsch. anal. Chem. 1899, 38, 78). Indeed, more than fifty cupropotassic solutions are known. They may be divided into four groups, in which potassium hydrogen tartrate, (2) potassium sodium tartrate, (3) potassium tartrate, and (4) tartaric acid are employed. That recommended by Soxhlet is usually preferred, partly on account of its small alkali content.

34·64 grams of pure crystallised copper sulphate, powdered and dried by pressure between filter paper, is dissolved in distilled water and diluted to 500 c.c.; and 70 grams sodium hydroxide (of not less than 97 p.c.) and 180 grams of potassium sodium tartrate (Rochelle salt) are dissolved in 400 c.c. of distilled water and diluted to 500 c.c. Equal volumes of the two solutions are mixed to form the test, which should be kept in a carefully closed bottle to prevent absorption of carbon dioxide, and should not be unduly exposed to light. As the solution is liable to decomposition, a small portion should always be heated to boiling before commencing the test, and the liquid should not be used if any precipitation occurs. It is, however, preferable to keep the two solutions separate until shortly before use (Zeitsch. anal. Chem. 1890, 29, 615).

The Rochelle salt used is best prepared by dissolving commercial cream of tartar in hot water, rendering the liquid slightly alkaline after boiling by addition of sodium carbonate, filtering off the precipitated calcium carbonate, and crystallising the Rochelle salt from the filtrate.

Addition of small quantities of mineral acids to Barreswil's solution by lessening its alkalinity effects its reduction, even when it is still alkaline to litmus. Often the action commences before the liquid is warmed, reduction being completed by gentle heating. The reduction is attributed to the decomposing action of the mineral acid upon the tartaric acid (Jovitschitsch. Ber. 1897, 2431). Evidence of the negative character of the blue ion in Barreswil's solution was first adduced by Kahlenberg (Zeitsch. physikal Chem. 1895, 17, 586), and later by Küster (Zeitsch. Elektrochem. 1897, 105) and Masson (Phil. Trans. 1899, 192, 331).

Masson employed a solution as free as possible from alkali, and electrolysed it in conjunction with a solution of copper sulphate, the blue ions in the two solutions travelling in opposite directions along a tube containing a jelly solution of potassium chloride. The presence of an invisible ion, probably tartaric ion, accompanying the negative blue ions, was demonstrated by the formation of a precipitate at the boundary of the positive blue ions, when the negative ions were still some way off.

The constituent salt of the neutral Barreswil's solution was isolated and analysed by Masson and Steele (Chem. Soc. Trans. 1899, 75, 725), who represented its formation from cupric tartrate thus:

$$5NaOH+4CuC_4H_4O_6$$
$$=Na_2C_4H_4O_6+Na_3C_{12}H_7Cu_4O_{18}+5H_2O$$

They also obtained evidence that the excess of alkali in Barreswil's solution, as usually made, is combined with the blue salt.

F. Bulluheimer and E. Seitz (Ber. 1899, 2347; 1900, 817) showed that three classes of cupric tartrates exist; monotartrates, containing carboxylic and hydroxylic hydrogen, all replaced by metal; double salts consisting of monotartrate, probably united through copper to a molecule of basic alkali tartrates; and a third class consisting of monotartrate combined with basic cupric tartrate.

The salts in Barreswil's solution, from their general reactions, appear to belong to the second class, and compounds having the formulæ $C_8H_4O_{12}CuNa_2K_2$ and $C_8H_4O_{12}CuNa_3K$ have been isolated.

The neutral cuprotartrate of Masson (*l.c.*) requires the addition of alkali in order to form the usual Barreswil's solution with its characteristic colour.

Barreswil's solution is *not reduced* by cane sugar, dextrin, or cellulose, but *is reduced* by dextrose, lævulose, maltose, lactose, mannose, galactose, arabinose, gallisin, aldehyde, chloral, chloroform, valeraldehyde, resorcinol, pyrogallol, gallotannic and trichloracetic acids, and by arsenious acid.

The action of these substances on the solution is doubtful. Among the products are formic, acetic, tartronic, and some acids of doubtful composition and a gum-like substance. Its use is almost restricted to the detection and estimation of reducing sugars. For the *detection* of sugars, the clear, acid-free liquid is heated with two volumes of Barreswil's solution. If one of the above reducing compounds be present, a yellow precipitate of cuprous oxide, which rapidly becomes converted into the orange-red or bright red oxide, is produced. The composition of the oxide whatever its colour may be is identical, the varying colour being due to differences of subdivision, depending upon the conditions during precipitation. Microscopical examination shows that as the different colours are developed there is a gradual increase in the size of the particles (Fischer and Hooker, J. Lab. and Clin. Med. 1918, 3, 6).

If the liquid to be tested is much coloured, it must be first clarified, as described under **Saccharimetry**. When the clarification has been performed with lead, an amount of the solution containing a known weight (2 to 5 grams) of glucose or other body, estimated, is placed in a 100 c.c. flask and is treated with sulphurous acid gas, or with a strong solution of that gas, until the whole of the lead is precipitated, and, after the addition of a little freshly precipitated, washed alumina, is diluted to 100 c.c., agitated and filtered.

Cane sugar, when estimated, is first clarified, if necessary, and then 'inverted'—*i.e.* converted into a mixture of dextrose and lævulose. For this purpose, a solution containing not more than 1 gram of sugar to 4 c.c. of solution is mixed with one-tenth its bulk of fuming hydrochloric acid, and is heated to 70° for 10 to 15 minutes, and finally neutralised by addition of sodium carbonate.

Starch and starchy bodies may also be converted into invert sugar, and estimated by Barreswil's solution. Two or three strong flasks, each containing from one-half to one gram of the substance and 50 or 60 c.c. of decinormal sulphuric acid solution, are closed with caoutchouc corks carefully tied down, and are heated in a water-bath. After 4 hours, one flask is taken out and contents neutralised and titrated with Barreswil's solution as hereafter described, and after a further interval of 2 hours the second is similarly examined. If the amount of sugar found in the second flask does not exceed that in the first, the result may be taken as correct; but if the quantities differ markedly, the third flask is heated a further period of from 2 to 4 hours, and then titrated. Each 100 parts of invert sugar found represents 90 parts of starch.

In titrating solutions of these substances, 10 c.c. of Barreswil's solution is measured into a wide test-tube and diluted to 40 c.c., and heated to boiling. The neutralised sugar solution, which should contain not more than one gram per 100 c.c., is then run in from a burette in portions of 2 c.c., the mixture being boiled after each addition until the blue colour has nearly disappeared. The sugar is then added cautiously until the liquid is colourless or slightly yellow. A few drops of the filtered solution are tested for copper by sulphuretted hydrogen or by a mixture of potassium ferrocyanide and acetic acid.

The solution may be standardised for invert sugar as follows: 4·75 grams of sucrose are dissolved in 75 c.c. water, and 5 c.c. of hydrochloric acid (sp.gr. 1·188) added. The solution is warmed to 70° for about 7 minutes, making a total of 10 minutes' heating. After inversion, the acid is neutralised with sodium hydroxide, and the liquid diluted to 1 litre. 10 c.c. of this solution contains 0·050 gram of invert sugar, and should reduce 10 c.c. of the copper solution (*see also* Börntrager, Zeitsch. angew. Chem. 1893, 600).

Experience shows that the time occupied in the analysis, the amount of excess of copper present in the solution, the concentration of the liquid, and other details, affect the result. Soxhlet (Pharm. J. [3] 1880–1, 11, 721) recommends adherence to the following process. Having approximately found the strength of the solution by running the sugar solution into 50 c.c. of Barreswil's solution as above until the blue colour disappears, dilute it until containing about 1 gram per 100 c.c., and heat 50 c.c. Barreswil's solution with as much of the diluted solution as should precipitate all the copper. When the sugar estimated is invert sugar, grape sugar, or lævulose, the heating should occupy 2 minutes, while for maltose and lactose 4 and 6 minutes respectively should be allowed. The whole fluid is then filtered and tested for copper. A third titration is next performed with a larger amount of the fluid, with 1 c.c. less of sugar (according to the presence or absence of copper), and the titrations are repeated with varying amounts of sugar solution, each time adding the whole of that solution at once, until 1 c.c. more or less would give a filtrate free from or containing a trace of copper, after which the variation in the amount of sugar solution is decreased. In this way, the volume of sugar solution required may be determined to 0·1 c.c. Under these conditions, 100 c.c. of the mixed copper reagent require 0·475 gram anhydrous dextrose or 0·494 gram of invert sugar for complete reduction. The following may be taken as the weight of sugar capable of reducing 10 c.c. of Barreswil's solution:—

	gram
Dextrose, lævulose, or invert sugar	0·0500
Cane sugar (inverted) . . .	0·0475
Milk sugar (lactose) . . .	0·0678
Malt sugar (maltose) . . .	0·0807

Soxhlet (*l.c.*), operating by his method as described above, has obtained the following results. (His method of 'inverting' cane sugar has been somewhat objected to)—

WEIGHT OF SUGAR REDUCING 10 C.C. OF BARRESWIL'S SOLUTION.

—	Time of heating (mins.)	Un-diluted	Diluted with			
			One vol. of water	Two vols. of water	Three vols. of water	Four vols. of water
Dextrose	2	0·0475	0·04825	0·0488	0·0492	0·0494
Invert sugar	2	0·0494	0·05030	0·0509	0·0514	0·0515
Lævulose	2	0·0513	0·05235	0·0530	0·0536	0·0526
Lactose	6	0·0676	Unaffected by dilution			0·0676
Lacto-glucose	2	0·0511	„		„	0·0538
Maltose	3 to 4	0·0778	„		„	0·0740

The titration of raw sugars and other coloured commercial products is very unsatisfactory when potassium ferrocyanide is used as an indicator, mainly because the amino compounds present cause the solution of much cuprous oxide, which then gives a precipitate with potassium ferrocyanide. On this account, indicators have been proposed which will show the presence of a trace of cupric salt without previous filtration, the best of these being ferrous thiocyanate (A. R. Ling, T. Rendle, and G. C. Jones, Analyst, 1905, 30, 182; 1908, 33, 160–170), which gives the characteristic red colour of ferric thiocyanate when treated with cupric salt solution. The reagent is prepared by dissolving 1 gram of ferrous ammonium sulphate and 1·5 grams of ammonium thiocyanate in 10 c.c. of warm water, adding 2·5 c.c. of conc. hydrochloric acid, and completely removing all trace of ferric salt by addition of zinc-

dust. The titration of the sugar solution is carried out much as usual, except that it must be done as quickly as possible to avoid oxidation (Ling. J. Inst. Brewing, 1906, 12, No. 1).

A modification of Barreswil's process, devised by Pavy, is based on the fact that precipitation of the cuprous oxide is prevented by the presence of excess of ammonia, the solution losing its intense blue colour and becoming absolutely colourless after the whole of the copper has been reduced.

The solution used is prepared by mixing 120 c.c. of Barreswil's solution with 300 c.c. of ammonia (0·880 sp.gr.) and 400 c.c. of 12 p.c. caustic soda solution, and diluting to 1 litre. 100 c.c. of this solution corresponds with 10 c.c. of Barreswil's solution. The larger quantity of Barreswil's solution (120 c.c. instead of 100 c.c.) used to prepare this test is required on account of the lower oxidising power of Pavy's solution, the action of which on invert sugar is only five-sixths of that of Barreswil's solution. Its action on maltose and lactose also differs from that of Barreswil's solution.

To prevent reoxidation of the decolourised solution, with reproduction of the blue colour, the operation should be performed without access of air, by connecting the burette supplying the sugar solution with a tube passing through a cork into the flask containing the Barreswil's solution, the steam from which escapes through another tube dipping beneath the surface of mercury. A slow current of coal gas may be passed through the flask during the operation.

The sugar solution is run into the flask, in which 100 c.c. of the copper solution has been heated to ebullition, and the boiling is continued until the colour has disappeared. Hehner (Analyst, 1881, 6, 218) has shown that alkaline tartrates, carbonates, and other salts affect the results.

The method is most used in clinical chemistry, particularly for urine analysis. It is also of great value in studying the saccharine products of enzyme action, especially as it gives with glucose a very much larger 'copper' value than with maltose (Croft Hill, Chem. Soc. Trans. 1898, 73, 634).

The most accurate method of using Barreswil's solution, especially when the sugar solution is unclarified, consists in separating and estimating the precipitated cuprous oxide One of the many processes recommended is that of Pavy. The Barreswil's solution is boiled, in slight excess, with the sugar solution, the strength of which should be about 1 p.c., and the precipitated suboxide is rapidly separated by filtering the liquid through a funnel loosely packed at the neck with glass wool or asbestos. The precipitate, after washing, is dissolved in hot dilute nitric acid, or 2 p.c. conc. nitric acid, or a mixture of dilute sulphuric and nitric acids, and the copper estimated by electro-deposition. The weight of copper obtained is multiplied by 0·5395 to obtain its equivalent in inverted cane sugar, or by other factors, which may be calculated from the tables given above, to obtain the equivalent of any other sugar which may be estimated.

Brunner recommends solution of the cuprous oxide, filtered as above, in a solution of pure ferric chloride or sulphate acidulated with sulphuric acid, and the estimation of the ferrous salt so produced, by titration with a standard solution of potassium permanganate or dichromate.

The cuprous oxide can also be weighed directly after washing with alcohol and ether. It may also be estimated as metallic copper after reduction by hydrogen or as cupric oxide after ignition in porcelain.

For the influence of light on Barreswil's solution, *see* Leighton (J. Phys. Chem. 1913, 17, 205).

BARUS CAMPHOR *v.* CAMPHORS.

BARUTIN. Trade name for the double salt of theobromine barium and sodium salicylate; a white amorphous powder of sweetish taste and alkaline reaction, sparingly soluble in water. Used in the treatment of renal disease. *V.* SYNTHETIC DRUGS.

BARWOOD. Barwood is the wood of a large, fine tree, *Baphia nitida* (Lodd.), and is imported from the west coast of Africa, *e.g.* Sierra Leone, Angola, &c. In the log its physical properties are generally similar to those of sanderswood; in the rasped condition it has a somewhat brighter red colour and is devoid of aromatic odour. According to Girardin and Preisser, boiling water extracts about 7 p.c. of colouring matter, alcohol about 23 p.c., and hydrated ether about 10 p.c.

Anderson (Chem. Soc. Trans. 1876, ii. 582) extracted ground barwood with anhydrous methylated ether free from alcohol. By spontaneous evaporation of the concentrated ethereal solution a small quantity of *baphic acid* is deposited in the form of tabular crystals. After further evaporation, mixing the concentrated extract with alcohol, and allowing to stand for some days, there is deposited a crystalline magma of *baphiin* contaminated with a solid red colouring matter and some dark viscous colouring matter not yet examined.

After exhaustion with ether the wood is extracted with alcohol, and after concentrating the solution it is left at rest for some time, when it congeals to a semi-crystalline mass which contains a viscous red colouring matter and a crystalline constituent not examined.

Baphiin, $C_{24}H_{20}O_8$ (m.p. about 200°), crystallises from alcohol in the form of lustrous tabular crystals having an odour of orris root; from ether it crystallises in tufts of needles. It is insoluble in water, and very sparingly soluble in benzene or in carbon disulphide. In alcoholic solution it rapidly oxidises on exposure to air, producing orange-red or pale purple colours.

Baphic acid $C_{24}H_{22}O_9$ or $C_{24}H_{22}O_{10}$ is prepared by boiling baphiin with dilute caustic potash, and adding hydrochloric acid, when it is thrown down as a yellowish-white precipitate. Crystallised from ether it forms white nacreous scales, very soluble in ether, slightly less so in alcohol, and insoluble in water (*cf.* Santal).

Baphinitin $C_{24}H_{24}O_6$ is thrown down as a crystalline precipitate on the addition of water to the filtrate from the precipitate of lead baphate which is formed on mixing alcoholic solutions of baphiin and lead acetate. It is also the chief product of the action of boiling dilute caustic potash on baphiin. Baphinitin forms white needles, soluble in alcohol or in ether, but insoluble in water; it has the same odour as baphiin but stronger (*cf.* Pterocarpin).

Baphinitone $C_{26}H_{26}O_6$.—On boiling baphiin with a strong aqueous solution of caustic potash without access of air, an insoluble residue is left which contains three substances: (1) baphinitin, moderately soluble in alcohol or ether; (2) baphinitone, very readily soluble in these liquids; (3) a small quantity of an unexamined substance, m.p. 164·1°, very sparingly soluble even in hot alcohol, and separating therefrom in granular crystals. Baphinitone is extracted from the above-mentioned residue insoluble in caustic potash, by treating it with cold alcohol, in which it readily dissolves along with a very small amount of baphinitin. The solution is evaporated, and the treatment with alcohol is repeated until the crystals thus obtained, after drying over sulphuric acid, have a m.p. of about 88°. Baphinitone crystallises from alcohol in hemispherical masses composed of white lustrous radiating crystals insoluble in water (*cf.* Homopterocarpin).

Tribromo-baphinitone $C_{26}H_{23}Br_3O_6$ is obtained by mixing ethereal solutions of baphinitone and bromine; on evaporating off the ether it remains as a white substance, which may be purified by washing with alcohol or ether, in which it is almost insoluble. It separates from a hot ethereal solution in small granules, which melt with blackening at 180·2°.

Baphiin, baphinitone, and substance (3) above referred to, are all coloured orange-yellow by sulphuric acid; with nitric acid an orange-red colour is obtained, which changes gradually to green.

In addition to the above-mentioned substances, barwood contains, according to Anderson, at least three colouring matters. Ether extracts from the wood two of these; one (*a*) which is less soluble, and which tenaciously adheres to the baphiin, and another (*b*) which is crystalline and is easily removed from it. When the extraction with ether is completed, alcohol will dissolve out a third colouring matter (*c*). All are insoluble in benzene, and give purple lakes with lead acetate, and purple solutions with alkalis.

O'Neill and Perkin (*l.c.*) worked up barwood by the same methods they had previously applied to sanderswood, and isolated a colouring matter, corresponding with the santalin of this latter, This, which consisted of a chocolate-red powder, possessed the formula $C_{22}H_{16}O_5(OCH_3)_2$, and on heating commenced to soften at 240°, apparently decomposing, and at 270° had the appearance of a honeycombed carbonaceous mass. Its colour reactions are the same as those given by santalin, and it thus appears probable that the two compounds are identical.

When the crude colouring matter of barwood, dissolved in alcohol, is poured into ether the main bulk of the santalin is precipitated. The ethereal liquid now contains, in addition to a colouring matter resembling *deoxysantalin*, two crystalline substances identical with those previously stated by Wiedel (*l.c.*) as present in sanderswood. To isolate santal the ether solution is treated with hydrobromic acid to remove colouring matter, the colourless crystalline residue remaining after evaporation is washed with benzene, and recrystallised first from dilute and subsequently from absolute alcohol.

The analytical figures given by this compound agree with those obtained by Weidel, but methoxy determinations show that its formula is to be represented as $C_{15}H_9O_5(OCH_3)$, and not $C_8H_6O_3$, as proposed by this author.

Santal, which seems to be very similar to Anderson's baphic acid, melts at 222°–223°, is readily soluble in dilute alkali hydroxides, and sparingly so in absolute alcohol from which it crystallises in thin plates or flat needles. With alcoholic lead acetate it gives a colourless precipitate, and with alcoholic ferric chloride a violet-black colouration, although this, according to Weidel, is dark red. By the action of hydriodic acid santal is converted into *santol*, probably $C_{15}H_{10}O_6$, which consists of small colourless flat needles, m.p. 270°–273°. Its solution in dilute alkali hydroxide, at first colourless, rapidly develops a reddish-violet tint, and the liquid on acidification deposits yellow crystals. If the acid mixture is boiled these become colourless, apparently with regeneration of santol, for when collected and washed the product can again be made to produce the same changes. Santol thus appears to contain a lactone group. The hydrobromic acid liquid obtained during the isolation of the santal, was diluted with water, the precipitated colouring matter dissolved in a little ethyl acetate, the solution being allowed to evaporate spontaneously. Minute crystals were slowly deposited, and these were collected and digested with absolute alcohol to remove santal. This compound, evidently Weidel's substance $C_{14}H_{12}O_4$, and termed by O'Neill and Perkin *santalone*, is sparingly soluble in most organic solvents, and crystallises from alcohol in small red leaflets. It is soluble in dilute alkalis with a red colour, whereas alcoholic ferric chloride colours it a violet tint. As obtained by these latter authors its complete purity was doubtful, but the purest preparation obtained darkened about 280° and melted at 300°. Its true formula is probably either $C_{22}H_{13}O_4(OCH_3)_3$ or $C_{22}H_{15}O_4(OCH_3)_3$, and in case this is correct this compound has the composition of a *deoxysantalin monomethyl ether* with which its general properties are in harmony.

Ryan and Fitzgerald (Proc. Roy. Irish Acad. 1913, 5, 106), employing the following method, have isolated *homopterocarpin* from barwood. The ground material was percolated for a few days with warm alcohol, then with ether, and finally with chloroform. The residue obtained by evaporating these extracts was exhausted with ether, the ethereal solution washed with dilute alkali and then distilled. The product, when recrystallised from alcohol, formed colourless acicular crystals, m.p. 84°, and was identical with the baphinitone of Anderson and the homopterocarpin existing in sanderswood.

A fuller account of this compound, which possesses the formula $C_{17}H_{16}O_4$, is given in the article describing the latter dyewood. It is very probable, again, that the *baphinitin* described by Anderson as existing in barwood is pterocarpin. A. G. P.

BARYTA GREEN *v.* BARIUM.

BARYTES. Barite, or heavy-spar (from βαρύς, heavy); a common mineral consisting of barium sulphate ($BaSO_4$), and crystallising in the orthorhombic system. The name barytes is, however, sometimes loosely, but incorrectly, applied to include both this species and the mineral witherite ($BaCO_3$, *q.v.*), or these are occasionally referred to as 'sulphate of barytes' and 'carbonate of barytes' respectively. The reason for this confusion is that the two minerals are often mined together, although they are not always put to the same uses.

Barytes is frequently to be found as well-developed crystals, which vary considerably in their appearance and habit. They possess a perfect cleavage parallel to the base, and perpendicular to this are two prismatic cleavages parallel to the faces of the primitive rhombic prism, and inclined to one another at an angle of 78° 22½′. With these three directions of perfect cleavage, massive barytes sometimes presents a certain resemblance to calcite, and its hardness is also about the same (H.=3). The angles between the cleavages are, however, different; and, further, barytes may be readily distinguished from calcite by its heaviness (sp.gr. 4·5), and from both calcite and witherite by not effervescing with acid. The massive material is often white and opaque; but crystals are sometimes transparent and colourless, or with brownish, greenish, or bluish shades of colour.

Barytes is usually met with in veins, often in association with ores of lead. Some of the old lead-mines of the north of England, Derbyshire and Shropshire are now being reworked for barytes. A remarkable vein of barytes, consisting of pure white massive material with a thickness varying from a few inches to 16 feet, is extensively worked in the coal-measures at New Brancepeth Colliery, near Durham (L. J. Spencer, Mineralog. Mag. 1910, xv, 302). Beautiful crystallised specimens are abundant in the hæmatite-mines of west Cumberland, but, owing to the brown or yellow colour of this material, it is of no commercial value. A pure white granular barytes resembling marble in appearance is mined at Dunmanus Bay, in Co. Cork. Important deposits of the mineral are worked in the United States, Germany, Rhodesia, &c. Barytes occurs abundantly as a cementing material in Triassic sandstones in the Midlands of England (F. Clowes, 1889, 1890); and it has been recently suggested that this could be easily won by washing.

Barytes is mainly used in the manufacture of paints, not only of white paint, but as an inert body in coloured paints. Lithophone paint consists largely of barium sulphate with zinc oxide and sulphide. It is often suggested that barytes is used for adulterating various articles. Barium sulphide and carbonate are also prepared from barytes by roasting it with coal, and from the product, barium chloride, barium hydroxide, &c., are prepared. In preparing the crude barytes for the market, it is coarsely crushed and hand-picked; or when mixed with rock and dirt, these are separated by agitation (jigging) in water. Coloured impurities are sometimes extracted by steam-boiling with sulphuric acid. The purified material is kiln-dried and reduced to very fine white powder in a ball-mill provided with screens, or between millstones. The barytes flour so prepared stil consists of minute crystalline (cleavage) particles and it is this that gives the 'tooth' or adhesiv properties to the coarser barytes paints. Th finer qualities ('blanc fixe') are prepared from precipitated barium sulphate; and this is als used for dressing cloth and leather, and fo producing the smooth coating on 'art' papers

Survey, 2nd ed. 1916 For the United States, and a general accoun with bibliography, *see* Mineral Resources of th United States, for 1915, U.S. Geol. Survey 1916; H. Ries, Economic Geology, New York 1916. L. J. S.

BARYTIC WHITE or **PERMANENT WHIT** or **BLANC FIXE** *v.* BARIUM; also PIGMENTS.

BARYTO-CELESTITE *v.* BARIUM.

BARYTOCALCITE, Barium and calciu carbonate, $BaCO_3 \cdot CaCO_3$, crystallising as prismatic and blade-shaped crystals in the monoclinic system. There are good cleavages i three directions (the basal plane and a prism) and curiously the angles between these ar near to the angles between the three cleavage of calcite. The composition is the same as tha of alstonite (*q.v.*), but whilst alstonite is a isomorphous mixture of barium and calciu carbonates, barytocalcite is a double salt. Th mineral is white or colourless, and has a vitreou lustre. Sp.gr. 3·65; hardness 4. Apart from a doubtful record from Glamorganshire, th mineral has been found only in the old Blagill or Bleagill,[1] lead mine, near Alston, in Cumberland. Here it occurs in considerable quantity and was at one time mined as a 'low-grad witherite.' Large blocks of massive material with crystal-lined cavities may still be found lying outside the mine. Although containing less barium carbonate (66·3 p.c.) than witherite, it may prove to be of commercial value. L. J. S.

BASALT. A group of volcanic rocks of basic composition (SiO_2 45–55 p.c.), corresponding with the plutonic gabbros. The name is one of the oldest in petrography, being of Ethiopian origin and said to signify a stone that yields iron. Many of the ancient Egyptian and Assyrian monuments were carved in basalt, and it is the material of the famous Rosetta stone. The term is used in rather different senses. A quarryman often recognises amongst the difficultly-worked igneous rocks only granite and basalt, and commonly any dark-coloured fine-grained rock is included under the term basalt or trap-rock. Also petrographers are not agreed amongst themselves as to the limitations of the term. Strictly, it should be applied to a rock which has flowed as a lava on the earth's surface, and is composed of a basic plagioclase-felspar (bytownite or labradorite) and augite, together with small amounts of magnetite and ilmenite, and sometimes glassy (uncrystallised) material in the groundmass. Sometimes porphyritic crystals are present, but usually the component minerals can only be recognised when thin sections of the rock are examined under the microscope; the rock appearing compact and homogeneous to the unaided eye. Other minerals are sometimes present, particularly olivine, and we then have the varieties olivine-basalt, hornblende-basalt, &c. In a less common type of alkali-basalt the felspars are partly or wholly replaced by felspathoid minerals (nephelite, leucite, and melilite). When the felspars are wholly replaced we have the varieties nephelite-basalt, leucite-basalt, &c.; and when both felspar and felspathoid are present the rock is termed tephrite or basanite, according as olivine is absent or present. A leucite-basanite, then, consists of plagioclase, augite, olivine, and leucite. Analyses of some of these types of basaltic rocks are given below: I, average of 198 analyses of typical basalts, including olivine-basalts; II, basalt from Disko Island, west Greenland; III, olivine-basalt from the Isle of Skye, Scotland; IV, leucite-tephrite from Rome; V, leucite-basalt from Highwood Mountains, Montana.

---

As a consequence of their volcanic origin, basalts often exhibit a vesicular texture, owing to the expansion of water-vapour in the rock before consolidation; and in these cavities secondary minerals (chalcedony, calcite, and zeolites) are often deposited. A well-marked columnar structure, often on a large scale, is a common character; *e.g.* at the Giants' Causeway in Co. Antrim, the Staffa caves in the Western Isles of Scotland, and in the Linz basalt quarry on the Rhine. It is a dense, black rock weathering to brown or dark green. Sp.gr. 2·8–3·1. The crushing strength is high (2000–3000 tons per square foot); the absorption for water low (about 1 p.c.); and the conductivity for heat considerable, buildings of basalt being for this reason cold in winter and hot in summer.

Basalts are of world-wide distribution, and sometimes cover enormous tracts of country; *e.g.* the Arctic region extending to the Western Isles of Scotland, and the north of Ireland, the Deccan traps of India, and the lava-fields of Washington, Oregon, and Idaho. The rock is quarried at many places for road-metal and paving stones, and on the Continent as a building stone. But it is to be remembered that much of the rock quarried under the name of basalt is included by petrographers under other terms, particularly dolerite and diabase (*q.v.*). The types of alkali-basalts are less widely distributed, but are abundant in central Italy, in the neighbourhood of Rome and Vesuvius, and are known in Germany, Bohemia, Wyoming, Montana, and Brazil. These are of importance on account of their high content of potash (analyses IV and V above). L. J. S.

BASE OILS *v.* Oils and Fats.

BASIC BESSEMER STEEL *v.* Iron.

BASILICON. *Resin cerate.* A mixture of oil, wax, and resin.

BASIL OIL *v.* Oils, Essential.

BASLE BLUE *v.* Azines.

BASSIA MAHWA or MOWRAH FLOWERS. The flowers of *B.* (*Illipé*) *latifolia* (Roxb.) or Mahwa, a tree growing to the height of 60 feet, very abundant in Central India, are very succulent, and fall from the tree in large quantities every night, a single tree affording from 200 to 400 lbs. of flowers in a season, which lasts during March and April. They are used as an article of food, both cooked and raw. By fermentation and distillation they yield upwards of 6 gallons of proof spirit per cwt. It is of superior quality, and when the operations have been carefully performed, is very much like good Irish whisky, having a strong smoky and rather fœtid flavour, which disappears with age.

They have also been used as a cattle food with success. It is said that the flesh of pigs and other animals is much improved, acquiring a delicate flavour.

The dried flowers have been recommended as a source of sugar. Negri found in them 57·9 p.c. of glucose, yielding 26·74 p.c. of alcohol on distillation (Rev. Chim. Med. Pharm. 2, 384; *cf.* von Lippmann, Ber. 1902, 35, 1448).

BASSIA OILS. Under this name are comprised a number of oils belonging to the genus *Bassia*. The most important oils (or fats) derived from *Bassia* species are: Mowrah Seed Oil, Illipé Butter, Shea Butter, Njave Oil, and Phulwa Butter. For a description of the fats derived from the kernels of different species of Bassia, *see* Bull. Imp. Inst. 1911, 9, 228.

Mowrah Seed Oil is the fat obtained from the seeds of *Bassia latifolia* (Roxb.) (*Illipé latifolia*, Roxb. or Engler; *Bassia villosa*, Wall.), a tree widely distributed in the northern provinces of India, and especially in Bengal. The tree is frequently cultivated in East India, and forms small plantations; but even under the incentive of modern demand for a solid fat, the cultivation of the Mowrah Seed tree for the production of fat is not likely to be taken in hand in the near future. The tree gradually disappears towards Calcutta, and is only sparingly met with in the Madras presidency, where its place is taken by *Bassia longifolia* (*see* below).

The kernels are 1-2 cm. long, and are enclosed in a light-brown shiny husk. The seeds are very similar in appearance to those of *Bassia longifolia*, with which they are frequently confounded, much as the fat obtained from both species is frequently confounded in commerce. This is partly due to the fact that the two kinds of fats are mixed together when exported to Europe, a practice which is greatly favoured by the fact that both species are known to the natives under such similarly sounding names as Illipi, Elupa, Katillipi.

The kernels dried at 100° contain, according to Valenta:

Fat extracted (by petroleum ether) .	51·14
,, soluble in absolute alcohol . .	7·83
Tannin	2·12
Bitter principle, soluble in water . .	0·60
Starch	0·07
Vegetable mucilage	1·65
Albuminous substances soluble in water	3·60

Extractive substances soluble in water	15·59
Insoluble proteins	4·40
Total ash	2·71
Fibre and loss	10·29

In its fresh state the fat is yellow; on exposure to the air the colouring matter is bleached. The oil can also be bleached chemically, as has been done by the author, on a large scale.

The fat has the sp.gr. of 0·9175 at 15°, melts at about 25·3°–30°, and solidifies at 18·5°–22°.

The fat has a bitter aromatic taste and a peculiar odour. The iodine value of the fat is 50, thus indicating a considerable amount of oleic acid. The chief constituent of the solid fatty acid is palmitic acid; arachidic acid is absent; stearic acid (13–25 p.c.) has been found to occur in specimens examined by Menon. The saponification value of the commercial fats is slightly lower than that of fats having the constitution due to the fatty acids named, owing to a somewhat high proportion of unsaponifiable matter, viz. 2·34 p.c. The fat is prepared in India in a crude manner, and the cakes are used as manure. Owing to a bitter principle (saponin) contained in the cakes, they are unfit as food for cattle. Nevertheless, the cake is frequently added as an adulterant to the so-called 'native linseed cake,' which, under this misleading name, has latterly found extensive sales on the Continent. The seeds and the oil have become an important article of commerce. They are imported to Europe in irregular quantities, and are chiefly used in the soap and candle industries. Endeavours have also been made to convert the fat into an edible fat. In India, Mowrah seed oil is largely used as an edible fat under the name 'Dolia oil,' and as a medicinal oil in the treatment of skin diseases under the name 'Mo oil.'

Illipé Butter is obtained from the seeds of *Bassia longifolia* (Linn.), a tree indigenous to the southern part of India; a variety of this *Bassia* species is known as *Illipé malabarica* (König), in the Western Ghats from Kanara to Travancore and the Anamalais, where the tree is found at an altitude of about 4000 feet. The seeds bear a close resemblance to those of *B. latifolia*, but are mostly 3–4 cm. long, and less rounded than the seeds of *B. latifolia*. The average weight of one seed is 1·4 grms. The kernels form 75 p.c. of the seeds, and contain 50–55 p.c. of a white to light-yellow coloured fat. The fat closely resembles Mowrah seed oil, but differs from it by its lower solidifying and melting points; in correspondence therewith the iodine value of the fat is 58–64, *i.e.* higher than that of *B. latifolia*. The fat contains from 12 to 20 p.c. of stearic acid; arachidic acid is absent (Menon).

Illipé seeds are imported into France and England (usually in admixture with Mowrah seeds), where the fat is expressed for use in candle-making. The proposal to employ the fat as a chocolate fat appears to be due to the confounding of true Illipé seeds with seeds from the Malayan States, erroneously described in the market as 'Illipé nuts.'

Owing to the fact that the term 'illipé' is applied to many fats, it has been suggested by Revis and Bolton (Fatty Foods, 183) that the confusion might be prevented by adopting the name 'Latifolia' and 'Longifolia fat' for the products of the preceding species.

Shea Butter is the fat obtained from the seeds of *Bassia Parkii*, De C. (Hassk.), *Butyrospermum Parkii*, [G. Don] (Kotschy), a tree belonging to the *Sapotaceæ*. The tree was first described by Mungo Park, who found it in the kingdom of Bambara. Hence the fat was known as Bambara fat and also Bambooi fat. Other native names are Galam Butter, Bambuk Butter, and, in French West Africa, Karité Oil. The Shea Butter tree, or Karité tree, which resembles in appearance the American oak, and grows to a height of about 40 feet, occurs in enormous quantities on the West Coast of Africa, and through the centre of Africa in the French and English Soudan. It is especially abundant in the middle basin of the Niger, and is as characteristic of the region of the middle Niger as is the palm tree of the lower reaches of the rivers and of the coast line. The Shea nut has the size and shape of an ordinary plum; the outer shell of some specimens is covered with fine fibres, whereas the shell of nuts coming from the middle Niger district has a polished surface. Owing to the wide distribution of the tree, the different specimens of nuts and fats exported to Europe show characteristic differences. A special variety appears to be represented by the specimen known as *Bassia niloticum* (Kotschy et Chevalier). The seeds contain from about 32 to 44 p.c. of fat, corresponding to about 49 to 59 p.c. in the kernel, the amount varying with the origin of the seed. The natives extract the fat by pounding the kernels and boiling the paste with water. The fat rises to the surface and is skimmed off into large calabashes, in which it is carried to the river for shipment. Since little care is taken in the preparation of the exported oil, much of the shea butter sent to Europe had at one time a dark-grey colour, which was considered to be characteristic of shea butter. The fat used by the natives for their own purposes is, however, prepared in a more careful manner, made into cakes and wrapped round with leaves, so that it may keep. This fat is of a white colour, and keeps well for several months.

Shea butter plays a very important part in the economy of the natives as an edible fat, and also as a burning oil, and for cosmetic purposes. Attempts have been frequently made to ship the fat and the nuts in bulk to Europe. Owing partly to the careless preparation, and partly to a resinous substance dissolved by the fat, shea butter contains considerable amounts of unsaponifiable matter which imparts to the fat an indiarubber-like taste. This large amount of unsaponifiable matter (5–9 p.c.) has prevented the extensive employment of the fat for soap-making purposes; but methods for removing part of the unsaponifiable matter have been devised. The fat is also used as a candle material, and, in the refined form, as a substitute for lard.

The specific gravity of the fat is 0·9177; its melting-point varies from 25° to 28°. Owing to the considerable amount of unsaponifiable matter, the saponification value varies from 171 to 192. The iodine value varies from 56 to 63, so that the proportion of oleic acid in the fat may be estimated at about 60 p.c. The author found in a number of shea butters from 33 to 37 p.c. of stearic acid. The remainder of the fatty acid appears to consist of lauric acid (Southcombe, J. Soc. Chem. Ind 1909, 499).

Njave Oil, *Njave Butter, Nari Oil, Noumgou Oil, adjab Oil*, is the oil obtained from the seeds of *Mimusops Njave* (De Lanessan), syn. *Bassia Djave* (De Lanessan); *Bassia toxisperma* (Raoul); *Tieghemella africana* (Pierre); *Baillonella toxisperma* (Pierre); *Baillonella Djave* (Pierre); *Tieghemella Jollyana* (Pierre), a tree belonging to the family of the *Sapotaceæ*. The wood of this tree is known in commerce as 'Cameroon mahogany.' The tree is indigenous to West Africa, the Cameroons, Gaboon, and Nigeria, and furnishes, like most trees belonging to the *Sapotaceæ*, guttapercha. The fruits are known in commerce as 'Mahogany nuts'; in the Gold Coast Colony they are termed 'Abeku and 'Bako' nuts. The weight of the nuts varies between 10 and 21·6 grams, one-third of which is made up by the shell. The kernels contain 43–64 p.c. of a white fat, which the natives (the *Jaundes* and the *Ngumbas*) prepare by drying the seeds over fire and breaking the shell with stones. The kernels are then pounded in a mortar or comminuted by rubbing between stones. The mass is next boiled out with water, the fat is skimmed off by hand, and freed from the bulk of water by squeezing between the hands, and then subjecting it to a somewhat stronger pressure in baskets, by heaping stones on the mass. By this process an extremely poisonous saponin, contained in the fresh seeds, is completely removed, so that the fat can be used for edible purposes. In case the seeds should be expressed on a large scale the press cakes would retain the poisonous substance, and hence be valueless as a feeding cake (Der Tropenpflanzer, 1910, 29), unless the saponin be removed completely by boiling out with water. But even if this process were feasible, a considerable amount of nutritive substances would be removed thereby. The economic prospects of the seeds are, therefore, still doubtful; nevertheless, the exports from the German Cameroons have increased from 3 tons in 1906 to 183 tons in 1908. The fat solidifies at about 21°, and has an iodine value of about 65.

Phulwa Butter is the fat expressed from the kernels of *Bassia* (*Illipé*) *butyracea* (Roxb.), the 'Indian butter tree,' which is indigenous to the Himalayas. The seeds, known as 'phulwara,' are smaller and thinner than those of *B. latifolia* and *longifolia*. The average weight of one seed is one gram. The kernels form 67·5 p c. of the total seed; they contain 50–66 p.c. of a white fat, having the consistence of lard. Phulwa Butter is one of the most important foodstuffs amongst the natives of the North-West Provinces, on account of its pleasant odour and agreeable taste, and is frequently used to adulterate Ghee. The butter is also highly valued by the natives as an ointment when properly perfumed. The melting-point of the fat is 39°, and its iodine value 42°. Stearic acid is absent (Menon).

Less-known Bassia Oils are: *Payena Oil* or *Kansive Oil*, from *Payena oleifera* (Chemical Technology and Analysis of Oils, Fats, and Waxes, ii. 800), and *Katio Oil*, from *Bassia Mottleyana*, which solidifies at 14°–15° and has an iodine value of 63–65 (Brooks, Analyst, 1909, 207). J. L.

BASSORIN *v.* Gums and Gum Tragacanth.

BASSWOOD OIL. An oil from *Tilia americana*, resembling cotton-seed oil, and consisting of glycerides rich in butyric acid (Wiechmann, Amer. Chem. J. 1895, 17, 305).

BAST FIBRES. Elongated narrow plant-cells that form strengthening tissue in stems and leaves, especially in connection with the fibro-vascular bundles, but not belonging to the wood. The raw material, bast or bast-like fibre, used for textile purposes or for the manufacture of paper, ropes, and the like, is of varied nature and source, but is always characterised by the abundance in it of bast fibres. It may be composed of a number of fibro-vascular bundles, or one such bundle (*e.g.* coco-nut fibre), or part of fibro-vascular bundle (*e.g.* fibre from leaves of monocotyledons), or merely a bundle of true bast fibres (from the fibro-vascular bundles or bark of dicotyledonous stems).

A typical bast fibre has a thick wall, with slit-like oblique pits, and a relatively small lumen. The ends usually taper to fine points, but may be blunt or even branched. The cell-wall varies in thickness in different species, from comparatively thin to extremely thick, and may vary in the same fibre, so that the lumen is alternately wider and narrower. When the wall is very thick the lumen is reduced to a line, and may be locally evanescent. There are similar differences in the width, length, and strength of the raw material and individual bast fibre. The colour varies from the usual whitish-grey or green or yellow, through yellow and brown to black.

The cell-wall is mainly composed of celluloses and in certain species (flax, *Calotropis gigantea*, and others) is entirely soluble in ammoniacal cupric oxide, and gives the colour reactions for celluloses; but the bast fibres of certain other species (jute, hemp, esparto, and others) show lignification, and give corresponding colour reactions.

Bast fibres in commercial use are mainly obtained from comparatively few alliances and families of dicotyledons, and genera of monocotyledons, namely, Malvales (Malvaceæ), Tiliaceæ, Sterculiaceæ, Urticales (Moraceæ, Urticaceæ, Ulmaceæ), Leguminosæ, Linaceæ, Apocynaceæ, and Asclepiadaceæ, Boraginaceæ; *Agave* and *Fourcroya*, *Aloë*, *Bromelia*, *Sanseviera*, *Musa*, *Stipa*, *Pandanus*, and several palms. (*See* articles on any of these, and Jute and Hemp. For a full authoritative account of vegetable fibres, *see* Wiesner, Die Rohstoffe des Pflanzenreichs, 1903, Bd. ii. 167–463.)

BASTNÄSITE. A fluocarbonate of cerium-metals (CeF)CO_3, long known as small yellowish masses with greasy lustre embedded between allanite crystals at the Bastnäs mine, Riddarhyttan, Sweden. It has also been observed as an alteration product of tysonite (CeF_3) in the granite of the Pike's Peak region in El Paso Co., Colorado. Recently large masses have been found in Madagascar in the weathered debris of pegmatite at Torendrika to the east of Ambositra and near Antsirabe. These have the form of rough hexagonal prisms of a yellow to reddish-brown colour. Some crystals show an separation parallel to the basal plane on which the lustre is then pearly, otherwise it is greasy in character. The crystals are optically uniaxial and positive. Sp.gr. 4·948. The mineral is difficultly attacked by hydrochloric acid, but is decomposed by sulphuric acid, with evolution of carbon dioxide and fluorine. It is infusible before the blowpipe. L. J. S.

BATATAS, or Sweet Potatoes, the tubers of *Ipomœa batatas* or *Batata edulis*, a convolvulus-like plant, usually with purple flowers, growing freely in tropical and sub-tropical countries. The tubers are sometimes of great size—up to 12 lbs. or more in weight.

It can be propagated by cuttings or by the tubers, and, once established, often yields several crops in succession. An average crop is about 5 tons per acre. Light friable soils are most suitable.

Average composition of sweet potatoes and their vines:

	Water	Protein	Fat	Soluble carbohydrates	Fibre	Ash
Tubers .	71·1	1·5	0·4	24·7	1·3	1·0
Vines .	41·6	7·6	2·1	29·3	13·6	5·8

A more detailed analysis of the tubers as grown in Monte Video, is given by Saco (Bied. Zentr. 1883, 337):

Water	Protein	Glucose	Mucilage	Pectic acid	Starch	Fibre	Ash
67·0	0·56	0·3	1·15	1·27	13	10	1·0
to	to	to			to	to	
68·2	0·64	4·0			15	17·8	

The sweet potatoes are largely used as food, and also in the manufacture of alcohol.

According to Stone (Ber. 1890, 23, 1406), they contain from 1·5 to 2·0 p.c. of cane sugar, and baking converts the starch into the soluble form and hydrolyses the cane sugar. The tops of sweet potatoes are greedily eaten by farm animals, but should be used with care, since they sometimes contain a poisonous cyanogetic glucoside. Amounts of hydrocyanic acid, varying from 0·014 to 0·019 p.c. of the green material, have been found. Sweet potato vines have often proved fatal to pigs in Queensland.

Hasselbring and Hawkins (J. Agric. Research, 1915, 5, 543) state that the amount of sugar in the tubers is comparatively small until after they are harvested; but when they are cut off from connection with the leaves, the starch is transformed, first, into reducing sugars, and ultimately into sucrose. The reaction proceeds rapidly at high temperatures, but soon reaches an end-point, while at lower temperatures the change is slower, but ultimately proceeds further. H. I.

BATH BRICK. A brick made from deposits of silicious and calcareous earth at Bridgwater, Highbridge, and elsewhere, and used for polishing metals.

BATH-METAL. An alloy of copper and zinc, containing a larger proportion of copper than ordinary brass, viz. 83 p.c. copper to 17 p.c. zinc; sp.gr. 8·451; fracture crystalline, and colour yellowish-red.

BATHYCHROME *v.* Colour and Chemical Constitution.

BATIST. A material consisting of cotton impregnated with caoutchouc on one or both sides, largely used in the French army for compresses and antiseptic dressings.

BAUXITE. A clay-like aluminium hydroxide first noticed by P. Berthier in 1821 (*alumine hydratée des Beaux*), and named beauxite by A. Dufrénoy in 1847, and bauxite by H. Sainte-Claire Deville in 1861; this name being from the village Les Beaux, or Les Baux, near Arles, dep. Bouches-du-Rhône, in the south of France, where the material was found. This material came to be regarded as a mineral species with the composition $Al_2O_3,2H_2O$, corresponding with Al_2O_3, 73·9; and H_2O, 26·1 p.c.; that is, intermediate between the definite crystallised species diaspore (Al_2O_3,H_2O) and hydrargillite or gibbsite ($Al_2O_3,3H_2O$). It, however, varies widely in composition, owing to intermixture with quartz-sand, clay, and iron hydroxide, and it passes insensibly into clays, iron-ores, and laterite. The variations shown by different analyses are: Al_2O_3, 30·3–76·9; H_2O, 8·6–31·1; Fe_2O_3, 0·1–48·8; SiO_2, 1·1–41·5; TiO_2, 1·6–4·0 (from table of analyses quoted by G. P. Merrill, The Non-metallic Minerals, New York, 1910). (For other analyses of French bauxite, *see* H. Arsandaux, Compt. rend. 1909, cxlviii, 936, 1115; Bull. Soc. franç. Min. 1913, xxxvi, 70.)

The material never shows any indications of crystalline structure, being always compact or earthy, or often with a concretionary (pisolitic or oolitic) structure. In colour it ranges from white, through creamy and yellow, to brown and deep red. Under the microscope it shows only optically isotropic, flocculent grains. Bauxite is thus no doubt a mixture of colloidal aluminium hydroxides (for which the mineralogical name kliachite has been proposed by F. Cornu, 1909, and sporogelite by M. Kišpatić, 1912) with various iron hydroxides, clays, &c., and possibly also the crystalloids diaspore and hydrargillite; and it is thus rather of the nature of a rock than a simple mineral.

In its mode of occurrence, and no doubt also in its mode of origin, it also shows wide differences. The extensive deposits in the south of France have the form of beds interstratified with limestones of Cretaceous age, or of irregular pockets in the limestone. Those of Co. Antrim and of the Vogelsberg and Westerwald in Germany, are associated with laterite, and are interbedded with basaltic lava-flows. In Arkansas the bauxite deposits occur only in Tertiary areas in the neighbourhood of eruptive syenites, while in Alabama and Georgia they overlie ancient sedimentary rocks. The frequent presence of pisolitic structures in the material and its association with limestones, has led to the suggestion that bauxite has been deposited by hot springs containing aluminium salts in solution (probably aluminium sulphate from the decomposition of pyritous shales), where these have come into contact with limestone rocks. On the other hand, the material associated with laterite and basalt has, no doubt, been produced by the weathering under special conditions (the agency of bacteria has been suggested) of basalt or of other igneous and crystalline rocks. (For papers on the constitution of bauxite and laterite, *see* M. Bauer, Jahrb. Min. 1898, ii., 163; T. H Holland, Geol. Mag. 1903, 59; A. Lacroix, Nouv. Archives du Musée, Paris, 1914, v, reviewed by L. L. Fermor, Geol. Mag. 1915; G. A. J. Cole, The Interbasaltic Rocks (Iron Ores and Bauxites) of North-East Ireland, Mem. Geol. Survey, Ireland, 1912; H. Ries, Economic Geology, New York, 1916; W. C. Phalen, Mineral Resources of the United States, for 1915, 1916, ii, 159.)

The alum-clay or bauxite mined in Co. Antrim is all sent to the aluminium works at Foyers and Kinlochleven in Scotland. In France the present source of supply is mainly in dep. Var; and in America the production is confined to the states of Alabama, Georgia, and Arkansas. The French bauxite is roughly divided into three classes: (1) white bauxite, with 60 p.c. alumina, not more than 4 p.c. iron, and no silica,—this being used for the manufacture of aluminium salts and alum; (2) red bauxite, with 60 p.c. alumina and 3 p.c. silica,—used for the manufacture of aluminium; (3) a special kind of white bauxite, with 45 p.c. alumina, a trace of iron, and much silica,—used for making refractory bauxite bricks. The greater part of the material is used in the manufacture of aluminium, but in America large quantities are fused in the electric furnace to produce artificial corundum, which, under the name of *alundum*, is largely used as an abrasive agent. L. J. S.

BAVALITE *v.* Thuringite.

BAY, BAY OIL *v.* Laurus nobilis.

BAYBERRY TALLOW *v.* Waxes.

BAYER'S ACID, 2-Naphthol-8-sulphonic acid. *V.* Naphthalene.

BAY-LEAF OIL *v.* Oils, Essential.

BAY-SALT *v.* Sodium chloride.

BAZILLOL. Trade name for a preparation of crude carbolic acid. Used as a disinfectant.

BDELLIUM *v.* Gum resins.

BDELLIUM RESIN *v.* Resins.

BEAN. The name given to many seeds which resemble in size and shape the ordinary kidney bean. Thus the seeds of coffee, cocoa, castor, &c., are often known as 'beans.' Usually, however, the term is restricted to seeds of various *leguminosæ.*

The most important species of beans are:

(1) Adzuki beans (*Phaseolus radiatus*).

(2) Field or horse beans, of which the broad bean is a variety (*Vicia faba*).

(3) French or kidney bean (*Phaseolus vulgaris*).

(4) Java or Lima bean (*Phaseolus lunatus*)

(5) Soy or Soja bean (*Glycine hispida* or *Soja hispida*).

(6) Velvet bean (*Mucuna utilis*).

(7) Carob or locust bean (*Ceratonia siliqua*).

In chemical composition beans are remarkable for the large proportion of albuminoid matter which they contain. They thus possess high nutritive value as foods.

In some cases the seed only is eaten, either green as in broad beans, or dried as in haricot beans, which are a variety of *Phaseolus vulgaris.* In others, *e.g.* in the kidney bean, the whole pod, in the unripe condition, is eaten; whilst in the case of the carob bean, the dried pod rather than the seeds is the valued product. The velvet bean is usually grown for its foliage, either for making into hay for cattle or for green manuring.

In the following table are given analyses of various beans, as far as possible of the products as they are usually consumed as food:—

—	(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)
Water	13·6	87·3	11·1	68·5	14·4	10·0	16·0	9·3	19·7
Protein	23·1	2·2	15·9	7·1	23·9	33·2	17·2	13·3	5·5
Fat	2·3	0·4	1·8	0·7	1·6	17·5	2·2	2·6	0·8

(8) *Mucuna utilis*, hay.

(9) *Ceratonia siliqua*, whole pod.

The proteins of beans were thought to consist largely of legumin, or 'vegetable casein,' first obtained from them by Einhof in 1805, but Hoppe-Seyler has shown that the vegetable casein is produced by the action of the alkali used in extraction upon the globulins and albumins present in the seeds.

The proteins of *Phaseolus vulgaris* are chiefly phaseolin, a globulin containing 16·45 p.c. N and 0·5 p.c. S, and phaselin (Osborne, J. Amer. Chem. Soc. 1894, 16, 633). In *Phaseolus radiatus* are present phaseolin and another globulin containing 16·31 p.c. N and 0·88 p.c. S (Osborne and Campbell, J. Amer. Chem. Soc. 1897, 19, 509). In *Vicia faba*, the same investigators found legumin, vicilin, legumelin, and a proteose (same Journal, 1898, 20, 393). In *Soja hispida* they found, as the chief proteid, a globulin resembling legumin, but containing twice as much sulphur, for which they propose the name glycinin. Legumelin, a trace of a proteose, and a globulin, probably identical with phaseolin, were also present (*l.c.* 20, 419).

The nitrogen-free extract of soja beans contains the following substances (Street and Bailey, J. Ind. Eng. Chem. 1915, 7, 853); galactans 4·86 p.c.; pentosans, 4·94 p.c.; organic acids (as citric acid), 1·44 p.c.; invert sugar, 0·07 p.c.; sucrose, 3·31 p.c.; raffinose, 1·13 p.c.; starch, 0·50 p.c.; cellulose, 3·29 p.c.; hemicelluloses, 0·04 p.c.; dextrin, 3·14 p.c.; waxes, tannins, &c. (by diff.), 8·60 p.c. The same investigators found soja beans to contain the following enzymes: urease, amylase, a glucoside-splitting enzyme, a protease, a peroxydase, and a lipase.

According to Fleurent (Compt. rend. 1898, 126, 1374), bean flour contains 31 p.c. of nitrogenous matter, comprising legumin, 18·9 p.c.; vegetable albumin, 0·2 p.c.; glutenin, 9·5 p.c.; and gliadin, 2·4 p.c.; and has been used to add to wheaten flour, since the addition of 2 or 3 p.c. to the latter increases the ratio of glutenin to gliadin in the mixture, and thus in many cases improves the flour for bread making. The flour made from haricot beans contains starch as ovoid grains with distinct elongated or fissured hila, and square or rectangular cells containing prismatic crystals of calcium oxalate.

The fat of beans contains choline, cholesterol, and glycerides of valeric, oleic, and palmitic acids, but no stearic acid (Jacobson, Zeitsch. physiol. Chem. 1889, 13, 32). According to Kosutany (Landw. Versuchs-Stat. 1900, 54, 463), bean oil resembles olive oil in appearance, has a sp.gr. of 0·967, Reichert-Messel number 2·46, iodine number (Hübl.) 119·9, and contains much lecithin and sulphur. Stanek (Zeitsch. physiol. Chem. 1906, 48, 334) found both betaine and choline in horse beans.

Several varieties of beans contain a cyanogenetic glucoside. In *Phaseolus lunatus*, Dunstan and Henry (Proc. Roy. Soc. 1903, 72, 285) found a glucoside which they named phaseolunatin $C_{10}H_{17}O_6N$, yielding dextrose, prussic acid, and acetone on hydrolysis. The wild plant contains it in much larger quantity than the cultivated one. From haricot beans Tatlock and Thomson (Analyst, 1906, 31, 249) obtained from 0·001–0·009 p.c. of hydrocyanic acid. Most of the cyanogen compound, and the whole of the enzyme which hydrolyses it, are destroyed by boiling.

The carob or locust bean is remarkable for the large amount of sugar (cane sugar 23 p.c., glucose 11 p.c.) contained in the pod, while the seed contains a carbohydrate, caroubin, a white, spongy, friable substance, of the same composition as cellulose (Effront, Compt. rend. 1897, 125, 38), which yields in contact with water a very syrupy liquid or jelly, 3 or 4 grams of the substance being sufficient to convert a litre of water into a thick syrup. Caroubin might be used with advantage in the preparation of nutrient media for bacteriological work.

It has been introduced under the name of 'tragasol' as a gum for sizing, colour printing and dyeing (J. Soc. Chem. Ind. 1894, 410, and 1896, 112).

Effront (Compt. rend. 1897, 125, 309) states that by hydrolysis, either by dilute acids or the enzyme caroubinase, present in the seeds, caroubin yields a sugar, which he calls caroubinose, resembling dextrose, but with lower rotatory power.

Van Ekenstein (Compt. rend. 1897, 125, 719), however, finds this sugar to be identical with *d*-mannose. So, too, Bourquelot and Herissey find that the action of dilute acid upon the carob seed yields a mixture of mannose and galactose so that carubin apparently consists of mannans and galactans (Compt. rend. 1899, 129, 228 and 391). For analyses of commercial carobs *v.* Balland, J. Pharm. chim. 1904, 19, 569.

All species of beans, like other leguminosæ, serve as hosts for the tubercle-forming, nitrogen fixing organisms (*Bacillus radicocola*), and thus, under suitable conditions, are independent of supplies of combined nitrogen in the soil. Beans are therefore sometimes used for enriching soils in combined nitrogen, being employed for green manuring, though the root *débris* of a crop of beans, even after the removal of the seed and haulms, often effects this object to a considerable extent. H. I.

BEAN OIL. *See* SOYA BEAN OIL.

BEARBERRY LEAVES. The dried leaves of *Arctostaphylos uva-ursi* (Spreng).

BEBEERINE (*beberine*, *bibirine*) is a name which has been applied variously.

1. Maclagan (Annalen, 1843, 48, 106; with Tilley, 1845, 55, 105) first applied it to the amorphous ether-soluble alkaloid of bebeeru bark (*Nectandra Rodiei*, Hook.), to which the formula $C_{35}H_{20}O_6N$ ($C = 6$; $O = 8$) was attributed. This base was accompanied by another amorphous alkaloid, sipeerine, which was insoluble in ether, whilst bebeeru wood contained a third amorphous alkaloid, nectandrine $C_{20}H_{23}O_4N$ (Maclagan and Gamgee, Pharm. J. 1869-1870, [ii.] 11, 19).

2. It was applied later to the total alkaloids of bebeeru bark, the sulphate of which was official in the B. P. 1885, and was used as a febrifuge, as a substitute for quinine.

3. Bebeerine (from bebeeru bark) has been stated to be probably identical with the alkaloids of true pareira root (*Chondodendron tomentosum*, Ruiz. and Pav.), with buxine, contained in *Buxus sempervirens* (Linn.), and with the pelosine of *Cissampelos Pareira* (Linn.), but the evidence of identification is inconclusive. It has led, however, to the use of the term bebeerine for alkaloids isolated from *Chondodendron tomentosum* by Scholtz (Arch. Pharm. 1898, 236, 530; 1906, 244, 255) and Faltis (Monatsh 1912, 33, 873). Scholtz' bebeerine $C_{18}H_{21}O_3N$ crystallises from methyl alcohol in colourless prisms, m.p. 214°, $[\alpha]_D -298°$ in alcohol, forms crystalline salts, is phenolic, and contains one ·OMe and one ·NMe group. Faltis has described *β* bebeerine, amorphous, m.p. 142°–150°, $[\alpha]_D +28·6°$ in alcohol, $-24·7°$ in pyridine; *iso*bebeerine, rhombic needles, m p 290°, optically inactive; and bebeerine-B, $C_{22}H_{23}O_5N$, yellow powder, m.p. 220°, $[\alpha]_D +56·7°$ in pyridine. To *β*- and *iso*bebeerine, Faltis attributes the formula $C_{21}H_{23}O_4N$, whilst Scholtz (Arch Pharm. 1913, 251, 136) prefers the formula $C_{18}H_{21}O_3N$. F. L.-P.

BECKELITE. A silicate of calcium and cerium-earths $Ca_3(Ce,La,Di,Y)_4(Si,Zr)_3O_{15}$, containing Ce_2O_3 28·1, La_2O_3 13·6, Di_2O_3 18·0, $(Y,Er)_2O_3$ 2·8, ZrO_2 2·5 p.c., etc. It occurs as wax-yellow grains and cubic crystals as an accessory constituent in a dyke rock associated with elaeolite-syenite in the Mariupol district on the Sea of Azov, South Russia. The crystals (½ cm. diameter) have the form of octahedra and rhombic-dodecahedra, and resemble pyrochlore in general appearance and physical characters, but they possess a cubic instead of an octahedral cleavage. Chemically, however, they are quite distinct from pyrochlore, containing no columbium, titanium, or fluorine. Sp.gr. 4·15; hardness 5. L. J. S.

BEECHNUT OIL. This oil is derived from the seed-kernels of the beech tree (*Fagus sylvatica*, L.), which contain from 30 to 42 p.c., the yield from the whole nuts being from 10 to 12 p.c. The oil derived from the nuts of the Japanese beech (var. *Sieboldi*, Maxim.) is used for food and as a lubricant, for which latter purpose it is not well suited, as it is a 'semi-drying' oil. The cold-drawn oil is pale yellow, and has a pleasant odour and taste. It has sp.gr. 0·9205 at 15°; iodine value 111–120; and m.p. of fatty acids 17°–17·5° (Higuchi, Bull. Forest Exp. Stat. Tokyo, 1915). In Europe beechnut oil is sometimes used to adulterate almond oil.

C. A. M.

BEECH TAR. According to Fisher, 100 parts of beech wood yield on dry distillation 45 parts of acetic acid, 23 parts of charcoal, 4 of oil, and 28 of gas, consisting of 20 parts carbon dioxide, 7 of carbon monoxide, 0·5 of marsh gas, 0·05 of hydrogen, and 0·45 of water (Dingl. poly. J. 238, 55).

The tar contains phenol, cresol, phlorol, guaiacol, and creosol, the dimethyl ether of propyl pyrogallol, the dimethyl ether of pyrogallol, which on oxidation yield cœrulignone or cediret, pittacal, and picamar.

According to Gratzel (J. Pharm. [5] 6, 520), ferric chloride colours beech tar creosote a blue passing to brown.

(For a history of the investigations made upon wood tars, *v.* Schorlemmer, J. Soc. Chem. Ind. 4, 152, where also will be found a bibliography of the subject; *v.* also CREOSOTE, and WOOD, DESTRUCTIVE DISTILLATION OF.)

BEESWAX *v.* WAXES.

BEET-ROOT. The root of *Beta vulgaris* (Linn.). Many varieties are known, differing in colour, shape, and size. Mangel-wurzel, or mangold, as it is often called, is a variety (of which there are many sub-varieties), largely grown as winter food for cattle; garden beet-root, employed as salad or vegetable, is often understood when the term 'beet-root' is used. The most important variety, however, is the sugar beet, of which many sub-varieties are known. These have been obtained by careful selection with a view to obtaining the highest proportion of cane sugar.

The presence of sugar in the juice of beet-root was observed in 1747 by Marggraf, who suggested its extraction on a commercial scale. The early attempts, however, proved failures, as the process could not compete with the cane-sugar industry. This is not surprising when it is remembered that the beets then grown only yielded about 2 p.c. of sugar.

Careful selection of seed, and improved cultivation and methods of extraction, aided by a system of bounties by continental Governments, have resulted in beet sugar almost entirely replacing cane sugar in the principal markets of Europe (*v.* SUGAR).

Beet-root contains water, nitrogenous matters (including true albuminoids and the bases glutamine, betaine, and choline), pectins, sugars (of which cane sugar and raffinose are the chief), colouring matter of an unstable character (Formanek, J. pr. Chem. 1900, ii. 62, 310), and ash. It will be well to consider, in turn, the composition of average specimens of the three principal varieties of beet-root mentioned above.

(*a*) *Mangel-wurzel*, or *Mangolds*, called sometimes field beets. Many varieties, differing in colour, size, and shape, are in cultivation. They may be classified into long, tankard, and globe forms.

Mangolds grow best in deep, somewhat clayey soils, and in warm, fairly dry climates. They demand abundant supplies of plant food, and, under favourable conditions, yield very heavy crops, from 20 to 30 tons per acre being usually obtained. They are better as food for cattle and sheep after they have been stored for some weeks.

As in almost all root crops, large mangolds are distinctly more watery than small ones.

The following is the average composition of mangolds, according to (1) Warington, (2) Kellner :—

—	1		2		
	Large	Small	Large	Medium	Small
Water . .	89·0	87·0	89·5	88·0	86·5
Nitrogenous substances	1·2	1·0	1·3	1·2	1·1
Ether extract	0·1	0·1	0·1	0·1	0·1
Soluble carbohydrates	7·7	10·2	6·7	8·7	10·6
Crude fibre .	1·0	0·8	1·0	0·9	0·8
Ash . .	1·0	0·9	1·4	1·1	0·9
	100·0	100·0	100·0	100·0	100·0

The nitrogenous substances comprise real albuminoids, in proportion varying from 33 to 60 p.c. of the whole (being lowest in the large and highest in the small roots), and amides. Quite considerable quantities of nitrates are often present in the juice.

The soluble 'carbohydrates' consist chiefly of sugars, pectins, cellulose, and pentosans; starch is not present. The ash of mangolds, according to Wolff, contains:

K_2O	Na_2O	MgO	CaO	P_2O_5	SO_3	Cl	SiO_2
53·1	14·3	5·1	4·6	9·6	3·3	6·6	3·3

The unusually large proportion of chlorine is a noticeable feature. Beets, being descendants of a maritime plant, are found to be benefited by applications of common salt to the soil in which they are grown. Oxalic acid, to the extent of about 0·1 p.c., is present in beet-root.

(*b*) *Garden beet-root.* These are almost always red-fleshed. In composition they resemble the mangel-wurzel.

The average of 17 American analyses shows: Water, 87·6 p.c.; nitrogenous substances, 1·6 p.c.; fat, 0·1 p.c.; soluble carbohydrates and fibre, 9·6 p.c.; ash, 1·1 p.c.

(*c*) *Sugar beets.* Of these, many varieties have been obtained by careful selection. They are usually white- or yellow-fleshed, conical in shape, and grow with the root entirely underground. The sugar content now ranges from 10 or 11 to 16, 18, or even 20 p.c.

Roots not exceeding 1½ to 2 lbs. in weight are preferred. A deep medium loam containing a fair proportion of lime is the soil best suited for their growth. Nitrogenous manuring must be only sparingly done, or the roots become watery and deficient in sugar.

It is difficult to give the typical composition of sugar beets, since their sugar content varies so greatly with variety of plant, season, size of root, cultivation, and manuring. Small roots are almost invariably richer than large ones, other things being equal; a dry period during the ripening and maturing of the roots is also favourable to sugar formation; well-tilled soil, regularity of shape of root, and suitable manuring, are all important factors in determining the yield of sugar.

There is evidence that the careful selection of beets for sugar production has altered the plant considerably, so far as content of ash is concerned (Schneidewind, Bied. Zentr. 1900, 29, 81). The proportion of ash is much lower than formerly, the quantity of potash is only about half of what it was, while the soda has doubled; magnesia has remained unchanged, while phosphoric acid is less.

According to Kellner, the average composition of sugar beets is: Water, 75 p.c.; crude protein, 1·3 p.c.; fat, 0·1 p.c.; soluble carbohydrates, 21·4 p.c.; fibre, 1·5 p.c.; ash, 0·7 p.c. In addition to the sugar content, the purity coefficient (the ratio of cane sugar to total sugar) is of importance (*see* SUGAR).

The leaves of mangolds and sugar beets contain much oxalic acid, up to 8 p.c. of the dry matter (Stoklasa, Bied. Zentr. 1901, 30, 393), and their ash is rich in lime, magnesia, and soda. They contain about 84 p.c. water, 2·3 p.c. nitrogenous matter, 0·4 p.c. ether extract, 7·4 p.c. soluble carbohydrates, 1·6 p.c. fibre, and 4·8 p.c. ash.

They are sometimes used as cattle food, either in the fresh or dried condition, or sometimes as silage. In order to prevent ill effects from the oxalic acid present, it is recommended to sprinkle powdered calcium carbonate on the leaves before giving them to animals. About 1 lb. calcium carbonate to 1000 lbs. of leaves is sufficient (Kellner). The leaves are sometimes dried by artificial heat, and then furnish a valuable food, equal to meadow hay. H. I.

BEET-ROOT GUM *v.* GUMS.

BEHENIC ACID $C_{22}H_{44}O_2$ is said to be present as a glyceride in ben oil (*q.v.*). The fatty acid prepared from the oil melted at 80°–82° and solidified at 76° 79° (J. pr. Chem. 1894, 61). The acid prepared synthetically from erucic acid has m.p. 83°-84°, and solidifies at 77°-79°; b.p. (60 mm.) 306° (Talanzeff, J. pr. Chem. 1895, 50, 71). It forms acicular crystals, soluble in alcohol (0·102 p.c. at 17°) and ether (0·1922 p.c. at 16°); m.p. of ethyl ester, 48°-49°. A method of detecting rape oil in olive oil has been based on the hydrogenation of the liquid fatty acids, and separation of the behenic acid formed from the erucic acid (Biazzo and Vigdorcik, Annali Chim. Appl. 1916, 6, 185). C. A. M.

BELLADONNA. (Fr. *Belledame.*) The *Atropa belladonna* (Linn.), or deadly nightshade. A poisonous plant of the *Solanaceæ* order. Employed in medicine as an anodyne, &c., and for dilating the pupil. The name appears to have been derived from the circumstance of its employment in an Italian cosmetic. Its physiological action is due to *atropine.*

BELLITE. An explosive prepared by mixing a nitrate with a nitro-compound such as dinitrobenzene, trinitronaphthalene, or nitrotoluene, and then subjecting the mixture to a temperature of from 50° to 100° (Eng. Pat. 13690, Nov. 10, 1885; *v.* EXPLOSIVES).

BELLITE. This name has also been used (W. F. Petterd, 1905) for an incompletely determined mineral, described as a chromo-arsenate of lead, and occurring as bright-red or yellow velvety tufts, or as powdery encrustations, at Magnet in Tasmania. L. J. S.

BELL-METAL. An alloy of copper and tin used in the manufacture of bells. Contains from 3 to 4 parts of copper to 1 part of tin.

BELL-METAL ORE *v.* STANNITE.

BENGALINE *v.* AZO- COLOURING MATTERS.

BENGAL LIGHTS. These fires may be made by mixing potassium chlorate, carbon, antimony sulphide, strontium nitrate, &c., together in suitable proportions; but all such mixtures of potassium chlorate and sulphur are dangerous from their tendency to inflame spontaneously owing to sulphur frequently containing sulphuric acid. Saunders suggests that 120 grains of potassium bicarbonate should be added to each pound of sulphur to neutralise the free acid.

An improvement in the manufacture of Bengal lights has been suggested by Chertier (Wagner's Jahr. 24, 464), who obtains a smokeless and odourless fire by melting shellac and adding, with continuous stirring, the nitrate. The proportions given are: for red fires, one part of shellac to five of strontium nitrate; for green, one of shellac to five of barium nitrate; and for yellow, one of shellac to three of sodium nitrate. They burn slowly, and are well adapted for theatres, &c.

C. Schmidt has patented (D. R. P. 34020, 1885) the following process. From 1 to 10 grams of magnesium dust are added to 100 grams of collodion, and 3 grams of barium or strontium chloride are added. On evaporation of the ether, thin plates are obtained which burn with great brilliancy.

Another formula recommended by a German firm is, for white fires, to fuse one part shellac with six barium nitrate, grind and mix with 2·5 parts magnesium powder. For red fires, five parts strontium nitrate is used instead of the barium nitrate. These mixtures can be made into ribbons or charged into thin zinc tubes so as to make torches (Dingl. poly. J. 256, 518). (*See* also FLASH LIGHTS; PYROTECHNY.)

BENITOITE. This interesting mineral is an acid titano-silicate of barium $BaTiSi_3O_9$, and forms beautiful sapphire-blue, transparent crystals suitable for cutting as gems. The crystals afford the only known example (except Ag_2HPO_4 (H. Dufet, 1886)) of the ditrigonal-bipyramidal class. Sp.gr. 3·64–3·67; H. 6½. The dichroism is intense, the ordinary ray being colourless, and the extraordinary ray greenish-blue to indigo-blue. The mineral was first found (and described by G. D. Louderback) in 1907, near the source of the San Benito river in San Benito Co., California, the crystals occurring embedded in natrolite veins traversing schistose rocks. L. J. S.

BENJAMIN, GUM, *v.* BALSAMS.

BEN OIL, Behen Oil, is obtained from the seeds of the *Ben nut,* from *Moringa pterygosperma* (*oleifera*) and *Moringa aptera* (Gärt.).

The Moringa trees are indigenous to India, Arabia, and Syria, and were introduced to Jamaica from the East Indies in 1784. *Moringa pterygosperma* has also been found in Northern Nigeria and Dahomey. Ben oil has a slightly yellowish colour, is odourless, and has a sweetish taste. The oil consists of the glycerides of oleic, palmitic, and stearic acids; it also contains a solid acid of high melting-point, which, according to Völcker (Annalen, 64, 342), is identical with behenic acid (m.p. 76°); though possibly this acid may be arachidic acid. In the East, ben oil is used for cosmetic purposes, it is also employed in the 'maceration' process for extracting perfumes from flowers. In the West Indies the oil is used for edible purposes. Jamaica oil, from which any solid deposit has been separated by filtration, is used for lubricating watches and other delicate machinery, for which purpose it is particularly suitable owing to its not readily oxidising when exposed to the air. This property is in accordance with the low iodine value of the oil. A genuine sample from Jamaica, examined by Lewkowitsch (Analyst, 1903, 28, 343) gave the following results: sp.gr. at 15°, 0·9127; iodine value, 72·2; iodine value of liquid fatty acids, 97·53; and butyro-refractometer reading, 50·0°. The low iodine value of the liquid fatty acids indicates that fatty acids more unsaturated than oleic acid were only present in small proportion. Commercial samples of ben oil frequently have much higher iodine values (*e.g.* 110), but the genuine character of these is open to question. J. L.

BENZACETIN *v.* SYNTHETIC DRUGS.

BENZAL CHLORIDE. *Benzylidene chloride, Benzidene chloride* (*v.* TOLUENE, CHLORINE DERIVATIVES OF).

BENZALDEHYDE C_7H_6O or $C_6H_5{\cdot}CHO$. *Benzoic aldehyde, Benzoyl hydride. Ethereal,* or *volatile,* or *essential oil of bitter almonds. Essence of bitter almonds.* (*Aldehyde benzoïque,* Fr.; *Bittermandelöl,* Ger.) Mortrès showed, in 1803, that, in addition to the fatty oil, a volatile oil could be obtained from bitter almonds; but pure benzaldehyde was first isolated, its composition determined, and its reactions studied, by Liebig and Wöhler in 1837 (Annalen, 22, 1). Benzaldehyde is not contained, as such, in bitter almonds: it is produced by the action of a soluble ferment, *emulsin* (also termed *synaptase*), present in the almond, on *amygdalin* $C_{20}H_{27}NO_{11}$. In this fermentation, which occurs when the bruised almonds are mixed with cold water, the amygdalin is hydrolysed, yielding benzaldehyde, together with hydrocyanic acid and glucose:

$$C_{20}H_{27}NO_{11}+2H_2O=C_7H_6O+HCN+2C_6H_{12}O_6$$

If boiling water is used, the ferment is destroyed and the reaction does not take place. Peach kernels and kernels of other stone fruits containing amygdalin also yield benzaldehyde. It occurs, ready formed, in the leaves of the cherry laurel (*Prunus laurocerasus*), of the bird cherry (*Prunus padus*), and of the peach (*Amygdalus persica*).

Preparation.—1. *From bitter almonds.* The bitter almonds (or more rarely, peach kernels) are ground and then cold-pressed, to extract the fatty oil. The press cake is made into a thin cream with cold water, introduced into a still, allowed to stand for 24 hours, and then distilled either by blowing in superheated steam, or, less advantageously, over a fire, in which case mechanical stirring must be employed to prevent the charring of the vegetable matter. The distillation is continued as long as the distillate appears milky. Most of the crude benzaldehyde separates as an oily layer under the aqueous distillate; some, however, remains in solution and may be recovered by distilling the aqueous liquid, when the benzaldehyde passes over with the earlier portions.

Michael Pettenkofer (Annalen, 122, 77) modifies the foregoing process as follows:—12 parts of the coarsely powdered press cake are added to 100–120 parts of boiling water, stirring during the process, and the mixture is kept boiling for about half an hour. In this way all the amygdalin is obtained in solution. The liquid is then allowed to cool; 1 part of ground bitter almonds, suspended in 6–7 parts of cold water, is added, and after standing for 12 hours the whole is slowly distilled. According to Pettenkofer, the maximum yield of benzaldehyde is thus obtained, no amygdalin remaining undecomposed. Pelz, however, states (J. 1864, 654) that the yield of benzaldehyde in this process is no greater than is obtained by macerating merely the above-mentioned 1 part of ground bitter almonds with cold water and then distilling.

The oil prepared by either of these methods contains hydrocyanic acid, from which it may be freed by fractional distillation, the hydrocyanic acid coming over with the first part of the distillate. The hydrocyanic acid may also be removed without distillation by shaking the oil with a mixture of milk of lime and ferrous sulphate (Liebig and Wöhler). The purest benzaldehyde is obtained by shaking the crude product with 3–4 times its volume of a concentrated solution of sodium bisulphite, washing the crystals of the double compound

$$(C_7H_6O,NaHSO_3)_2H_2O$$

with alcohol, recrystallising them from water, and distilling them with a solution of sodium carbonate (Bertagnini, Annalen, 85, 183; Müller and Limpricht, *ibid.* 111, 136).

2. *From toluene.*—At the present day benzaldehyde is generally prepared artificially from chlorinated derivatives of toluene. The following are the chief processes that have been proposed:—

Lauth and Grimaux (Bull. Soc. chim. [2] 7, 105) boil 1 part of benzyl chloride $C_6H_5{\cdot}CH_2Cl$, 1½ parts of lead nitrate (or copper nitrate), and 10 parts of water with a reflux condenser for several hours, passing a current of carbon dioxide through the apparatus to prevent oxidation. Half the liquid is then distilled off, and the oil, which separates in the distillate, is rectified. The product, which consists mainly of benzaldehyde, may be further purified by converting it into the bisulphite compound.

The Dow Chemical Co. (U.S. Pat. 1272522) heat benzyl bromide with an aqueous solution of calcium nitrate or sodium nitrate. The reaction takes place between equimolecular proportions of benzyl bromide and sodium nitrate, and the benzaldehyde is practically a pure product.

H. Schmidt (D. R. P. 20909; J. Soc. Chem.

Ind. 1883, 274) chlorinates boiling toluene until it attains a sp.gr. of 1·175, when it consists essentially of a mixture of 2 mols. of benzyl chloride with 1 mol. of benzal chloride. This product is boiled with six times its volume of water and a quantity of powdered black oxide of manganese containing two atoms of available oxygen to the above molecular proportion. The reaction is supposed to take place according to the equation

$$2C_6H_5{\cdot}CH_2Cl + C_6H_5{\cdot}CHCl_2 + 2MnO_2$$
$$= 3C_6H_5{\cdot}CHO + 2MnCl_2 + H_2O$$

The product is steam-distilled, and the aldehyde purified in the usual way. A mixture of benzyl bromide and benzal bromide may be substituted for the chlorine compounds.

Another method consists in heating benzal chloride with milk of lime under pressure.

$$C_6H_5{\cdot}CHCl_2 + Ca(OH)_2 = C_6H_5{\cdot}CHO + CaCl_2 + H_2O$$

According to Espenschied (D. R. P. 47187), the reaction takes place under ordinary pressures if insoluble substances such as chalk or barium sulphate are added along with the milk of lime, so as to produce an emulsion of the benzal chloride.

E. Jacobsen (D. R. P. 11494 and 13127; Ber. 13, 2013, and 14, 1425) heats benzal chloride with an organic acid (or an ethereal salt of an organic acid) and a metallic chloride, oxide, or sulphide. Thus benzal chloride, when heated on the water-bath with acetic acid and a little zinc chloride, yields benzaldehyde, acetyl chloride, and hydrochloric acid.

$$C_6H_5{\cdot}CHCl_2 + CH_3{\cdot}CO_2H = C_6H_5{\cdot}CHO + CH_3{\cdot}COCl + HCl$$

The acetyl chloride, owing to its much lower boiling-point, may be readily removed from the benzaldehyde by distillation.

Benzaldehyde can be prepared by oxidising benzyl aniline to benzylidene aniline, which, on addition of acids, splits into benzaldehyde and aniline. For this purpose 100 kilos. of benzyl aniline, and from 500–1000 litres of water are placed in a large retort fitted with an agitator; during agitation and boiling the following mixture is gradually run in during a few hours: potassium or sodium bichromate, 50 kilos; water, 200 litres, acidulated with hydrochloric acid (20°B.), 165 kilos, or its equivalent of sulphuric acid; distillation ensues, water and benzaldehyde coming over. The nitrobenzaldehydes may be obtained by substituting the corresponding nitrobenzylaniline. Another method consists in oxidising the salt of the benzylaniline sulphonic acid to the benzylidene compound, and then treating it with the salt of an aromatic base, followed by hydrochloric acid. The aldehyde is formed, and the aromatic base can be recovered and used for another operation (Farb. vorm. Meister, Lucius, and Brüning, Eng. Pat. 10689 and 30118; D. R. P. 110173; J. Soc. Chem. Ind. 1897, 558, and 1899, 36). It has been prepared by passing a current of air charged with the vapour of toluene through a chamber containing a catalyser such as oxide of iron, and heated between 150° and 300°. By substituting porous carbon for oxide of iron and using a higher temperature, benzoic acid may be obtained (Chavy, Delage, and Woog, Fr. Pat. 379715; J. Soc. Chem. Ind. 1907, 1254, Ipatieff, Ber. 1908, 993).

It has also been prepared by the oxidation of benzyl aniline, or benzyl toluidine with chromic acid mixture or with potassium permanganate solution in acetone (D. R. PP. 91503, 92084; Frdl. iv. 129, 131).

It has also been prepared from phenyl magnesium bromide and orthoformic ester (Farb. vorm. Fried. Bayer & Co. D. R. P. 157573; Chem. Zentr. 1905, i. 309). By using 15 grams of magnesium, 100 grams of bromobenzene, and 60 grams of orthoformic ester, a 90 p.c. yield can be obtained (Bodroux, Compt. rend. 1904, i. 92). Gatterman's adaptation of the Friedel and Crafts reaction (Annalen, 1906, 347, 347) has also been employed for the preparation of benzaldehyde. In this process benzene is condensed with hydrogen chloride and carbon monoxide in the presence of aluminium chloride and cuprous chloride, the mixture of gases acting potentially as formyl chloride; condensation following the usual course (D. R. P. 126421)

$$C_6H_6 + Cl{\cdot}CHO = C_6H_5{\cdot}CHO + HCl$$

Schulze (D. R. PP. 82927, 85493) heats benzotrichloride at 25°–30° with some ferric benzoate or finely divided iron, water is then added, and the mixture warmed to 90°–95°, when hydrochloric acid distils over. The residue is decomposed by milk of lime and distilled in a current of steam to obtain the aldehyde.

Owing to the fact that the product obtained from the chlorinated derivatives of toluene frequently contains chloro- compounds, methods have been devised for the direct oxidation of toluene to the aldehyde. Raschig (Chem. Zeit. 1900, 24, 446) uses manganese dioxide in the presence of 65 p.c. sulphuric acid at 40°. 300 kilos of toluene are mixed with 700 kilos sulphuric acid, and 90 kilos finely powdered precipitated manganese dioxide are added, the whole being violently shaken during the addition, and the temperature kept at 40°. After completion of the action the benzaldehyde and unaltered toluene are driven over and the aldehyde separated in the usual manner (*cf.* D. R. PP. 101221, 107722). The Badische Anilin u. Soda-Fabrik use nickel and cobalt oxides, as oxidants (D. R. P. 127388), whilst the firm of Meister, Lucius, und Brüning (D. R. P. 158609) have suggested the use of cerium compounds.

By passing a stream of carbon monoxide and hydrochloric acid gas (2 : 1) through a cooled mixture consisting of equal weights of aluminium bromide and benzene, and $\frac{1}{10}$ their weight of copper chloride, a solid mass is obtained: this is decomposed by ice water, extracted with ether, and fractionated. The yield is 85–90 p.c. (Reformatsky, D. R. P. 126421; Chem. Zentr. 1901, i. 1226; ii. 1372).

Benzaldehyde has also been prepared by the electrolytic reduction of benzoic acid or its salts. An electrode of finely divided graphite and benzoic acid is employed as the cathode of the cell, the anode being of lead or platinum. The solution in the cell is 20 p.c. sulphuric acid, saturated with benzoic acid, the current used is 1·5 amp. per sq. dcm., and 12–15 volts (Mithack, D. R. P. 123554; Chem. Soc. Abstr. 1902, i. 291). Mettler (Ber. 1908, 4148) uses a sodium-amalgam electrode; and Moest (D. R. P.

138442; Chem. Zentr. 1903, i. 370) electrolyses a solution of sodium phenylacetate.

A method has been described for purifying benzaldehyde by dissolving it in sulphurous acid and precipitating the bisulphite compound by adding potassium chloride (Chem. Fab. Griesheim-Elektron, D. R. P. 154499; Chem. Zentr. 1904, ii. 965).

Other modes of formation.—Benzaldehyde is also formed in the following reactions, which, however, are not of practical importance. By distilling a mixture of calcium benzoate and calcium formate (Piria, Annalen, 100, 105); by the oxidation of benzyl alcohol (Cannizzaro, Ann. Chim. Phys. [3] 40, 234); of cinnamic acid (Dumas and Peligot, Annalen, 14, 50; Harries, Ber. 1903, 1296); or of stilbene (Harries, *l.c.*); by the reduction of benzoic acid, either with sodium amalgam in acid solution (Kolbe, Annalen, 118, 122), or by passing its vapour over heated zinc-dust (Baeyer, Annalen, 140, 296); by treating toluene with chromyl chloride and then with water (Étard, Ann. Chim. Phys. [5] 22, 225); by treating 1 molecule of benzal chloride with slightly more than 2 molecules of acetic acid (Béhal, Compt. rend. 148, 179); by acting on benzophenoneoxime with phosphorus pentasulphide, and decomposing the thiobenzanilide thus formed with boiling alkali and zinc-dust (Cuisa, Chem. Zentr. 1907, i. 28).

Properties.—Benzaldehyde is a colourless, strongly refractive liquid with a pleasant aromatic odour, boiling at 179°–180°, and solidifying at −13·5° (Pictet, Compt. rend. 119, 955; Altschul and Schneider, Zeitsch. physical. Chem. 1895, 24); sp gr. 1·0504 15°/4° (Mendeléeff, J. 1860, 7). It is soluble in 300 parts of water, and miscible in all proportions with alcohol and ether. It is non-poisonous, the poisonous properties of ordinary oil of bitter almonds being due to the presence of hydrocyanic acid. Its magnetic rotatory power has been studied by Perkin (J. Chem. Soc. 1896, 1064).

Reactions.—Benzaldehyde readily undergoes oxidation; thus it absorbs oxygen from the air, forming benzoic acid. The presence of hydrocyanic acid protects it from oxidation; according to Dusart (Bull. Soc. chim. 8, 459), it is therefore usual to add hydrocyanic acid to artificial benzaldehyde. Taken internally, benzaldehyde is oxidised in the organism, reappearing in the urine as hippuric acid and benzamide. Aqueous *caustic potash* converts it into benzoic acid and benzyl alcohol

$$2C_6H_5{\cdot}CHO+KOH=C_6H_5{\cdot}CO_2K+C_6H_5{\cdot}CH_2OH$$

When warmed with alcoholic potassium cyanide it is converted into benzoin

$$C_6H_5{\cdot}CHOH{\cdot}CO{\cdot}C_6H_5$$

It forms crystalline compounds with the *bisulphites of the alkali metals*; thus:

$$(C_7H_6O,NaHSO_3)_2H_2O$$

Under the influence of dehydrating agents, it readily undergoes condensation with various other substances; thus when heated with *acetic anhydride and dry sodium acetate* it yields cinnamic acid.

$$C_6H_5{\cdot}CHO+CH_3{\cdot}CO_2H=C_6H_5{\cdot}CH:CH{\cdot}CO_2H+H_2O$$

(Perkin, J. Chem. Soc. 31, 389); cinnamic acid is also obtained from *ethyl acetate* and benzaldehyde (Claisen, Ber. 1890, 976; Farb. vorm. Meister, Lucius and Brüning, D. R. P. 53671; Ber. 1891, Ref. 180). It combines with hydrazine to form benzalazine $C_{14}H_{12}N_2$, which, on distillation, yields stilbene (diphenyl-ethylene) $C_6H_5{\cdot}CH:CH{\cdot}C_6H_5$. With *dimethylaniline* in presence of zinc chloride it forms the compound $C_6H_5{\cdot}CH(C_6H_4{\cdot}NMe_2)_2$, the leuco- base of benzaldehyde green which, by oxidation, is converted into that colouring matter (O. Fischer, Ber. 11, 950).

When hydrogenated in presence of nickel between 210° and 235°, benzaldehyde yields a mixture of benzene and toluene, together with their hexahydrides. Under other conditions it may be reduced by the catalytic action of metals and hydrogen to benzyl alcohol.

With pyrogallol benzaldehyde forms dyestuffs of the triphenylmethane series (Hofmann, Ber. 1893, 1139), and with chloracetopyrogallol a golden-yellow dyestuff (Kusselkaul and Kostanecki, Ber. 1896, 1886). By heating benzaldehyde with a little sulphur in a sealed tube, stilbene and benzoic acid are formed (Barbaglia and Marquardt, Ber. 1891, 1881).

Derivatives.—The most important derivatives are the sulphonic acids, which are the parent substances of various dyestuffs (Gnehm and Schüle, Annalen, 299, 347). Benzaldehyde *o*-sulphonic acid (Kafa, Ber. 1891, 791; Wallach and Wüster, Ber. 1893, 150; Gnehm and Schüle, Annalen, 1898, 24; D. R. P. 88952), Benzaldehyde *p*-sulphonic acid (Farb. vorm. Sandoz, D. R. P. 151528; Chem. Zentr. 1904, ii. 1269).

Impurities and adulterations.—Benzaldehyde very frequently contains hydrocyanic acid, either originally present or subsequently added (*v. supra*), and benzoic acid, formed by spontaneous oxidation. The artificial product generally contains chlorinated benzaldehydes. Alcohol, ethereal oils, and nitrobenzene are sometimes fraudulently added: the latter substance resembles benzaldehyde in smell.

In order to test the purity of a sample of benzaldehyde, the sp.gr. and boiling-point should first be determined, as both of these are altered by the presence of impurities. The substance should also dissolve without residue in a solution of sodium bisulphite.

Of the impurities above mentioned, hydrocyanic acid may be detected by distilling the oil and then testing the first portions of the distillate by the Prussian-blue test; chlorine compounds, by heating the oil with metallic sodium, when sodium chloride will be formed, in which the chlorine can be detected by silver nitrate, taking care, however, to distinguish between silver chloride and silver cyanide, as this latter will be formed if hydrocyanic acid or nitrobenzene is present; alcohol, by the iodoform test; and ethereal oils or nitrobenzene, by dissolving the sample in sodium bisulphite, when these admixtures remain behind. Bourgoin (Ber. 5, 293) tests for nitrobenzene in benzaldehyde by mixing the sample with twice its volume of caustic potash: if nitrobenzene is present, the mixture turns green, and on adding water the liquid forms two layers, of which the under layer is yellow and the upper green, this latter turning red on standing for some hours.

Estimation.—The reagent employed consists of 1 c.c. of freshly redistilled phenylhydrazine, 0·5 c.c. glacial acetic acid dissolved in 100 c.c. distilled water. The liquid containing the benzaldehyde is heated on the water-bath for half an hour, set aside for 12 hours, and filtered through a Gooch crucible, dried over conc. sulphuric acid, and weighed. Weight of phenyl hydrazone ×0·5481 gives the amount of benzaldehyde present. Small quantities may be satisfactorily estimated by this method (Hérissey, J. Pharm. 1906, 60; Dennis and Dunbar, J. Soc. Chem. Ind. 1099, 488). Another method consists in estimating benzaldehyde colorimetrically with fuchsin decolourised with sulphurous acid (Woodman and Lyford, J. Amer. Chem. Soc. 1908, 1607).

To estimate the presence of benzoic acid, 50 c.c. of the sample are shaken with water and 10 c.c. N-sodium hydroxide, the excess alkali being then back titrated with N-acid, using phenolphthalein as indicator.

SUBSTITUTION DERIVATIVES OF BENZALDEHYDE.

o-**Nitrobenzaldehyde.** It may be prepared by the oxidation of the dimercury derivative of *o*-toluene (Reissert, D. R. P. 186881; Chem. Soc. Abstr. 1907, i. 1046; Kalle & Co., D. R. P. 199147; Chem. Soc. Abstr. 1909, i. 76); by the oxidation of *o*-nitrotoluene with manganese dioxide or by passing the vapour of the hydrocarbon over manganese dioxide heated to 210°–250° (Gilliard, Monnet and Cartier, D. R. P. 101221; Chem. Zentr. 1899, i. 960; Bad. Anil. u. Sod. Fab., Eng. Pat. 21947; J. Soc. Chem Ind. 1900, 892); by the oxidation of *o*-nitrotoluene with nickel oxide, nickel chloride, and hypochlorite (Bad. Anil. u. Sod. Fab., D. R. P. 127388; Chem. Zentr. 1902, i. 150); by the oxidation of *o*-nitrobenzylaniline (*q.v.* benzaldehyde); by the oxidation of *o*-nitrobenzylalcohol and its esters (Eug. Fischer, D. R. P. 48722; Frdl. ii. 98; Kalle & Co., D. R. PP. 104360, 106712; Chem. Zentr. 1899, ii. 950; 1900, i. 885); by the hydrolysis of *o*-nitrobenzaldehyde diacetate, which is obtained by the oxidation of *o*-nitrotoluene with a mixture of acetic anhydride, acetic acid, and sulphuric acid (Thiele and Winter, Annalen, 311, 356; Fried. Bayer & Co., D. R. P. 121788; Chem. Zentr. 1901, ii. 70); or by the oxidation of the sodium salt of *o*-nitrophenylnitromethane by potassium permanganate at low temperature in aqueous solution (Soc. Chim. des Usines du Rhône, D. R. P. 237358)

$$3C_6H_4(NO_2)CH : NOONa+2KMnO_4+H_2O$$
$$=3C_6H_4(NO_2)CHO+3NaNO_2+2MnO_2+2KHO$$

Properties.—Large yellow needles, m.p. 46°. When treated with acetone and caustic soda it yields indigotin (Baeyer, Ber. 15, 2856). With methyl- and ethyl-aniline or their sulphonic acids it condenses to form leuco-bases of blue-green triphenyl methane dyestuffs (Clayton Aniline Co., D. R. P. 108317; Chem. Zentr. 1900, i. 1081).

m-**Nitrobenzaldehyde.** It may be prepared by dissolving 1 volume of benzaldehyde in a mixture of 5 volumes of fuming nitric acid, and 10 volumes of sulphuric acid, precipitating by addition of water and recrystallising from dilute alcohol (Widmann, Ber. 13, 678; Bertagnini, Annalen, 79, 260).

Properties.—Pale-yellow needles, m.p. 58°. It condenses with the sulphonic acids of the tertiary aniline bases to yield dyestuffs (Kalle & Co., D. R. P. 73147, Frdl; iii. 85).

p-**Nitrobenzaldehyde.** It is prepared by similar methods to those by which the ortho-compound is obtained (D. R. PP. 91503, 92084, 93539; Frdl. iv. 129); by heating *p*-nitrobenzylalcohol with copper oxide or other metallic oxides (Schmidt, D. R. P. 15881; Frdl. i. 60).

Properties.—Colourless prisms, m.p. 106°. It condenses with benzene and its homologues by addition of sulphuric acid to form *p*-nitrotriphenylmethane (Stolz, D. R. P. 40340; Frdl. i. 58); with secondary and tertiary amines to form alkyl- and aryl- derivatives of *p*-nitrodiaminotriphenylmethane (O. Fischer, D. R. PP. 16766, 16707; Frdl. i. 54); and with the sulphonic acids of tertiary aniline bases (Kalle & Co., D. R. P. 73147; Frdl. iii. 86). The sulphonic acid of *p*-nitrobenzaldehyde is prepared by the oxidation of *p*-nitrotoluene *o*-sulphonic acid, and from it blue and bluish-red dyestuffs of the triphenylmethane series are easily obtainable (Green and Wahl, Eng. Pat. 21825; J. Soc. Chem. Ind. 1898, 915). 2.4-**Dinitrobenzaldehyde** has been prepared by Sachs (Ber. 1902, 35, 1228) by condensing 2·4-dinitrotoluene with *p*-nitrosodimethylaniline and decomposition of the resultant product by acid

$$(NO_2)_2C_6H_3{\cdot}CH_3+NO{\cdot}C_6H_4{\cdot}N(CH_3)_2$$
$$=(NO_2)_2C_6H_3{\cdot}CH=NC_6H_4N(CH_3)_2$$
$$(NO_2)_2C_6H_3{\cdot}CH=NC_6H_4N(CH_3)_2+H_2O$$
$$=(NO_2)_2C_6H_3CHO+H_2NC_6H_4N(CH_3)_2$$

o-**Chlorbenzaldehyde**  It is prepared by the oxidation of *o*-chlortoluene with manganese dioxide and sulphuric acid (Gillard, Monnet et Cartier, D. R. P. 101221; Chem. Zentr. 1899, i. 960), by extraction from the products of the incomplete chlorination of *o*-nitrotoluene (Kalle & Co., D. R. PP. 110010, 115516; Chem. Zentr. 1900, ii. 460, 1168).

Properties.—It is a liquid, freezing at −4°, and boiling at 208° (748 mm.); sp.gr. 1·29 at 8°. By heating with sulphite it is converted into benzaldehyde *o*-sulphonic acid (Geigy & Co., D. R. P. 88952; Frdl. iv. 113). It is easily condensed with aromatic secondary and tertiary amines to yield dyestuffs of the triphenylmethane group (Geigy & Co., D. R. P. 94126; Chem. Zentr. 1898, i. 296). By sulphonation, 1 : 3 : 6-chlorbenzaldehyde sulphonic acid is produced, which when condensed with secondary or tertiary amines and then oxidised yields greenish-blue or blue dyestuffs (Soc. Chem. Ind. of Basle, Eng. Pat. 25128; J. Soc. Chem. Ind. 1897, 137; Gnehm and Schüle, Annalen, 299, 347).

m-**Chlorbenzaldehyde.** It is obtained from *m*-nitrobenzaldehyde by replacing the nitro-group by chlorine (Erdmann and Schwechten, Annalen, 260, 259; Eichengrün and Einhorn, *ibid.* 262, 135). It crystallises in prisms, m.p. 17°, and boils at 213°.

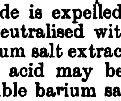
p-**Chlorbenzaldehyde.** It is associated with the ortho- compound in most preparations, and may be obtained from the mixture by sulphonating the ortho- compound by treatment with fuming sulphuric acid (Gesel. f. Chem. Ind., D. R. P. 98229; Chem. Zentr. 1898, ii. 743); by nitrating the ortho- compound with nitric and sulphuric acids, and steam-distilling the para-compound (Gesel. f. Chem. Ind., D. R. P. 102745; Chem. Zentr. 1899, ii. 408); by fractional distillation (Farb. vorm. Meister, Lucius and Brüning, D. R. P. 207,157; J. Chem. Soc. Abst. 1909, i. 307). It is a crystalline solid, melting at 47·5°, and boiling at 213°–214°.

Of the **dichlorbenzaldehydes** the 2 : 5- and 2 : 6-dichlor- compounds are the parent substances of many dyestuffs 2 : 5-**dichlorbenzaldehyde** (Gnehm and Bänziger, Ber. 1896, 875; Schüle, Annalen, 299, 34) melts at 57°–58°, and is obtained by the action of antimony pentachloride on benzaldehyde in the presence of iodine. 2 : 6-**dichlorbenzaldehyde** (Anil. Fabw und Ext. Fabrik., D. R. P. 199943; Chem. Soc. Abstr. 1908, i. 986). Reduction of the nitrobenzaldehydes yields the amino-benzaldehydes, of which the most important is the para-compound. This may also be prepared by heating *p*-nitrotoluene with sulphur and sodium hydroxide (Geigy, D. R. P. 86874). Bayer & Co. (D. R. P. 218364) separate the amino-benzaldehydes by reducing the crude nitro- compounds with hot sodium hydrosulphite solution, cooling to 50°, and acidification with hydrochloric acid. The mixture is then boiled for one minute, and, on cooling, the anhydro-compound of the *o*-aminoaldehyde separates, whilst the *m*-aminobenzaldehyde remains in solution, and can be recovered, and hence used for the preparation of the *m*-hydroxybenzaldehyde. *p*-Dimethylamino benzaldehyde $(CH_3)_2N{\cdot}C_6H_4{\cdot}CHO$ is best obtained by Ullmann and Frey's method (Ber. 1904, 37, 859), in which *p*-dimethylaminobenzyl alcohol (from dimethylaniline and formaldehyde) is condensed with *p*-nitrosodimethylaniline, and the resulting compound decomposed by nitrous acid. It crystallises in colourless needles, melts at 73°, and is used in the preparation of triphenylmethane dyes.

Hydroxybenzaldehydes (*q.v.*) **Salicylaldehyde.**

BENZALDEHYDE GREEN *v.* TRIPHENYLMETHANE COLOURING MATTERS.

BENZALDEHYDE-*o*-SULPHONIC ACID



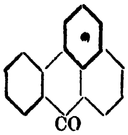
The most technically important member of the group, is obtained by heating *o*-chlorobenzenealdehyde with an aqueous solution of sodium sulphite under pressure at 170°–180°, and treating the product with sulphuric acid. When the sulphur dioxide is expelled by boiling, the cooled liquid is neutralised with sodium carbonate, and the sodium salt extracted with alcohol. Or the sulphonic acid may be converted into the sparingly soluble barium salt (Geigy & Co., D. R. P. 88952).

The free acid is a syrup; the sodium and barium salts crystallise in prisms (Gnehm and Schüle, Annalen, 1898, 299, 347).

The acid may also be prepared by oxidising stilbene disulphonic acid with potassium permanganate (Levinstein. Eng. Pat. 21968, 1897).

BENZAMIC ACID *v.* AMINO- ACIDS (aromatic).

BENZANTHRONE,



Prepared by heating a mixture of anthranol with sulphuric acid and glycerol at 120°, treating the product with water, washing the crude substance with sodium hydroxide solution, pressing, and drying. May be prepared from anthracene by treatment with sulphuric acid and glycerol (Badische Anilin und Soda Fabrik, D. R. P. 176019); and by condensing anthranol with acetin, or 2-aminoanthraquinone with dichlorohydrin (*idem.* D. R. P. 204354); or by heating phenyl-α-naphthyl ketone with aluminium chloride or ferric chloride. For other syntheses, *v.* Schaarschmidt and Korten, Ber. 1918, 51, 1074; Schaarschmidt and Georgeacopol, Ber. 1918, 51, 1082; *v.* KETONES.

Crystallised from alcohol benzanthrone forms pale yellow needles, m.p. 170°. Used in the manufacture of indanthrene dyes (*see* Benzanthrone Colours, art. INDANTHRENE).

BENZAURIN *v.* AURIN.

BENZENE AND ITS HOMOLOGUES.

Benzene. (*Benzol, Benzole*, Fr.; *Benzol*, Ger.) The name of this substance was derived in its original form from that of gum benzoïn, probably as *benzoïn oleum*, hence *benzole*, which latter form is still in use amongst nearly all distillers and users of it both in this country and on the Continent. In more strictly scientific literature, however, the name *benzene* has now become generally accepted, and the systematic termination *-ene* is employed in the names of its various homologues, as toluene, xylene, cymene, &c.

Pure benzene is a limpid, colourless, highly refracting liquid at ordinary temperatures. Its sp.gr. at 0° is 0·8991 (Kopp), 0·90023 (Adriaansz), and at 15° 0·8841 (Mendeléeff).

Its refraction index for the D line at 15·2° is 1·4957 (Adriaansz); at 9°, 1·4593 for A, 1·5050 for D, 1·5037 for H (Gladstone); at 8·5°, 1·50381 for H_α (Perkin, Chem. Soc. Trans. 1900, 77, 273).

When surrounded by ice it becomes solid, and if crystallisation is allowed to take place slowly, rhombic crystals are produced, the axes of which, *a, b, c*, are 0·891, 1, 0·799 (Groth). The solid melts at 5·483° (Richards and Shipley, J. Amer. Chem. Soc. 1914, 36, 1825).

It contracts on solidification, the difference in the specific volume of the liquid and solid $v_l - v_s = \Delta v$ is between 0·1219 and 0·1304 at 5·35° (Heydweiller, Ann. Phys. Chem. 1897, (iii.) 61, 527).

It exhibits no absorption lines or bands in the visible portion of the spectrum. Beyond H, however, photographs show a series of four bands covering the region lying between W.L. 3171 and 2190 tenth-metres. The methylated benzenes, toluene, and the three xylenes exhibit a similar absorption, requiring, indeed, very careful measurement to distinguish one from the other (Hartley, Chem. Soc. Trans. 1885, 47, 685; Proc. Roy. Soc. 1908, 80, A, 162; Hartley and Dobbie, Chem. Soc. Trans. 1898, 73, 695; Baly and Collie, *ibid.* 1905, 87, 1332; Friederichs, Zeitsch. photochem. 1905, 3, 154; Grebe, *ibid.* 376; Mies, *ibid.* 1909, 7, 357; 1910, 8, 287; Witte, *ibid.* 1915, 14, 347; Massol and Faucon, Compt. rend. 1918, 166, 819).

Benzene is an excellent solvent, easily dissolving caoutchouc and asphaltum, if they have not been exposed to light, though the protective effect of the light on the asphaltum is but slight, and prolonged treatment with benzene causes it to dissolve. Nearly all the gum resins, sulphur, phosphorus, fats, oils, most of the natural alkaloids, and many other organic compounds, are soluble in it. It has also, in common with carbon disulphide, the property of dissolving iodine with production of a violet solution.

Benzene is itself soluble to a very slight extent in water, considerably more so in alcohol, whilst ether, glacial acetic acid, acetone, and carbon disulphide, dissolve it readily.

Benzene boils under normal pressure at 80·36° (Regnault). For benzene from coal tar, Adriaansz found 80·53° to 80·62°; and for that obtained from benzoic acid prepared from gum benzoin, 80·60° to 80·67°; 80·2° (corr.) Thorpe and Rodger. Its specific heat at temperatures between $-185°$ and $+20°$ is 0·176 (Nordmeyer and Bernouilli, Ber. Deut. physikal. Ges. 1907, 5, 175) and at 94° is 0·4814 (Schlamp, Ann. Phys. Chem. 1896, (iii.) 58, 759). The latent heat of vaporisation is 94·37 (Griffiths and Marshall, Phil. Mag. 1896, (v.) 41, 1) or 94·93 (Campbell Brown, Chem. Soc. Trans. 1905, 87, 265).

For observations on its thermal expansion, *see* Kopp (Jahr. 1847–1848, 66), Louguinine (Ann. Chim. Phys. 4, 11, 465), Adriaansz (Bull. Soc. chim. 20, 1873).

The vapour when inhaled produces giddiness and ultimately insensibility.

Benzene forms with picric acid the molecular compound $C_6H_2(NO_2)_3OH,C_6H_6$, which melts with decomposition at 90°.

Oxidising agents, such as potassium permanganate or manganese dioxide and sulphuric acid, convert it into formic, propionic, and oxalic acids, together with small quantities of benzoic and phthalic acids, the latter substances being produced by the simultaneous oxidation of formic acid and benzene, the process of condensation resembling that occurring in the conversion of dimethylaniline into methyl violet. When strongly heated in sealed tubes or when passed slowly through strongly heated open tubes, condensation and decomposition go on together, acetylene, diphenyl, diphenylbenzene, &c., being formed with evolution of hydrogen and deposition of carbon (*cf.* Smith and Lewcock, Chem. Soc. Trans. 1912, 101, 1453; Zanetti and Egloff, J. Ind. Eng. Chem. 1917, 9, 350).

There can be little doubt that toluene and xylenes can also be produced in this way, and since Berthelot has shown that toluene and xylene when passed through strongly heated tubes can produce anthracene and naphthalene, and since he also obtained anthracene by so treating a mixture of benzene and ethylene, we may assume that if benzene is *not* the mother substance of the whole series of hydrocarbons obtained from coal tar, it is yet capable, under proper conditions, of generating all the others.

Vapour of benzene mixed with hydrogen passed over finely divided nickel heated to 170°–190° yields cyclohexane C_6H_{12}. The homologues of benzene behave similarly.

By passing dry ammonia through benzene containing calcium shavings a calcium-ammonia compound $Ca(NH_3)_4$ is formed, which with the benzene produces *dihydrobenzene* C_6H_8:

$$Ca(NH_3)_4=Ca(NH_2)_2+2N_2H+H_2$$
$$H_2+C_6H_6=C_6H_8$$

(Dumanski and Zvereva, J. Russ. Phys. Chem. Soc. 1916, 48, 994).

When chlorine acts on pure benzene in sunshine, benzene hexachloride $C_6H_6Cl_6$ is formed. The substitution of chlorine for hydrogen in the nucleus or benzene ring is a very slow operation if chlorine alone is used, but if in every litre of benzene about 10 grams of iodine are dissolved, and the liquid kept boiling while a brisk current of chlorine is passed into it, substitution readily takes place and chlorinated benzenes are produced. The reaction may be continued until the whole of the hydrogen is replaced with production of hexachlorobenzene C_6Cl_6. (For the electrolytic chlorination of benzene and toluene, *see* Name and Maryott, Amer. J. Sci. 1913, (iv.) 35, 153; Fichter and Glantzstein, Ber. 1916, 49, 2473). Corresponding bromine and iodine compounds, and mono- and *p*-di-fluoro- derivatives are known.

When subjected to the action of strong nitric acid or a mixture of nitric and sulphuric acids, substitution of hydrogen by NO_2 takes place with great ease. If the mixture is kept cool only mononitrobenzene is formed, but if heated, the three dinitrobenzenes are produced, the metadinitro- product (m.p. 89°) always greatly predominating. The ortho- and para- compounds can only be produced in quantity by indirect methods. Trinitrobenzenes can only be obtained by the action of a great excess of a mixture of nitric acid and fuming sulphuric acid.

All the nitro- compounds on reduction with appropriate reagents, such as iron, zinc, or tin, in the presence of acid, preferably hydrochloric and water, yield amino- compounds corresponding with the nitro- compound reduced. Such are aniline $C_6H_5{\cdot}NH_2$, the three diaminobenzenes or phenylenediamines $C_6H_4(NH_2)_2$, &c.

The amino- compounds, by the action of nitrous acid or nitrites in the presence of an excess of acid, preferably hydrochloric, are converted into diazo- compounds. If a diazobenzene salt, *e.g.* $C_6H_5{\cdot}N_2Cl$, is dissolved in absolute alcohol, and the solution heated, the nitrogen is evolved as gas whilst benzene is regenerated. If a diazo- salt is dissolved in water and boiled in the presence of an acid, nitrogen is also evolved and the corresponding phenol is produced.

The diazo- compounds react with certain amino- compounds or phenols, giving rise to the almost innumerable series of dyes known as azo-colouring matters (*q.v.*). Solutions cooled with ice should be employed, and all rise of temperature must be carefully avoided. Under proper conditions some diazo- compounds, however, attack the *amino-* group of amino- compounds, forming diazoamino- compounds such as diazoaminobenzene $C_6H_5\cdot N : N\cdot NH\cdot C_6H_5$. These can be made to undergo an isomeric change resulting in the formation of what are known as aminoazo-compounds, of which aminoazobenzene

$$C_6H_5\cdot N : N\cdot C_6H_4\cdot NH_2$$

is a typical example. Such substances, when treated with a reducing agent, split up into an amine and a paradiamine, while diazo- compounds yield hydrazines only, and diazoamino-compounds a mixture of a hydrazine and an amine.

If the nitro- compounds are submitted to the action of alkaline reducing agents in alcoholic solution, such as a mixture of zinc-dust and alcoholic soda, the reaction takes a different course altogether. The action of alcoholic soda and heat alone will convert mononitrobenzene into azoxybenzene $C_6H_5\cdot\underset{\underset{O}{\|}}{N} : N\cdot C_6H_5$; this, by nascent hydrogen, is converted into azobenzene $C_6H_5\cdot N : N\cdot C_6H_5$, which under the action of the same reagent is still further reduced to hydrazobenzene $C_6H_5\cdot NH\cdot NH\cdot C_6H_5$. The latter, when treated with an acid, is converted into a salt of benzidine (paradiaminodiphenyl)

$$NH_2\cdot C_6H_4\cdot C_6H_4\cdot NH_2$$

which is a strongly basic compound isomeric with hydrazobenzene.

When heated with concentrated sulphuric acid or treated in the cold with solutions of sulphur trioxide in sulphuric acid, sulphonic acids are produced by substitution of HSO_3 for hydrogen. These are either mono-, di-, or poly-sulphonic acids, according to the treatment adopted. They are all powerful acids, and form well-defined and generally well-crystallised salts with sodium, potassium, and ammonium, and equally definite, though less easily crystallised salts with calcium, barium, copper, iron, etc. These, especially the sodium or potassium salts, if fused with caustic potash or soda, or heated under great pressure (40 atmospheres) with aqueous soda or potash, are decomposed with production of a sulphite of the alkali metal, and conversion of the benzene residue into the corresponding hydroxy- or phenolic compound.

Only the methyl homologues of benzene will be considered here, as these are the chief ones which occur in coal-tar.

The monomethyl derivative is known as *toluene*, and under all treatments behaves as a completely homogeneous substance.

The dimethyl derivative is known as *xylene*, the substance of that name occurring in coal tar, which occurs as three isomeric compounds: *Orthoxylene*, boiling at 341°–142°, which, when gently oxidised with weak nitric acid, gives a toluic acid melting at 102°; *metaxylene*, boiling at 139°, which gives a toluic acid melting at 106°: *paraxylene*, melting at 15°, and boiling at 138°, giving a toluic acid melting at 178°.

Each of these different xylenes is, however, absolutely identical in percentage composition, and this isomerism is considered to be due to the *configuration* of the molecule, or, in other words, to the positions in space occupied relatively to each other, and to the benzene residue, by the two substituting molecules.

This method of regarding the constitution of benzene and its innumerable series of derivatives is usually, for purposes of discussion, investigation, or explanation, represented by drawing a hexagon to represent the molecule of

benzene, the six angles representing the six groups of CH at any of which substitution is supposed to take place. Since only one mono-substitution compound of a given kind (*i.e.* containing a given substituting group) is known, all the six CH- groups in benzene are supposed to be of equal value. The fact that disubstitution compounds exist in three distinct isomeric modifications (compare the above-mentioned xylenes), is explained in this scheme by the following suppositions as to the relative positions occupied by the substituting groups. First, substitution is supposed to take place at two adjacent angles, *e.g.* 1 and 2, 2 and 3, 4 and 5, &c., in which case the word *ortho-* is prefixed to the name of the substance, as orthodimethylbenzene (commonly called orthoxylene), or orthodichloro-, orthodibromo-, or orthodiamino-benzene, etc. Or the substitution is supposed to take place at two angles not adjacent, but with one interposing, as at 1 and 3, 2 and 4, or 1 and 5, etc. In this case the product is indicated by the prefix meta-, as metadimethylbenzene (commonly called metaxylene, &c. Lastly, the substitution is supposed to take place at opposite angles, such as 1 and 4, 2 and 5, 3 and 6, etc. In such a case the substance is known as a para- compound, as paradimethylbenzene, or paraxylene, paradinitro benzene, etc.

This theory is due to Kekulé, and satisfactorily agrees with most of the phenomena. (For a *résumé* of work on the constitution of benzene, *see* Kauffmann, Chem. Zeitschr. 4, 289; Holleman, Chem. Weekblad, 1915, 12, 440.)

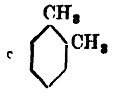
Toluene and xylene generally react under similar conditions in the same way as benzene, producing a similar series of compounds. Since, however, toluene itself is a mono- substituted benzene, mono- substituted toluenes are really di- derivatives of benzene. For instance, there is but one mononitrobenzene, but there are three mononitrotoluenes. There are three dinitro- and three diamino- benzenes, but there are six dinitrotoluenes and six diaminotoluenes, and so on.

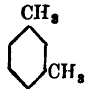
It is to be borne in mind that in all substitution derivatives higher than the di- substitution series, the number of possible modifications is greater when the substituting groups are dissimilar than when they are all alike; thus, although there are only three isomeric tri- substitution compounds of the formula $C_6H_3X'_3$ or $C_6H_3Y'_3$, there are six such compounds of the formula $C_6H_3X'_2Y'$.

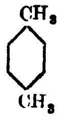
It follows that the xylenes being di- derivatives, their mono- are tri- derivatives of benzene, and consequently correspond in number with the di- derivatives of toluene.

The introduction of the methyl group, moreover, permits of another kind of substitution which gives rise to a totally different class of compounds from those described above as configurational isomerides, in which substitution takes place not in the benzene nucleus, but in the methyl group itself. Such substitution is said to be *extra-nuclear.*

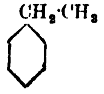
Thus, as mentioned above, there are three substances having the formula C_8H_{10} known as ortho-, meta-, or para-xylene. These isomerides are represented as dimethylbenzenes of the following configurations:—







but there is another C_8H_{10} only known to occur in one form, and always behaving as a monoderivative of benzene; this is ethylbenzene



Just as in this case a methyl group has been introduced into the methyl instead of into the nucleus, so chlorine, bromine, &c., may be introduced, and in this manner such compounds as benzyl chloride $C_6H_5 \cdot CH_2Cl$, the di- or trichloride, benzaldehyde, and many others are formed.

The physical properties of *toluene* greatly resemble those of benzene. As solvents, there is little or no difference in their powers, and though the boiling-point of toluene is so much higher than that of benzene, yet in a current of air at ordinary temperatures it evaporates nearly as quickly.

Toluene is a colourless limpid liquid which solidifies at −94·2° (Ladenburg and Krügel, Ber. 1899, 32, 1818) or −97° to −99° (Archibald, and McIntosh, J. Amer. Chem. Soc. 1904, 26, 305). Its specific gravity is less than that of benzene, being at 0° 0·882, at 15° 0·872, its index of refraction at 25·5° is for A 1·4709, D 1·4794, H. 1·5090 (Gladstone and Dale), at 8·5° for Hα 1·49891 (Perkin).

Toluene boils constantly at 111°, 110·56° (corr.) (Thorpe and Rodger); the vapour has much the same physiological effects as that of benzene, but its odour is decidedly less pleasant. If ingested into the stomach, it is eliminated in the urine as hippuric acid.

Of the three *xylenes* the meta- is chiefly used in commerce. Orthoxylene boils at 141°–142° 144·07° (corr.) (Thorpe and Rodger). Metaxylene boils at 139°, and its specific gravity is 0·8668 at 19°, 138·8° (corr.) (Thorpe and Rodger); sp.gr. 0·8812 (Pinette). Paraxylene boils at 138°, and at 19° its sp.gr. is 0·8621, 138·23° (corr.) (Thorpe and Rodger); sp.gr. 0·8801 (Pinette). The two former are liquid at all temperatures down to at least −20°, but paraxylene becomes solid when exposed to a freezing mixture, and when once frozen it only melts at 15°.

The xylenes are distinctly less volatile than toluene and benzene in an air current. The smell of the vapours is unpleasant and pungent, and they possess the power of producing unconsciousness when inhaled.

Both benzene and toluene when prepared from coal tar are accompanied by sulphur compounds known as *thiophens.* That derived from benzene, no doubt by the action of sulphur from the pyrites of coal at a high temperature during distillation in the gas retort, is represented by the formula C_4H_4S or .

It was isolated in 1882 by V. Meyer, who obtained by constant and repeated agitation with sulphuric acid about 2 kilos from 2000 kilos of commercial benzene. It is a colourless liquid, boiling constantly at 84°; sp.gr. at 15° 1·100. In many of its reactions it behaves exactly like benzene. *V.* THIOPHEN.

Two thiotolens corresponding with toluene, *i.e.* being methylthiophen, are known. They both boil at about 113°, sp.gr. 1·0194. The very minute quantity in which these substances occur renders them of no industrial importance, even as impurities.

Benzene was first isolated by Faraday in 1825, in the liquid separating from condensed oil gas.

It is unnecessary here to describe the processes by which Mitscherlich, D'Arcet, Kopp, and many others obtained benzene, as the first practically industrial process was that of Mansfield, founded entirely at first on Faraday's, and dealing with a similar product as the source, namely, coal tar (Mansfield, Quart. Jour. Chem. Soc. 1848, 1, 244). Mansfield took the lower boiling portion of coal tar, which was then used under the name of naphtha for lighting purposes, and distilled it over a flame in a still provided with a jacketed head and a simple form of dephlegmator made by connecting the upper part of the condensing worm with the still body by an inclined tube. The water in the jacket round the long egg-shaped head partially condensed the vapours rising from the boiling fluid until it reached a temperature of 100°, when those vapours condensable at that temperature were alone affected and returned to the still, those requiring a lower temperature passing on to the worm, and being condensed and collected. Much of the spray carried upward by the vapours was stopped in the head, and what passed it and was condensed in the connecting tube between the still head and the worm flowed into the inclined tube, and found its way back to the body of the still. Finally, when nothing more could pass the boiling water in the jacketed head, this inclined tube, on a cock being fully opened, which during the first part of the process was partially closed, could be made use of to distil over the higher boiling portions.

Such an apparatus could, of course, only effect a rough separation of the oil into a 'benzol' mainly distilling below 100° and a 'naphtha,' most of which would not distil below 100°.

If, however, the water of the water jacket round the head were carefully kept at a stated temperature, say 80°–82°, a much purer product could be obtained. For some years the process was only carried out with the object of getting oils for the Read Holliday lamp, and for the use of rubber manufacturers.

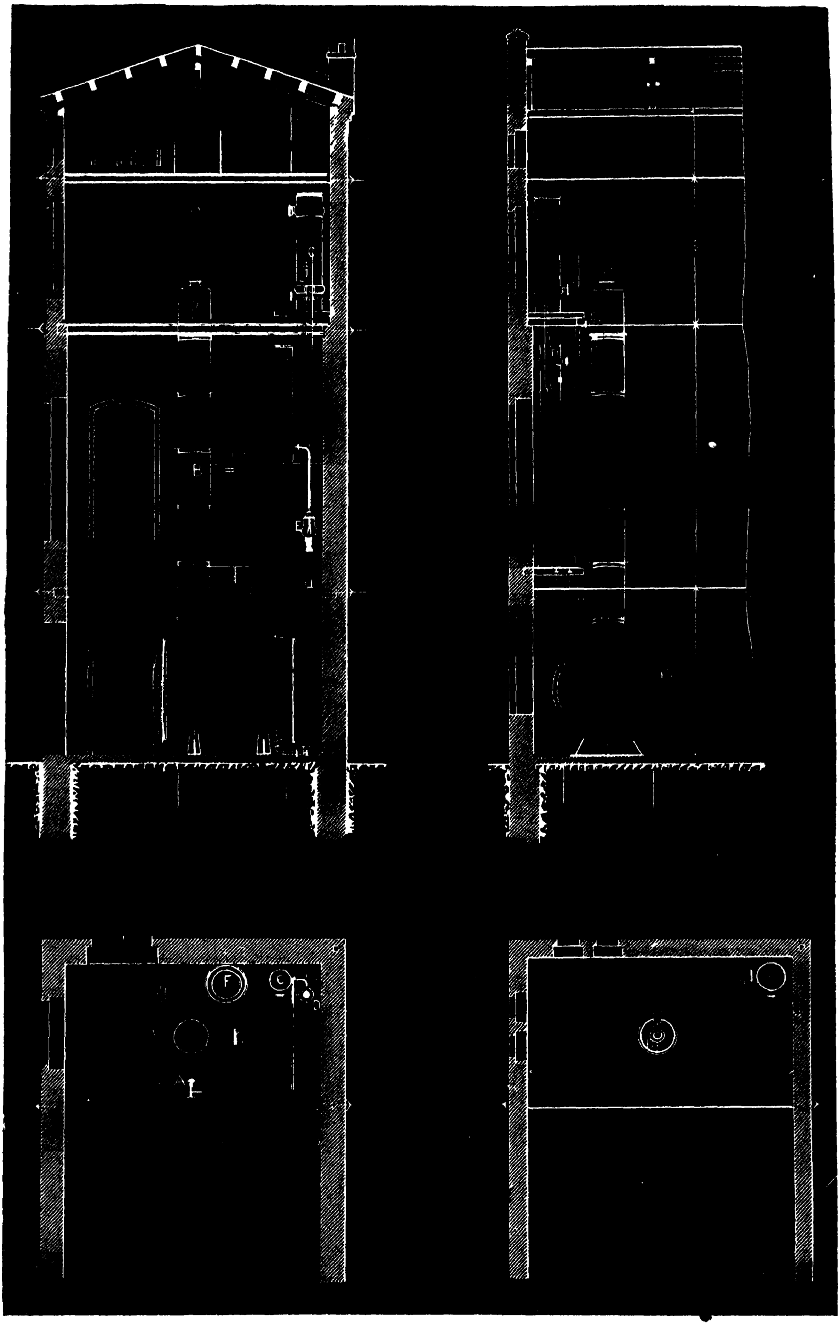


FIG. 1.

A, Still body. **B**, Analysing column. **C**, Cooler kept at temperature of distillate wanted. **D**, Condenser for pure distillate. **E**, Vase into which distillate flows. **F**, Automatic regulator.

The early demands for 'benzol' for use in the aniline colour industry were confined to what were known as 30 p.c., 50 p.c., and 90 p.c. benzols, which terms were understood to mean that 30, 50, or 90 p.c. by measure of the sample boiled below 100°. Of these the 30 p.c. was mainly used for the production of aniline for red, and the 90 p.c. for aniline for blue. Mansfield had, however, subjected his distillates to a careful but most laborious fractionation in glass retorts, finally obtaining perfectly pure benzene by recourse to freezing and pressure, and he pointed out that 'it is evident that any of the summary processes of rectification which are practised by distillers in the manufacture of alcoholic spirits are applicable to the separation of benzole from the less volatile fluids of the naphtha' (Reports of the Royal College of Chemistry, 1849, 257).

Mansfield, in fact, in the remarkable paper just quoted, laid the foundations of the whole benzene industry, and his processes with scarcely a change are in use to this day. The departures from them have been one by one abandoned in favour of his method of absolute separation of the light oils into their constituents, and it is not too much to say that had it not been for his terrible death[1] in February, 1855, we should have had the pure hydrocarbons in the market many years ago.

The introduction of the aniline black printing processes and other improvements in the dye industry, however, slowly gave rise to a demand for a purer benzene, while later on a demand for toluene and xylene stimulated the improvement of the distillation process.

The movement was naturally, as Mansfield had suggested, towards the use of such a still as had been introduced by Mr. Coffey in his patent of 1832 and subsequently carried to great efficiency by succeeding generations of spirit distillers. Coupier of Paris appears first to have worked on a large scale in this direction about 1863. He modified the original Mansfield apparatus in the way mentioned above, and showed that at one operation he could separate ordinary 50 p.c. commercial benzol as follows:—

100 *litres yielded*:

44	litres between	80°	and 82°	('Pure benzol')
6	,, ,,	82°	,, 110°	(Crude toluol)
17	,, ,,	110°	,, 112°	('Pure toluol')
5	,, ,,	112°	,, 137°	(Crude xylol)
9	,, ,,	137°	,, 140°	('Pure xylol')
13–14	,, ,,	140°	,, 150°	last runnings.

In addition there were about 6 litres between 62° and 80°, consisting of various impurities such as carbon disulphide, acetonitrile, etc.

Vedlé, Savalle of Paris, and others followed with various improvements in the same direction, Savalle being most generally considered to have produced the best still, though it had two great drawbacks, viz. it was manufactured of copper, which made it very costly, and it was hampered, as far as its condensation arrangements were concerned, by an expensive and useless attempt to use air from a fan driven by steam, as a means of cooling the condensers.

The latter attempt was soon given up. In Fig. 1 (p. 573) is seen the apparatus in its latest form as made by the Metallwerke vormals T. Aders, of Magdeburg-Neustadt.

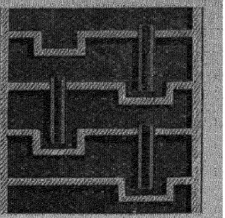

FIG. 2.

The still being charged with the proper quantity of naphtha or crude benzol, which has undergone the necessary washings with sulphuric acid and sodium hydroxide, steam is admitted into the coils, where it circulates, the condensed water escaping through another tube in the usual fashion. As soon as the liquid begins to boil, the vapour ascends into the head *a* and passes through the curved tube *a'* into the bottom of the column B. This contains 25 to 30 flat diaphragms, each pierced with a number of small holes, and one larger, into which is fitted a short wide overflow tube, the end of which stands up about 2 inches above the level of the plate. On the opposite side of the plate is a small depression about 2 inches deep and 4 inches in diameter, into which the overflow tube from the plate above dips, its own tube dipping in the same way into a depression in the plate below. The condensed fluid acts to each overflow tube as a trap (Fig. 2), and prevents the ascent of vapour through it.

The rising vapour condenses rapidly on these plates, and the fluid thus produced, unable to penetrate the small holes through which the hot vapour is rushing, rises to the brim of the overflow tube, and then pours down from plate to plate into the still body. The non-condensed vapour rises through the perforations of the next plate, where it undergoes a similar operation, and so on to the top, the vapour passing away from which has thus been successively washed by bubbling through some thirty layers of fluid, each slightly cooler than the one beneath. Finally, the vapour passes through a surface or multitubular condenser, C, which is provided with a water supply so regulated that its temperature is about that of the boiling-point of the liquid required. The liquid here condensed flows back into the column at a suitable point, while the now purified vapour passes on to the second condenser, D, and is finally completely condensed into the liquid form. Thence it flows into the glass vase E, which is fitted on to a stand-pipe communicating with the distributing-pipes which convey it to the store tanks. The fractions taken should now boil as follows: Benzene, 80°; toluene, 110°; xylene, 140°.

If pure products are required, each fraction is washed with concentrated sulphuric acid, and a washing with soda solution follows. The fraction is introduced into a cast-iron vessel provided with a lid with manhole and inlet pipe. Through the centre passes a vertical shaft rotated by mitre geared wheels. The shaft is provided with arms so arranged that the contents can be thoroughly churned up. A good form of apparatus is seen in Fig. 3. The details need no description except to point out that the screws used to force the fluids through the two vomiting tubes A and A′ should be set on the shaft with their helices reversed right and left, so that the lower one causes the lower fluid to rush up, and the upper one the upper fluid to rush down; they thus cause the two currents to meet together violently and thoroughly mingle. The centre shaft may also consist of an Archimedean screw or of a truncated hollow cone. Air agitation is not advisable on account of the loss of benzol which it is apt to cause.

---

[1] Mansfield was burned to death by the boiling over of a benzene still.

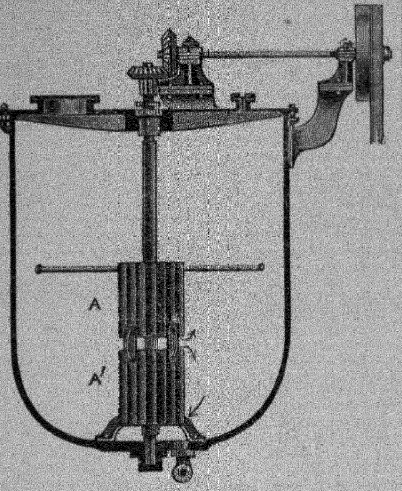

FIG. 3.

If the fraction is of fairly good quality and has been properly separated from the crude benzol or light oils, the amount of acid required need not be more than one-twentieth of its weight. In some cases, however, where the impurities are difficult to remove, more must be used, and the operation repeated. After the acid has been run off, a washing with enough soda solution to neutralise excess of acid and remove traces of phenols follows, and the fraction is then ready for a second rectification.

If crude naphtha has been used to charge the still, it will have yielded, *inter alia*, 50 p.c. or 90 p.c. benzol according to requirements. On redistillation, 100 parts of the former should yield 45–48 parts of pure benzene, and from 100 parts of the latter 70 parts of pure benzene should be obtained.

When re-rectified, the benzene and toluene should each distil constantly within 0·5° and 1·0° respectively, and the xylene within 2°.

The treatment for obtaining toluene is exactly the same as that described for benzene, the toluene following the benzene from the crude benzol still and being subsequently re-rectified. Toluene is also accompanied by the corresponding thiophen (thiotolen), and requires very careful and thorough washing with sulphuric acid, or it cannot be properly nitrated.

After the separation of the toluene, more or less crude xylene is obtained, and the residue in the still is then cooled and run out. When good crude benzol has been worked, the residue contains a very large quantity of naphthalene, which separates from it when cold, and is known in the works as 'naphthalene salts.' As it has all been brought off from the tar at a low temperature, it is extremely free from higher boiling substances, and very pure naphthalene can be obtained from it with little trouble. Of the rest, some 20–30 p.c. consists of phenol, to which the same remarks apply. The remaining third consists of a mixture of hydrocarbons from which some more xylene could no doubt be recovered, but the bulk of this 'dead oil,' as it is often called, is used for burning. Metaxylene can be prepared from the purified mixed xylenes by agitation with sulphuric acid, as described for benzene and toluene, to remove the thiophens, when a subsequent treatment with its own weight of sulphuric acid converts the metaxylene into a sulphonic acid, which after separation from the insoluble portion is hydrolysed, and metaxylene of great purity obtained.

Benzene, it is stated, is formed by passing the vapour of petroleum mixed with hydrogen through a tube containing a suitable catalyst,—iron, copper, zinc, nickel, &c.—at a temperature between 180° and 300° (Eng. Pat. 17272, 1913; 20470, 1913; 2838, 1914).

Benzene and toluene may be obtained by the demethylation or 'cracking' of the higher benzenoid hydrocarbons. The optimum temperatures for the production of benzene and toluene are respectively 800° and 750°, the solvent naphtha containing the higher hydrocarbons being passed through a heated steel tube under a pressure of 11 atmospheres. About 25 p.c. of the solvent naphtha is demethylated, the percentage yields of benzene and toluene at the foregoing temperatures being 15·9 and 20·6 respectively (Egloff and Moore, J. Soc. Chem. Ind. 1917, 36, 128; G. T. Morgan, Report for 1917, J. Soc. Chem. Ind.).

Valuation of Commercial 'Pure Benzol.'—As stated above, the whole should boil within 0·5° of the correct boiling-point. It should give no crystalline precipitate on standing with a few drops of phenylhydrazine (test for carbon disulphide). When shaken with concentrated sulphuric acid the latter should be only slightly darkened (thiophen or aliphatic hydrocarbons). On shaking with sulphuric acid and a trace of isatin, no blue colouration should be produced (thiophen). On treatment with a mixture of nitric and sulphuric acids, and subsequent distillation in a current of steam, no unnitrated hydrocarbons should be obtained (aliphatic hydrocarbons). Lastly, it should solidify when cooled below 0°.

Pure toluene of commerce should not impart any colouration to sulphuric acid when shaken with it. On shaking 90 c.c. of toluene with 10 c.c. of nitric acid (sp.gr. 1·44) in a stoppered bottle, the acid should assume only a red colour, and remain quite clear and bright, not turning greenish or blackish. (For much information as to the commercial valuation of 'benzols,' *see* Lunge, Coal Tar and Ammonia, 5th ed. 1916; and Northall-Laurie, Analyst, 1915, 40, 384; James, J. Soc. Chem. Ind. 1916, 35, 236; Spielmann and Jones, *ibid.* 911; 1917, 36, 489; Spielmann and Wheeler, *ibid.* 396; Edwards, *ibid.* 587; Wilson and Roberts, J. Gas Lighting, 1916, 134, 225; Harker, J. Roy. Soc. New South Wales, 1916, 50, 99; Egloff, Met. and

Chem. Eng. 1917, 16, 259; Jones, J. Soc. Chem. Ind. 1918, 37, 324; Weiss, J. Ind. Eng. Chem. 1918, 10, 1006.)

Nitration of Benzene, Toluene, etc.—Nitrobenzene first made its appearance in the arts under the name of *essence de myrbane*, manufactured in France by Collas. It was used to scent soap and as a bitter-almond flavouring. Mansfield had taken out a patent for its manufacture in 1847 from coal-tar benzene. The usual arrangement now adopted for its manufacture (*see* Fig. 4) is as follows:[1]—

The nitrating pan has a total capacity of 1600 gallons, and is capable of treating 500 gallons or 4420 lbs. of benzol in one charge. It is of cast iron, 1½ inches thick, the sides, from the lid down to a depth of 3 feet, being ¼ inch thicker. The vertical agitating shaft is suspended from the lid on ball bearings, and carries two propellor agitators. The internal cooling pipes consist of two separate coils of thin lead pipe 2 inches diameter, each coil being about 150 feet long. They are supported on circular cast-iron grates or tables, as shown. The coils are spaced out so as to allow free passage of the liquid between them. To direct the upward flow of the liquid, the lower propellor agitator is surrounded by a cast-iron cylinder with large perforations at the bottom to admit the descending liquid. This serves also as a support for the grates and coils. Five hundred gallons of pure benzol are first run by gravity into the machine. The acid-mixing tank, which stands

[1] See Chem. Trade Jour. 1906, 38, 59. The writer is indebted to Messrs. Davis Bros. for permission to reproduce the sketch of the apparatus.

bove, is charged with 5000 lbs. of nitric acid, ·43 sp.gr. or 86°Tw., and 6600 lbs. of sulphuric cid of 96 p.c., and these are thoroughly mixed by ir agitation. In some factories the acids are ixed in the above proportions in large stock nks. The mixed acid is run in a thin stream to the benzol, while the agitators are revolving t a speed of about 60 revs. per minute. The eat of the reaction is indicated on a long ermometer suspended in a metal tube, which asses through the lid and dips into the liquid. he temperature is kept below 60° by checking e flow of acids if the temperature rises. With good supply of cooling water passing through he coils, very little attention is required, and he process, which a few years ago was attended ith danger and frequent loss, is now carried n almost automatically. This is principally wing to the purity of the benzol employed, and he use of internal cooling coils in place of the utside water-jacket.

It is important that the coils should be of ure chemical lead, without flaw, and before eing used, they should be examined minutely. ome of these coils have been known to work early 4 years continuously. The vertical ortions, connecting the coils with the exterior, ould be protected, as these are quickly ttacked. This is done by 'threading' them rough lead pipes of slightly larger diameter, nd filling up the intervening space with any cid-proof cement. After the full charge of ixed acids has been run into the machine, e agitation is continued for about 4½ hours, nd the benzol will then be completely transformed into nitrobenzol. If a sample is then ken while the agitators are running, and llowed to settle, the weak sulphuric (called aste acid) will contain less than 1 p.c. of nitric cid, and the upper layer of nitrobenzol will ave a sp.gr. of 1·235. The agitation is then opped, and the contents of the machine llowed to settle for 5 hours. The 'waste cid,' having settled to the bottom, is run off to the air-pressure egg below, and blown to e sulphuric acid concentrating department to e rectified. The nitrobenzol is next run off to the air-pressure egg and blown into the ashing pan above, where it is washed by iolent air agitation with an equal volume of ater containing sufficient sodium hydroxide neutralise any trace of acid left in it. After ettling a few hours the nitrobenzol settles to e bottom, and is run down into the air-pressure gg, and forced from there into a large store tank, hich is set at a high level, so that the contents an run by gravity to the aniline machine. he wash-water, which contains a little nitroenzol in suspension, is run into a series of ettling tanks, and the oil recovered. Although is possible to work a charge of benzol in each achine daily, it is customary to have a duplicate et of machines, and to work each machine on lternate days. For an output of 150 tons of ure aniline oil per month, six nitrobenzol achines are required, with their corresponding djuncts, as shown in the figure. The yield of itrobenzol from the pure benzol employed is 54½ p.c. by weight, and this approaches so ear the theoretical yield, viz. 157·6 p.c., that ere is little room for improvement. It is ossible slightly to increase this yield by settling the waste acid for 48 hours in a series of tanks, and skimming off the nitrobenzol, but in practice it has not been found to pay for the trouble, especially if the previous separation be carefully watched.[1] Several plants have been proposed for the continuous process of nitration of benzene, the hydrocarbon and nitrating acid being led into the apparatus at certain points and the nitrobenzene emerging at another (*see* Cain, The Manufacture of Intermediate Products for Dyes, Macmillan, 1918).

For a cryoscopic method of determining nitrobenzene in commercial nitrobenzenes, *see* Simpson and Jones, J. Soc. Chem. Ind. 1919, 38, 325; Analyst, 1919, 379.

When the nitrobenzol is to be sold as 'myrbane,' it is distilled under diminished pressure in order to obtain a perfectly clear and transparent liquid such as the users of myrbane demand. It is customary to use toluene imperfectly freed from benzene for this purpose, that article being cheaper and yielding a somewhat more fragrant myrbane than benzene alone.

The treatment adopted with toluene and xylene is in all essential particulars the same as with benzene. In the former case, however, if the nitrotoluene is not employed direct, the product is separated into *p*- and *o*-nitrotoluene by fractional distillation under diminished pressure through a Savalle column. The distillation is stopped when 40 p.c. has distilled, and the distillate on redistillation gives nearly pure *o*-nitrotoluene (b.p. 233°). The residue on cooling deposits crystals of *p*-nitrotoluene (b.p. 238°; m.p. 54°), which are freed from oil by centrifugating.

(For the estimation of *o*- and *p*-nitrotoluene, *see* Reverdin and De la Harpe, Bull. Soc. chim. 1888, (ii.) 50, 44; Glasmann, Ber. 1903, 36, 4260; Chem. Zeit. 1904, 28, 187; Holleman, Proc. K. Akad. Amsterdam, 1904, 7, 395; Rec. trav. chim. 1908, 27, 458.)

Dinitrobenzene and *dinitrotoluene* are obtained by treating a charge of the hydrocarbon with double the proportion of the mixed acids, the operation being carried out in two stages, and the second charge of acids run in directly after the first. The cooling water is shut off and the temperature allowed to rise rapidly. Or nitrobenzol already manufactured may be taken and again treated with the necessary acid.

The product of the reaction is separated from the acid as usual, and then thoroughly washed with cold, and lastly with hot, water. As dinitrobenzene is sensibly soluble in the latter, the hot wash-water had better always be preserved and used for first washing a subsequent batch. Finally, it is allowed to settle, and, while still warm, run out into iron trays, in which it solidifies in masses 2 to 4 inches thick. The principal product of the reaction is meta-dinitrobenzene, m.p. 89·8°, but **orthodinitrobenzene**, m.p. 118°, and **paradinitrobenzene**, m.p. 172°, are also produced, the m.p. of the commercial product being about 85°–87°. It should not contain any nitrobenzene, and should be well crystallised, hard, and almost odourless, and should not render paper greasy.

---

[1] Benzene may also be nitrated by using sodium nitrate instead of nitric acid. For example: 85 kilos. of benzene and 115 kilos. of sodium nitrate are mixed at 60°–80°, and 150 kilos. of 90–96 p.c. sulphuric acid added slowly. The temperature rises to about 100°, when 65 kilos. of benzene are added, and when the nitration is complete the lower layer of bisulphate is drawn off. The yield is stated to be 150–154 kilos. of washed nitrobenzene, sp.gr. 1[illegible]8 at 15°, or 148 kilos. of the pure substance boiling at 96° under a pressure of 18 mm. (Saccharin-fabrik. Akt.-Ges. vorm. Fahlberg, List & Co. D. R. P. 221787; F. P. 401679).

Dinitrotoluene is prepared by a process similar to the above, and, since ortho- and para-nitrotoluene yield, when nitrated at a high temperature, most of the 2 : 4-dinitrotoluene, it is better to proceed straight on from the toluene.[1]

The subsequent treatment is the same as when dinitrobenzene is manufactured. Commercial dinitrotoluene consists mainly of the last-named and the 2 : 6- modifications, but always contains small quantities of the other isomerides. The 2 : 6- only occurs in small proportion, and mainly in the oily drainings from the crude product. The nitration of the pure metaxylene does not differ from the processes already described.

To obtain the more highly nitrated derivatives nitrosyl sulphate may be employed. *m-Dinitrobenzene* (1 part) is slowly heated with nitrosyl sulphate (2 parts) until dissolved, when nitric acid (2 parts) is added and the mixture maintained at 100°–120° until *s-trinitrobenzene* is produced (Heinemann, Eng. Pat. 102216 of 1915).

Trinitrotoluene. There are six possible isomerides of this compound, viz. :—

		m.p.
α or 2.4.6	trinitrotoluene . .	80·8°
β or 2.3.4	„ . .	112°
γ or 2.4.5	„ . .	104°
δ or 3.4.5	„ . .	137·5°
ε or 2.3.5	„ . .	97·2°
ζ or 2.3.6	„ . .	79·5°

All of them are of practically equal value as explosives, but the best-known is the α-compound, the product known as T.N.T., or trotyl or trilite. The other isomerides in the commercial product are derived from *m*-nitrotoluene, which is present in the ordinary mononitrotoluene to the extent of 4–5 p.c. The various trinitrotoluenes give different colourations with acetone and ammonia, viz. α, deep red; β, greenish-yellow; γ, blue; ζ, orange-red; and ε, rose-red.

In the manufacture of α-trinitrotoluene (T.N.T.), mononitrotoluene is first prepared by using the waste acid resulting from the manufacturing process. The nitration is carried out in a jacketed apparatus provided with rotating arms. The toluene is run into the apparatus, and whilst it is kept agitated, the waste acid and fresh nitric acid are added. The temperature is kept below 30°. After setting for six hours the mononitrotoluene is separated from the waste acid. To the latter fuming sulphuric acid and nitric acid are added. This fresh mixture is added to the mononitrotoluene in the agitating vessel, and kept in continuous motion for six hours at a temperature of 90°. The steam is then shut off in the jacket, agitation is discontinued, and cold water and finally a refrigerated liquid at 2° are passed round the jacket. The dinitrotoluene is thus crystallised out in the mixing vessel, and the waste acid can be run off. The latter is revivified by the addition of fuming sulphuric acid, and this fresh mixture is added to the dinitrotoluene. After warming and agitating nitric acid is added and the temperature raised very gradually to 92°. After heating for twenty hours the whole of the contents of the vessel is run into cooling tanks, where the trinitrotoluene is allowed to crystallise out slowly, during some four to five days. The waste acid is then separated and used for the preparation of mononitroluene. The trinitrotoluene is washed with water, ground under edge runners, and finally washed in an alkali solution. It is then dissolved in acetone, and sodium carbonate is added. The solution is heated in a steam-jacketed vessel for four hours, after which the acetone is distilled off and condensed, and the molten trinitrotoluene is run into cooling vessels to crystallise out. The crystals are thoroughly washed with water, dissolved in hot 96 p.c. alcohol, the solution filtered and allowed to crystallise (Vasquez, Z. ges. Schiess- u. Sprengstoffw. 1911, 6, 301; J. Soc. Chem. Ind. 1911, 30, 1046).

Langenscheidt (Z. ges. Schiess- u. Sprengstoffw. 1912, 7, 425) describes the process as follows:

A mixed acid (1400 kilos), consisting of equal quantities of sulphuric acid and nitric acid (94–95 p.c.), is allowed to flow slowly into a cast-iron vessel containing a solution of orthonitrotoluene (500 kilos) in sulphuric acid (1400 kilos of 100 p.c. acid) which has been warmed to 60°–70°. This vessel is steam-jacketed, and has also water-cooling coils, and a screw agitator, which runs at about 182 revolutions per minute. At the commencement the temperature of the mixture is prevented from rising by means of the water coils until the whole of the orthonitrotoluene is converted into dinitrotoluene. Steam is now passed through the jacket to start the conversion of the dinitrotoluene into trinitrotoluene, and the temperature is not allowed to rise above 150°. When nitration is complete, the temperature is maintained at this point for one hour. It is then allowed to fall to 100°, and 200 litres of water are added in order to increase the yield. The molten trinitrotoluene is separated from the acid and washed until neutral. This product has a m.p. of 72°–74°, and is used in the ammonium nitrate class of explosives. To produce the trinitrotoluene of higher m.p. (81°–82°), which is used for filling shells, the lower melting product (500 kilos) is dissolved in 2300 litres of a mixture of 90 p.c. alcohol containing 5–10 p.c. of benzene, and, after filtering, the solution is crystallised in a water-jacketed enamelled pan. By evaporating the mother liquor to one-third of its bulk, a quantity of brownish-coloured crystals are obtained, which are used in the ammonium nitrate class of explosives, whilst, on further evaporation, a dark-brown or red liquid (16·6–17·2 p.c. N) is obtained, which is used in the explosive industry for gelatinising collodion cotton under the name of liquid trinitrotoluene (J. Soc. Chem. Ind. 1912, 31, 1147).

---

[1] For a detailed description of the manufacture, see Kayser, Zeitsch. Farb. Ind. 1903, 2, 16, 31. *Cf.* Kidokoro, J. Chem. Ind. Tokyo, 1917, 20, 460; J. Soc. Chem. Ind. 1917, 36 1065.

The chief difficulties in the nitration process are due to the presence of inorganic impurities, chiefly lead and iron salts, derived from the sulphuric acid and from the action of the nitrating acid on the apparatus, and organic by-products formed by sulphonation, oxidation, and reduction. Among the by-products may be: (1) Trinitrobenzoic acid or tetranitromethane, owing to oxidation in case of overheating or pressure; the last-named may be recognised by its intense odour; metallic salts may act as catalysts in promoting oxidation. (2) Phenolic compounds, such as cresols, formed by the reduction of the nitro- compounds by hydrogen produced by the action of the nitrating acid on the apparatus, the amino- compounds being then converted into diazo- and hydroxy-compounds; in presence of metallic salts, highly explosive salts of nitro-cresols may be formed. (3) Sulphonic acids owing to too low a concentration of nitric acid. To obtain good results the following conditions should be observed: (1) The amount of nitric acid used should exceed the theoretical quantity by at least ½ mol. (2) The degree of nitration should be controlled by the concentration of nitrating acid, temperature, and duration of reaction rather than by the actual quantity of nitric acid used. (3) The reaction product should be separated from the spent acid as quickly as possible. (4) The action of the nitrating acid on the apparatus should be reduced to a minimum by suitable choice of material and concentration of acid (Copisarow).

BENZENEAZOSALICYLIC ACID is obtained by diazotising a cooled mixture of aniline and hydrochloric acid with sodium nitrite, and adding the diazonium chloride to an aqueous solution of sodium salicylate when the yellow sodium salt of the azo- compound is formed (Fischer and Schaar-Rosenberg, Ber. 1899, 32, 81).

BENZENE DIAZONIUM SALTS *v.* DIAZO COMPOUNDS.

BENZENE SULPHONIC ACIDS.

Benzene sulphonic acid (*phenyl sulphurous acid, sulphobenzolic acid*) $C_6H_5{\cdot}SO_3H$ may be prepared by shaking benzene with fuming sulphuric acid, or by passing benzene vapour into heated sulphuric acid; by oxidising benzene sulphinic acid; by boiling *p*-diazobenzene sulphonic acid with alcohol.

On the large scale it is made as an intermediate product for the manufacture of phenol by sulphonating benzene in a closed cast-iron steam-jacketed pan fitted with a helical stirrer. For details of the various methods of carrying out this operation, *see* Cain's Intermediate Products for Dyes, Macmillan and Co., 1918. The free acid is best obtained by decomposing the lead or barium salt with sulphuric acid. Forms small deliquescent plates containing 1½ mols. H_2O.

Benzene-m-disulphonic acid $C_6H_4(SO_3H)_2$. Obtained by the further action of sulphuric acid upon benzene, or on the preceding compound, at a temperature of 240°–250°. At higher temperatures, or under the influence of catalysts (mercury, ferrous sulphate), the *p*-isomeride is formed in addition. Lamberts (D. R. P. 113784) employs as sulphonating agent *sodium hydrogen disulphate* $NaH_3(SO_4)_2$ (obtained by heating acid sodium sulphate with sulphuric acid). This is mixed with benzene and heated to 200°, treated with milk of lime, and the solution of the sodium benzene-*m*-disulphonate filtered off and evaporated. The free acid forms very deliquescent crystals containing 2½ mols. H_2O.

Benzene-tri-sulphonic acid $C_6H_3(SO_3H)_3$, prepared by heating an alkaline salt of the mono- or *m*-disulphonic acid with sulphuric acid until the sulphuric acid volatilises.

BENZOIC ACID $C_7H_6O_2$ or $C_6H_5{\cdot}CO_2H$. (*Acide benzoïque*, Fr.; *Benzoësäure*, Ger.) *Acidum benzoicum.* Blaise de Vigenère, in his Traité du feu et du sel, published in 1608, described the preparation of benzoic acid by sublimation from gum benzoïn. Lemery, in 1675, called attention to its acid properties; and Scheele showed, in 1775, that it could be extracted from gum benzoïn by boiling the gum with lime, concentrating the solution, and decomposing the salt with hydrochloric acid. Scheele also, in 1785, obtained benzoic acid from cow's urine; but it was not until 1829 that Liebig showed that the substance contained in the urine, by the decomposition of which benzoic acid is formed, is hippuric acid.

Occurrence.—Benzoic acid occurs in gum benzoïn, tolu balsam, storax, dragon's blood, and various other natural resins; in oil of bergamot and oil of cinnamon; in vanilla, calamus root, and the ripe fruit of the clove tree; in various sweet-smelling flowers—thus in the flowers of *Unona odoratissima*, from which the perfume *ylang-ylang* is prepared; as hippuric acid (and sometimes even, it is asserted, as free benzoic acid) in the urine of herbivora; and in *castoreum*, a viscid, fœtid secretion, found in pouches situated in the perinæum of the beaver.

Formation.—By the oxidation of all compounds which contain the phenyl group united to a single lateral chain, such as toluene, benzyl chloride, benzyl alcohol, benzaldehyde, cinnamic acid, &c. By heating benzotrichloride $C_6H_5{\cdot}CCl_3$ with water. By heating benzonitrile $C_6H_5{\cdot}CN$ with acids or alkalis. By boiling hippuric acid with hydrochloric acid

$$(C_7H_5O)NH{\cdot}CH_2{\cdot}CO_2H+H_2O$$
$$=C_7H_6O_2+NH_2{\cdot}CH_2{\cdot}CO_2H.$$

By passing carbon dioxide into benzene containing aluminium chloride

$$C_6H_6+CO_2=C_6H_5{\cdot}CO_2H.$$

Preparation.—1. *From gum benzoïn.* In order to obtain the acid from gum benzoïn by sublimation, the gum, broken up into small pieces, is introduced into a flat iron vessel, over the mouth of which filter paper is then pasted. A large conical cap of strong paper, exactly fitting the iron vessel, is placed over the filter paper, tied round the rim, and the whole is gently heated over a sand-bath at a temperature of about 170°. The benzoic acid sublimes through the filter paper and collects in colourless crystals inside the paper cone, from which it is removed at the end of the operation (Mohr, Annalen, 29, 177). The yield is about 4 p.c. of the gum employed, and from three to four hours are required for the sublimation of a pound of benzoic acid. A trace of an aromatic oil from the gum adheres to the crystals, imparting to them a pleasant odour of vanilla, and enhancing their value as a pharmaceutical preparation. On a manufacturing scale a modification of the foregoing laboratory process is employed, in which the gum is heated in a closed vessel and the vapour of the subliming acid flows over into a side chamber and condenses at a point below the source of heat, thus obviating all risk of fusing the sublimate. The gum benzoïn is introduced by means of a metal drawer, which is heated from beneath by gas-jets; whilst the sublimed acid collects in a second drawer, and can thus be removed at the end of the operation (comp. Starting, Arch. Pharm. 231, 342). By other methods the yield from gum benzoïn may be increased to 25 p.c.

Wöhler's method (Annalen, 49, 245) consists in dissolving the powdered gum in an equal volume of alcohol of 90–95 p.c., adding fuming hydrochloric acid to the hot solution until a precipitate begins to be formed, and distilling the mixture. The distillate contains ethyl benzoate, alcohol, and hydrochloric acid. The residue is again distilled with water as long as ethyl benzoate passes over, and the united distillates are boiled with caustic potash to decompose the ethyl benzoate. From the solution the benzoic acid is precipitated with hydrochloric acid. It smells like the sublimed product.

Scheele's method of extracting the benzoic acid from the gum with slaked lime and water (*v. supra*), may also be employed.

2. *From urine.* The urine of the cow or horse is allowed to putrefy, so as to induce a hydrolytic decomposition of the hippuric acid into benzoic acid and glycocoll. Milk of lime is then added, the filtered solution is evaporated to a small bulk, and the benzoic acid precipitated with hydrochloric acid. In order to avoid the evaporation and the attendant disagreeable smell, the excess of lime may be removed by carbon dioxide, the benzoic acid precipitated by the addition of ferric chloride, and the ferric benzoate, after separating it by filtration, decomposed by hydrochloric acid. The acid thus prepared smells of urine, and must not be used in medicine. The smell may, however, be removed or concealed by mixing the acid with a small quantity of gum benzoïn and subliming it.

The fresh urine may also be evaporated to one-third of its bulk, filtered, mixed with hydrochloric acid, and allowed to cool. Hippuric acid crystallises out, which, by boiling with concentrated hydrochloric acid, is decomposed into glycocoll hydrochloride and benzoic acid. Benzoic acid may also be prepared by the action of ammonia and zinc-dust on gallic acid and catechu-tannic acid (Guignet, Compt. rend. 113, 200).

3. *From toluene.* Most of the benzoic acid employed at the present day, and certainly all that is employed in the coal-tar colour industry, is manufactured from toluene (*v. infra*). Toluene by oxidation with nitric acid, may be directly converted into benzoic acid; but it is better to chlorinate it first to benzyl chloride, which is more readily attacked by the oxidising agent. Lunge and Petri (Ber. 10, 1275) boil benzyl chloride (1 part) and dilute nitric acid (3 parts of acid of 35° Baumé with 2 parts of water) in a reflux apparatus until the smell of benzyl chloride and benzaldehyde is no longer perceptible. A. v. Rad (Dingl. poly. J. 231, 538), however, states that this method is unsuited for preparing the acid on a manufacturing scale, and prefers to decompose benzotrichloride by heating it with water under pressure:

$$C_6H_5{\cdot}CCl_3+2H_2O=C_6H_5{\cdot}CO_2H+3HCl;$$

but it is difficult to prepare pure benzotrichloride, and the benzoic acid manufactured by this process is always contaminated with chlorobenzoic acids formed from chlorinated benzotrichlorides.

Espenschied (D. R. P. 47187) boils the benzotrichloride with milk of lime, or with a solution of caustic soda mixed with whiting or other insoluble matter, the presence of which aids the reaction by preventing the benzotrichloride from forming a separate layer and also by promoting local superheating.

E. Jacobsen (D. R. P. 11494 and 13127) heats benzotrichloride with acetic acid to which a little zinc chloride has been added:

$$C_6H_5{\cdot}CCl_3+2CH_3{\cdot}CO_2H=C_6H_5{\cdot}CO_2H+2CH_3{\cdot}COCl+HCl$$

The acetyl chloride is distilled off, the residue extracted with sodium carbonate, and the benzoic acid precipitated with hydrochloric acid.

P. Schulze (D. R. PP. 82927, 85493) heats benzotrichloride with lime-water in the presence of some iron powder. In order to avoid the formation of chloro-derivatives, the direct oxidation of toluene either by nitric acid or by manganese dioxide and sulphuric acid, has been suggested (*see* D. R. PP. 101222, 107722, 175295, 216091).

The Weston Chem. Co. and J. Savage (Eng. Pat. 116348) convert benzyl chloride into benzyl alcohol by boiling with sodium hydroxide solution or milk of lime, and oxidising the alcohol to alkali benzoate by hypochlorite in presence of alkali.

The benzoic acid required in the coal-tar colour industry is obtained as a by-product in the manufacture of benzaldehyde by heating benzal chloride with milk of lime (*v.* BENZALDEHYDE), a portion of the benzaldehyde being converted into calcium benzoate in this process.

4. *From coal-tar oil.* Aktiengesellschaft fur Theer und Erdöl Industrie, Eng. Pat. 7867; D. R. P. 109122; J. Soc. Chem. Ind. 1899, 785. The carbolic or creosote oil fraction, obtained from coal tar, and boiling between 160° and 240°, contains benzonitrile. The fraction from which phenol is obtained is washed with dilute soda lye (sp.gr. 1·1) to remove the phenol and cresol, and the remaining oil placed in a jacketed vessel, provided with an agitator and connected with a condenser and receiver. Caustic soda lye (sp.gr. 1·4) is added in about twice the quantity corresponding to the benzonitrile present. The mixture is agitated, and wet steam passed in for some hours, as long as ammonia is evolved in considerable quantity. The receiver then contains the lower boiling constituents of the oil, together with a somewhat concentrated ammonia solution, whilst the contents of the still consist of a lower alkaline layer and an upper oily one. The former is neutralised with carbonic acid or a mineral acid, separated from traces of phenol or resinous matters, and the resulting solution of sodium benzoate decomposed whilst hot by adding an excess of acid. On cooling, pure benzoic acid separates in white crystals.

5. *From the naphthols and other naphthalene derivatives.* Basle Chemical Works, J. Soc. Chem. Ind. 1901, 1139; D. R. P. 136410; Fr. Pat. 313187; Eng. Pat. 15527; U.S. Pat. 702171. (*See also* Chem. Zentr. 1903, i. 546, 857, 1106; D. R. PP. 138790, 139956, 140999.) By heating the naphthols or other naphthalene derivatives to about 250°, in presence of alkali with metallic oxides or peroxides such as copper or iron oxide, barium, lead or manganese peroxide, they yield phthalic and benzoic acids, and a few intermediate products. The excess of alkali is removed by lixiviation with a little water; the acids are then dissolved in water and decanted from the reduced oxide. This solution is saturated with carbon dioxide and filtered from unchanged naphthol. The filtrate is decomposed with sulphuric acid and evaporated, the precipitated acids being purified by distillation.

6. *By the electrolytic oxidation of phenanthrene.* Farbwerke vorm. Meister, Lucius and Brüning, Chem. Zentr. 1904, ii. 71; D. R. P. 152063.

Properties.—It crystallises in lustrous leaflets or flat needles of sp.gr. 1·2659 15°/4°, melting at 121·4°. It boils at 249°, but is volatile even at 100°, so that it may readily be sublimed; the vapour excites coughing. It may be distilled with steam; 2 litres of aqueous distillate contain 1 gram of benzoic acid. 100 parts of water dissolve at

4·5°	10°	81°	75°
1·823	2·068	4·247	21·931

(Ullmann, Enzyklop. ii.); it is soluble in about twice its weight of ether and in about its own weight of absolute alcohol at ordinary temperatures.

Traces of impurity lower the melting-point of benzoic acid very considerably. The impure acid is also deposited from its solutions in smaller crystals than the pure.

(For *absorption spectra, see* Hartley and Headley, Chem. Soc. Trans. 1907, 319.)

Reactions.—When heated with *lime*, benzoic acid yields benzene and calcium carbonate (Mitscherlich). It is very stable towards oxidising agents; dilute *chromic acid* is without action on it, but by warming it with *manganese dioxide and sulphuric acid* it is converted into formic acid, carbon dioxide, and phthalic acid—the latter being formed by the simultaneous oxidation of formic and benzoic acids (Carius, Annalen, 148, 72). *Sodium amalgam* reduces benzoic acid in boiling alcoholic solution to benzyl alcohol, benzaldehyde, and tetrahydrobenzoic acid (Aschan, Ber. 24, 1864, and Annalen, 271, 231). By electrolytic reduction, benzaldehyde is obtained (Mettler, Ber. 41, 4148), and by reduction with hydrogen and platinum, hexahydrobenzoic acid is the chief product (Willstätter and Mayer, Ber. 41, 1479). When distilled over heated *zinc-dust* it yields benzaldehyde (Baeyer, Annalen, 140, 296). Calcium benzoate yields on distillation benzophenone $C_6H_5{\cdot}CO{\cdot}C_6H_5$, together with a small quantity of benzene and anthraquinone $C_{14}H_8O_2$ (Kekulé and Franchimont, Ber. 5, 908). Taken internally, benzoic acid is excreted in the urine as hippuric acid (Wöhler).

When a solution of ferric chloride which has been mixed with sufficient ammonia to turn it dark-red is added to a solution of a benzoate, a flesh-coloured precipitate of basic ferric benzoate $(C_7H_5O_2)_3Fe,Fe(OH)_3$ is formed. This reaction is used in the separation of benzoic acid, and also in separating iron from manganese.

Uses.—Benzoic acid is used in medicine; but for this purpose only the natural product, obtained from gum benzoin by sublimation, is suitable. Adulteration with the artificial acid is detected by heating a portion of the acid on platinum wire and holding a porcelain dish moistened with phloroglucolvanillin over the flame; the production of a red colour, due to the presence of hydrochloric acid, indicates the presence of the artificial acid. Artificial benzoic acid is employed in the manufacture of aniline blue. It has been used as a mordant in calico-printing. Benzoic acid, dissolved in a mixture of 1 part of ether and 20 parts of alcohol, has been recommended for the preservation of anatomical preparations. It is said to be used in giving an aroma to tobacco.

As an antiseptic it is injurious to health, producing serious disturbance of the metabolic functions, attended with injury to the digestion (Wiley, U.S. Dept. of Agric., J. Soc. Chem. Ind. 1908, 914).

For its use as an acidimetric standard, *see* Morey, J. Amer. Chem. Soc. 1912, 34, 1027; Analyst, 1912, 458.

Detection in foodstuffs.—By the production of diaminobenzoic acid (Mohler, Bull. Soc. chim. 3, 414); by the action of the acid on rosaniline hydrochloride dissolved in aniline oil, when aniline blue is formed (De Brevans, J. Pharm. Chim. 14, 438); by converting the acid into salicylic acid with hydrogen peroxide, and then adding ferric chloride (Jonescu, J. Pharm. Chim. 29, 523). *In butter*: By the formation of ammonium diaminobenzoate, which gives a brownish-red colouration in alkaline solution (Halphen, Pharm. J. 28, 201; Robin, Ann. Chim. anal. 14, 53). *In fermented beverages and milk*: As in butter (Robin, Ann. Chim. anal. 14, 53; Breustedt, Arch. Pharm. 237, 170). *In meats and fats* (Fischer and Gruenert, J. Soc. Chem. Ind. 28, 849).

Examination of the commercial product.—The artificial benzoic acid of commerce is almost always contaminated with chlorobenzoic acids (*v. supra*), the presence of which in any considerable quantity is stated to be detrimental in the aniline blue manufacture. The chlorine may be detected by heating the acid with metallic sodium, extracting the residue with water and testing the solution with silver nitrate. The acid should have the proper melting-point, and should dissolve without residue in boiling water.

Salts and esters of benzoic acids. Benzoic acid is monobasic. Most of the benzoates are soluble both in water and in alcohol. *Potassium benzoate* $C_7H_5O_2K,3H_2O$: efflorescent laminæ. *Sodium benzoate* $C_7H_5O_2Na,H_2O$: efflorescent needles, used for inhalation in tuberculosis. *Ammonium benzoate* $C_7H_5O_2(NH_4)$, rhombic crystals, also used in medicine. *Calcium benzoate* $(C_7H_5O_2)_2Ca,3H_2O$, lustrous needles, used in the preparation of benzophenone. Other hydrates are known. Forms an unstable dialcoholate. *Basic ferric benzoate*

$$(C_7H_5O_2)_2Fe,Fe(OH)_2$$

(*v. supra*). *Mercuric benzoate* small white odourless tasteless crystals; powerful antiseptic; successfully employed in syphilitic and similar diseases (Merck's Bull. 1890, [5] 33; [6] 49; [7] 73).

The esters of benzoic acid are obtained either by distilling benzoic acid with the alcohol and sulphuric acid, or, better, by saturating a solution of benzoic acid in the alcohol with hydrogen chloride, digesting the mixture on the water-bath for some hours, precipitating the ester with water, and purifying by distillation. *Methyl benzoate* $C_7H_5O_2{\cdot}CH_3$ is a liquid boiling at 198·6° (Perkin, Chem. Soc. Trans. 69, 1025). *Ethyl benzoate* $C_7H_5O_2{\cdot}C_2H_5$, boils at 211·8° (Perkin, *l.c.*). *Propyl benzoate* $C_7H_5O_2{\cdot}C_3H_7$, boils at 230·7° (Perkin, *l.c.*).

Benzyl benzoate. This ester forms the therapeutically active portion of Peru balsam, and also the larger fraction of the product formerly known by the name of *cinnamein*, and generally described as consisting chiefly or entirely of benzyl cinnamate. Benzyl benzoate is a colourless oil, boiling at 173° under 9 mm. pressure, whilst the benzyl cinnamate is crystalline, melting at 37°, and boiling at 213°–214° under 9 mm. pressure. It is stated that benzyl benzoate is as efficacious, therapeutically, as the ester obtained direct from Peru balsam, whilst it has the advantages that it is free from colour and smell, is constant in composition, and does not cause the irritation sometimes occasioned by Peru balsam owing to the free acids present (E. Erdmann, Pharm J. 65, 387).

Substitution Derivatives of Benzoic Acid.—*o-Chlorobenzoic acid* $Cl{\cdot}C_6H_4{\cdot}COOH$ melts at 140°, and is obtained by the oxidation of *o*-chlorotoluene. The chlorine atom in this acid is very easily replaceable (Ullmann, Annalen, 1907, 355, 312). The *m*-acid melts at 150°, the *p*- acid at 243°. Nitration of benzoic acid yields mainly the *m*-acid, the relative proportions of the *o*-, *m*-, and *p*-acids formed at different temperatures being shown in the subjoined table (Holleman, Zeitsch. physikal. Chem. 31, 79):

	o.	*m.*	*p.*
−30° . .	14·4	85·0	0·6
0° . .	18·5	80·2	1·3
+30° . .	22·3	76·5	1·2

The *o*-acid, melting at 144°, is prepared by oxidising *o*-nitrotoluene with potassium permanganate, or with manganese dioxide and sulphuric acid (D. R. P. 179589). The *m*-acid, by the action of sodium nitrate and sulphuric acid on benzoic acid, or by oxidising *m*-nitrobenzaldehyde with sodium hypochloride (Badische, Anilin u. Soda Fabrik, D. R. P. 211959). It melts at 140°–141°. The *p*-acid, melting at 238°, is obtained by the oxidation of *p*-nitrotoluene with chromic and sulphuric acids.

Sulphobenzoic acids. The *o*-acid

$$HOOC{\cdot}C_6H_4{\cdot}SO_3H,3H_2O$$

is obtained by the oxidation of toluene-*o*-sulphonic acid, or of thiosalicylic acid, or by diazotising anthranilic acid and adding sulphurous acid. It melts at 68°–69°, and in the anhydrous condition at 134°. Direct sulphonation of benzoic acid yields chiefly the *m*-acid.

BENZOIC ANHYDRIDE $(C_6H_5{\cdot}CO)_2O$. First prepared by Gerhardt (Ann. Chim. Phys. [3] 37, 299) by the action of benzoyl chloride on sodium benzoate or on sodium oxalate, or of phosphorus oxychloride on sodium benzoate:

$$C_6H_5{\cdot}CO_2Na+C_6H_5{\cdot}COCl=(C_6H_5{\cdot}CO)_2O+NaCl;$$

$$2C_6H_5{\cdot}COCl+Na_2C_2O_4 =(C_6H_5{\cdot}CO)_2O+2NaCl+CO+CO_2;$$

$$4C_6H_5{\cdot}CO_2Na+POCl_3 =2(C_6H_5{\cdot}CO)_2O+NaPO_3+3NaCl$$

Preparation.—Pour 100 grams of phosphorus oxychloride over 500 grams of dry sodium benzoate contained in a flask; complete the reaction by heating at 150°; remove sodium salts by washing the cooled mass with dilute sodium carbonate, and purify the anhydride by distillation.

Anschütz (Annalen, 226, 15) heats benzoyl chloride with anhydrous oxalic acid. This avoids the formation of metallic salts altogether.

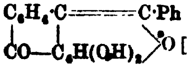
It may also be prepared by heating benzoyl chloride with fused and powdered sodium nitrite for 12 hours; the product is extracted with ether and freed from traces of benzoic acid by rapidly washing with a very dilute solution of sodium carbonate, and finally with distilled water; yield 70 p.c. (Minunni and Caberti, Gazz. chim. ital. 20, 655). By mixing together benzoyl chloride and pyridine and adding water after half an hour, pure benzoic anhydride is precipitated; yield 80 p.c. (Minunni, Gazz. chim. ital. 22, ii. 213). By treating benzoyl chloride with sodium carbonate and pyridine; yield quantitative (Deninger, J. pr. Chem. 50, ii. 479). By treating benzoyl chloride with sodium hyposulphite in the presence or absence of pyridine (Binz and Marx, Ber. 40, 3855); by treating benzenesulphonic chloride with sodium benzoate (Chem. Fab. von Heyden, D. R. P. 123052; Chem. Zentr. 1902, 2, 518); by treating benzoic acid or sodium benzoate with methylchlorsulphate (Bad. Anil. und Sod. Fabrik, D. R. P. 146690; Chem. Zentr. 1904, i. 65); by treating benzoic acid with acetic anhydride in the presence of an indifferent solvent such as benzene or xylene (Kaufmann and Luterbacher, Ber. 42, 3483); from benzotrichloride and acetic acid (Béhal, Compt. rend. 148, 648); by the action of concentrated sulphuric acid on benzotrichloride; and by the action of sulphuryl chloride on a mixture of sodium and calcium benzoates (D. R. P. 161882).

Properties.—Rhombic prisms, sp.gr. 1·1989 15°/4°, melting at 42°, and boiling at 360° (corr.) (Lumsden, Chem. Soc. Trans. 1905, 93). Insoluble in water; readily soluble in alcohol and ether.

Reactions.—Water decomposes it very slowly in the cold, more rapidly on boiling, with formation of benzoic acid. Towards ammonia, amino- and imino- compounds, alcohols and phenols, it behaves like benzoyl chloride, replacing by a benzoyl- group a hydrogen atom attached to nitrogen or oxygen. For this reason it is, like benzoyl chloride (*q.v.*), used as a reagent for amino-, imino, and hydroxyl- groups, and it has the advantage over the latter reagent that no hydrochloric acid, a substance which has a very prejudicial effect on many organic compounds, is liberated during its action.

BENZOÏN GUM *v.* BALSAMS.

BENZOÏN YELLOW. This compound is obtained by condensing benzoin with gallic acid. Benzoïn is added to a solution of gallic acid in sulphuric acid, kept at a temperature of 0°–5°, and, after being stirred during 24 hours, the mixture is poured into water, the dye being precipitated. It crystallises from a mixture of acetic acid and alcohol in yellow needles. Its constitution is given as



$$\begin{array}{l} C_6H_4{\cdot}C \!=\!=\!=\!=\! C{\cdot}Ph \\ \quad | \qquad | \\ CO\!-\!C_6H(OH)_2\!>\!O \end{array}$$

[O : (OH)$_2$: CO = 1 : 2 : 3 : 4] (Bad. Anil. Sod. Fab. D. R. P. 95739; Chem. Zentr. 1898, i. 870, and Graebe, Ber. 31, 2975) (*v.* ALIZARIN AND ALLIED COLOURING MATTERS).

BENZONAPHTHOL, β-NAPHTHOL BENZOATE *v.* SYNTHETIC DRUGS.

BENZOPHENONE (*Diphenyl Ketone*) (*v.* KETONES).

BENZO-QUINONE. *See* QUINONE.

BENZOSALIN. Trade name for benzoyl-salicylic-acid-methyl ester, used in the treatment of articular and muscular rheumatism, neuritis, neuralgia, and sciatica. *V.* SYNTHETIC DRUGS.

BENZOSOL GUIACOL BENZOATE *v.* SYNTHETIC DRUGS.

BENZOTRICHLORIDE *v.* TOLUENE, CHLORINE DERIVATIVES OF.

BENZOYL CHLORIDE $C_6H_5{\cdot}COCl$. First obtained by Liebig and Wöhler, by passing chlorine into benzaldehyde (Annalen, 3, 262). By the action of phosphorus pentachloride on benzoic acid (Cahours, Ann. Chim. Phys. [3] 23, 334).

Preparation.—Benzoic acid is heated with slightly more than the molecular proportion of phosphorus pentachloride

$$C_6H_5{\cdot}COOH + PCl_5 = C_6H_5{\cdot}COCl + POCl_3 + HCl$$

The resulting benzoyl chloride is freed from the phosphorus oxychloride by fractional distillation. Commercial benzoyl chloride is usually contaminated with chlorbenzoylchloride and frequently with small quantities of benzaldehyde (V. Meyer, Ber. 24, 4251, and 25, 209).

From oxalyl chloride, benzene, and aluminium chloride (Staudinger, Ber. 1908, 3566). From benzoic acid or sodium benzoate and methylchlorosulphate (Bad. Anil. und Sod. Fabrik, D. R. P. 146690; Chem. Zentr. 1904, i. 65).

From salts of benzoic acid. By treatment with sulphur dioxide and chlorine (Farb. vorm. Meister, Lucius and Bruning, D. R. P. 210805; Chem. Zentr. 1909, 279); or with sodium chlorosulphonate (D. R. P. 146690); or by the action of sulphuryl chloride on benzoic acid.

Properties.—Colourless liquid, with a pungent odour, boiling at 199° (Lumsden, Chem. Soc. Trans. 1905, 94); 197·2° (corr.) (Perkin, Chem. Soc. Trans. 69, 1244). Its vapour attacks the eyes, causing a flow of tears. Sp.gr. 1·2122 20°/4° (Bruhl, Annalen, 235, 11).

Reactions.—Benzoyl chloride reacts with *water*, slowly in the cold, rapidly on heating, with formation of benzoic and hydrochloric acids. With *ammonia* it forms benzamide

$$C_6H_5{\cdot}CO{\cdot}NH_2$$

together with ammonium chloride. In like manner it reacts with compounds containing hydroxyl-, amino-, or imino- groups, introducing benzoyl in place of hydrogen, and is therefore employed in organic chemistry as a test for the presence of those groups in a compound. Thus with *alcohol* it yields ethyl benzoate; with *aniline*, benzanilide and dibenzanilide.

BENZOYL ECGONINE *v.* COCAINE AND THE COCA ALALOIDS.

BENZOYL FORMIC ACID *v.* KETONES.

BENZOYL GLYCOCOLL *v.* HIPPURIC ACID.

BENZOYL PINK *v.* AZO- COLOURING MATTERS.

BENZOYL SULPHONIC IMIDE and **BENZOIC SULPHIDE** *v.* SACCHARIN.

BENZYLAMINE CARBOXYLIC ACIDS *v.* AMINO-ACIDS (aromatic).

BENZYL BLUE. A dye made by the Aktiengesellschaft für Anilinfabrikation, Berlin, by substituting three atoms of hydrogen in rosaniline by three benzyl-groups. It is easily soluble in water; dyes silks, wools, and cotton (Reimann's Färber-Zeit. 1879, 251; Industrie-Blätter, 39, 360).

BENZYL CHLORIDE *v.* TOLUENE, CHLORINE DERIVATIVES OF.

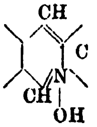
BENZYLDIPHENYLAMINE *v.* DIPHENYLAMINE.

BENZYLMORPHINE *v.* OPIUM.

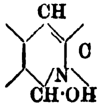
BENZYLPHENYLHYDRAZONES *v.* HYDRAZONES.

BERBERINE AND THE BERBERIS ALKALOIDS. Berberine $C_{20}H_{19}O_5N$ is contained in various species of *Berberis*, especially *B. vulgaris* (Linn.) (the barberry), which also contains berbamine $C_{18}H_{19}O_3N$ (Hesse, Ber. 1886, 19, 3193), and oxyacanthine (*v. infra*), in *Hydrastis canadensis* (Linn.), together with hydrastine and canadine in *Coptis Teeta* (Wall.), which contains as much as 8 p.c., and in many other plants, but not in calumba root (Gordin, Arch. Pharm. 1902, 240, 146).

Preparation.—The best available material from which to extract berberine is the root of *Hydrastis canadensis* (Linn.) ('Golden Seal'), which contains about 4 p.c. of the alkaloid. The finely-powdered hydrastis root is exhausted with alcohol, the greater part of the alcohol removed by distillation, and the alkaloid converted into sulphate or nitrate by the addition of sufficient dilute sulphuric acid or nitric acid. The crude berberine salt which separates is collected, dissolved in water, and mixed with acetone and sodium hydroxide, when the crystalline condensation product, anhydroberberineacetone, separates (Gaze, Zeit. Naturwiss. Halle, 1890, 62, 399). After recrystallisation, this product melts at 175° (corr.) (Pyman, Chem. Soc. Trans. 1911, 99, 1690); it yields with hot dilute mineral acids the corresponding berberinium salts. The free base exists in two isomeric forms, represented by the partial formulæ below:



I.



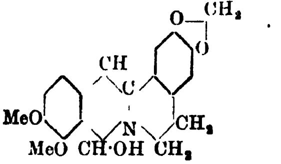
II.

as the quaternary ammonium hydroxide, berberinium hydroxide (I.), which is known only in aqueous solution, and as the carbinolamine, berberine (II.), also termed berberinal and berberinol. For the nomenclature of berberine and its salts, see Perkin (Chem. Soc. Trans. 1918, 113, 503). A solution of berberinium hydroxide is prepared by adding the equivalent quantity of barium hydroxide to an aqueous solution of berberinium sulphate, whilst the addition of an excess of sodium hydroxide to this solution affords a precipitate of the carbinolamine, berberine, which is extracted by ether, and crystallises on concentrating the solution (Gadamer, Arch. Pharm. 1905, 243, 31).

Properties.—Berberine $C_{20}H_{19}O_5N$ crystallises from ether in yellow needles, which melt at 144°, and are anhydrous. It is insoluble in cold water, but on warming gradually yields a solution of berberinium hydroxide. It dissolves in acids, giving salts of berberinium hydroxide. The berberinium salts $C_{20}H_{18}O_4NX$ (where X is a monobasic acid radical) crystallise well, and are of a yellow or red colour. They are sparingly soluble in water, especially in the presence of mineral acids or salts. Their aqueous solutions are neutral to litmus, optically inactive, and have a bitter taste. Berberine is not poisonous to man, and is used medicinally, like preparations of the plants containing it, as a tonic.

Detection and Estimation.—Chlorine water gives with a solution of the hydroxide a bright-red colouration even in very dilute solutions. For the detection of berberine in plants, *see* Gordin, Arch. Pharm. 1902, 240, 146. The same author recommends for its estimation the precipitation of the alkaloid as sulphate from its alcoholic solution, the decomposition of the sulphate by potassium iodide and the titration of the sulphuric acid liberated by means of *N*/40 potassium hydroxide (*ibid.* 1901, 239, 638).

Constitution.—The main features of the constitution of berberine were determined by Perkin (Chem. Soc. Trans. 1889, 55, 63; 1890, 57, 992) by a study of its oxidation products, and subsequent work by Gadamer (Chem. Zeit. 1902, 26, 291, 385; Arch. Pharm. 1905, 243, 31; 1910, 248, 43), Perkin and Robinson (Chem. Soc. Trans. 1910, 97, 321), and Tinkler (*ibid.* 1911, 99, 1340), established the formula given below, which has since been confirmed through the synthesis of the alkaloid by Pictet and Gams (Ber. 1911, 44, 2480).



Attention may be drawn to the similarity between the formula of berberine and that of hydrastine which occurs with it in *Hydrastis canadensis* (Linn.).

Oxycanthine $C_{19}H_{21}O_3N$ accompanies berberine in *Berberis vulgaris* (Linn.) (Polex, Arch. Pharm. 1836, [ii.] 6, 271; Hesse, Ber. 1886, 19, 3190; Rüdel, Arch. Pharm. 1891, 229, 631), and may be isolated from the mother-liquor from which all the berberine salt has crystallised by precipitation with sodium carbonate. It crystallises with difficulty from alcohol or ether, m.p. 208°–214° (Hesse), is insoluble in water, easily soluble in chloroform, less so in alcohol. The alcoholic solution is dextrorotatory, and has a bitter taste. It yields crystalline salts

F. L. P.

BERENGELITE. A bituminous resinous mineral from San Juan de Berengela, melting at 100°, soluble in alcohol and ether. According to Dietrich, specimens from Trinidad and Arica, Chile, contained 71·84 C, 9·95 H, and 18·21 of O (Chem. Zentr. 80, 559). Used for caulking ships.

BERGAMOT *v.* OILS, ESSENTIAL.

BERGMANN'S POWDER. An explosive composed of 50 parts potassium chlorate, 5 of pyrolusite, and 45 of bran, sawdust, or tan (J. 37, 1748).

BERLIN BLACK. A black varnish drying with a dead surface, used for coating ironwork.

BERLIN BLUE or **PRUSSIAN BLUE** *v.* CYANIDES.

BERNTHSEN'S VIOLET. *Isothionine. β-Amidothiodiphenylimide.* Formed by reducing β-dinitrodiphenylaminesulphoxide and oxidising the leuco- base with ferric chloride. The hydrochloride crystallises in needles. Dyes reddish-violet. Isomeric with *Lauth's violet* (Bernthsen, Annalen, 230, 133).

BERRY WAX *v.* WAXES.

BERTHIERINE *v.* THURINGITE.

BERTHIERITE. *Iron sulphantimonite* (*v.* ANTIMONY).

BERYL. A mineral consisting of glucinum aluminium silicate $Gl_3Al_2Si_6O_{18}$, crystallising in the hexagonal system. The ancient name, βήρυλλος, included also some other gem-stones of a greenish colour. The crystals are usually quite simple in form, with only the hexagonal prism and the basal plane; the habit being commonly prismatic and the prism faces striated vertically. They are usually cloudy or opaque, with a pale-greenish or yellowish colour and are often of considerable size, crystals weighing as much as one or two tons having been found at Acworth in New Hampshire. The sp.gr. is 2·63–2·80, and the hardness 7½–8. The material is not attacked by acids, except hydrofluoric; and before the blowpipe is fusible only with difficulty on the edges.

Crystals of a different type are found in association with lithia minerals (lepidolite and rubellite) in pegmatites in the Urals, California, and Madagascar. These are tabular in habit and rose-red or colourless. Further, they differ chemically in containing small amounts of alkalis (Cs_2O 3·1, Li_2O 1·4 p.c.). V. Vernadsky (1908) expresses the composition by the formula $x GlAl_2Si_4O_{12} \cdot yA$, where A is GlH_2SiO_4, $GlSiO_3$(?), Cs_2SiO_3, Li_2SiO_3, or Na_2SiO_3; and for the cæsium-bearing variety he proposes the name *vorobyevite*.

Being by far the most abundant of glucinum minerals, beryl is employed for the preparation of the little-used salts of glucinum. It finds more extensive application in jewellery. The clear grass-green variety is the *emerald*, one of the most valuable of gems on account of the rarity of flawless material. Gem-stones of a greenish, bluish, or sea-green colour are known as *aquamarine*. Pink beryl of gem quality has been called *morganite*, and a golden beryl from South-West Africa is given the name *heliodor*. For a fuller description of material of gem quality and its occurrences, *see* M. Bauer, Precious Stones, transl. by L. J. Spencer, London, 1904. On the gem beryls from Madagascar, *see* A. Lacroix, Minéralogie de la France, 1910, 1913. L. J. S.

BERYLLIUM *v.* GLUCINUM.

BERZELIANITE. Native copper selenide Cu_2Se, occurring in a black powdery form in calcite at Skrikerum in Sweden and at Lehrbach in the Harz. Named after the Swedish chemist J. J. Berzelius (1779–1848), who first analysed it. L. J. S.

BERZELITE. Arsenate of calcium, manganese, and magnesium $(Ca,Mn,Mg)_3As_2O_8$, occurring as small yellow cubic crystals, and as compact masses, with ores of iron and manganese at Långban in Wermland, Sweden. Also named after J. J. Berzelius. Other forms of the same name, berzeline and berzelite, have been applied to these, as well as to some other minerals. L. J. S.

BESSEMER STEEL *v.* IRON.

BETAFITE. The betafite group of minerals, recognised by A. Lacroix in 1912 in the pegmatites of Madagascar, includes betafite, samiresite, and blomstrandite (of G. Lindström, 1874). They are titano-columbates (and tantalates) of uranium, &c., crystallising in the cubic system, and closely allied to pyrochlore and hatchettolite. From the former they differ in containing only little lime and rare-earths and an absence of alkalis and fluorine; and from the latter in containing titanium. Betafite is a hydrated titano-columbate of uranium (UO_3 26–28 p.c.). Sharply developed octahedral crystals with the edges truncated by faces of the rhombic-dodecahedron have been found in considerable numbers at Ambolotara near Betafo, and other localities in Madagascar. They reach an inch in diameter, and show a dull yellow weathered surface, but in the interior the material is brownish-black with a bright greasy lustre. Sp.gr. 3·59–4·475 depending on the degree of hydration. Samiresite, a titano-columbate of uranium (UO_3 21 p.c.) and lead, is from Samiresy near Antsirabe. In blomstrandite a part of the columbium is replaced by tantalum. (A. Lacroix, Minéralogie de la France et de ses colonies, 1913, vol. v.) L. J. S.

BETAINE $(CH_3)_3N\left\langle\begin{matrix}CH_2\\O\end{matrix}\right\rangle CO$ may be regarded as the internal anhydride of the acid $(CH_3)_3N(OH) \cdot CH_2 \cdot COOH$ derived from acetic acid by the replacement of one atom of hydrogen by trimethyl hydroxyammonium. It occurs in beets and mangolds (especially unripe roots), in cotton seed, in the shoots of barley, in wormseed (*Artemisia gallica*) and in many other plants, often in association with choline, from which it may readily be obtained by oxidation. For observations on the localisation of betaine in plants and its part in the nitrogen metabolism, *see* Stanĕk (Zeitsch. physiol. Chem. 1911, 72, 402). Betaine is found in the extracts of muscles from the scallop, periwinkle, and lamprey.

Betaine can be synthesised by the interaction of chloracetic acid and trimethylamine (Liebreich, Ber. 1869, 2, 13). It can also be obtained by the action of a methyl haloid upon methyl dimethylaminoacetate (J. Chem. Soc. Abst. 1914, 1, 938).

It can be extracted from beet-root molasses by dilution with water, boiling with baryta, filtering, precipitating the excess of BaH_2O_2 with CO_2, evaporating the liquid to small volume, and extracting with alcohol. The alcoholic solution is treated with alcoholic zinc chloride, the ppt. recrystallised from water and decomposed by baryta water. The barium is then exactly removed from the filtrate by H_2SO_4, and betaine hydrochloride crystallises on evaporation (Liebreich, Ber. 3, 161; Frühling and Schulz. Ber. 10, 1070).

Urban (Zeitsch. Zuckerind. Bohm. 1913, 37, 339) gives the following method. The evaporated molasses residues are mixed with an equal volume of concentrated hydrochloric acid. After cooling, the alkali chlorides which have separated are removed by filtration, and the filtrate is evaporated. The volatile organic acids and hydrochloric acid pass away, and humus substances are precipitated. These are also filtered off, and the residue further evaporated to a thick syrup. This is dissolved in water, filtered, decolourised by charcoal, and concentrated, when nearly pure betaine hydrochloride separates out (*cf.* Ehrlich, Ber. 1912, 45, 2409; also Andrlik, Z. Zuckerind, Bohm. 1915, 39, 387; J. Soc. Chem. Ind. 1915, i. 781; J. Soc. Chem. Ind. 1915, 1064).

A general method of obtaining betaine from plant extracts is to precipitate with lead acetate, filter, remove the lead by sulphuretted hydrogen, filter, evaporate to dryness, extract residue with alcohol, and precipitate with alcoholic mercuric chloride. The mercuric double salt is then recrystallised, decomposed by sulphuretted hydrogen, and the hydrochloride obtained from the solution by evaporation. If choline is also present, it can be removed from the mixed hydrochlorides by extraction with cold alcohol, leaving the betaine hydrochloride (Schulze, Zeitsch. physiol. Chem. 1909, 60, 155).

Betaine crystallises from alcohol in large crystals containing one molecule of water. It is deliquescent in air, and loses its water when dried over sulphuric acid. Strong sulphuric acid has but little action upon it, even at 120° (Staněk, Zeit. Zuckerind, Bohm, 1902, 26, 287).

It is neutral to litmus, and has a sweet taste. It melts and decomposes at 293° (Willstatter, Ber. 1902, 35, 584), giving off the smell of trimethylamine and of burnt sugar. The aurichloride $C_5H_{11}NO_2\cdot HCl\cdot AuCl_4$, forms plates or needles which melt at 209° (Willstatter), or, according to Fischer (Ber. 1902, 35, 1593), at 250°. The platinichloride $PtCl_4 2(C_5H_{11}NO_2, HCl), 4H_2O$ forms large plates; after losing its water it melts and decomposes at 242° (Willstatter).

$C_5H_{11}NO_2\cdot HCl$ is very soluble in water, slightly soluble in cold alcohol. $C_5H_{11}NO_2\cdot HI$ is soluble in water or boiling alcohol, and melts at 188°–190°. A compound with KI crystallises as $(C_5H_{11}NO_2)_2\cdot KI, 2H_2O$, m.p. 139° (Korner and Menozzi, Gazz. chim. ital. 13, 351), or, if anhydrous, at 228°–229° (Willstatter).

Stoltzenberg (Zeitsch. physiol. Chem. 1914, 92, 445) prepared the following compounds of betaine:—

The hydrofluoride and acid hydrofluoride, basic hydrochloride $(C_5H_{11}NO_2)_2HCl\cdot H_2O$, monoclinic prisms, m.p. 250° (decomp.); $C_5H_{11}NO_2\cdot HBr$, m.p. 233° (decomp.); basic hydrobromide $(C_5H_{11}NO_2)_2HBr$, prisms, m.p. 262°; basic hydriodide $(C_5H_{11}NO_2)_2HI$, glittering plates, m.p. 242°; basic aurichloride $5C_5H_{11}NO_2\cdot 4AuCl_4\cdot H_2O$, yellow crystalline powder, m.p. 169° (decomp.); basic auribromide $5C_5H_{11}NO_2\cdot 4AuBr_4$, m.p. 185°; auribromide $C_5H_{11}NO_2\cdot HAuBr_4$, dark brown plates, m.p. 260° (decomp.); two platinichlorides, one with $4H_2O$, m.p. 254°–255°, the other with $3H_2O$, m.p. 255°–260°; a basic platinichloride $5C_5H_{11}NO_2\cdot 4H_2PtCl_6$, orange crystals, m.p. 246° (decomp.); the phosphate, m.p. 199°; the sulphate $(C_5H_{11}NO_2)_2H_2SO_4$, rhombic crystals, m.p. 180°; the nitrate, m.p. 124°; the chlorate, m.p. 115° the dichromate, m.p. 226°–227° (decomp.) and the permanganate, m.p. 120°. The chlorate and permanganate explode on percussion or rapid heating.

On heating betaine with potassium hydroxide at 200°–220°, about one-third of the nitrogen is eliminated as trimethylamine, carbon dioxide being evolved. The compound in alkaline solution gives a *hydrochloride* $C_4H_9O_2N,HCl$, m.p. 187°–189°. The platinochloride forms a yellow crystalline mass, m.p. 120°–121° (Albers, Chem. Zeit. 1913, 37, 1533).

The term 'betaine' is now generally used for substances containing the group

$$\equiv N{<}\begin{matrix}CH_2-\\O-CO-\end{matrix}$$

with other alkyl- groups than methyl, or other acyl- groups than acetyl.

Thus, *dimethylethylacetylbetaine* or (since acetyl is to be understood if no acyl- group is mentioned) *dimethylethylbetaine*

$$\begin{matrix}(CH_3)_2\\C_2H_5\end{matrix}{>}N{<}\begin{matrix}CH_2\\O\end{matrix}{>}CO$$

crystallises from alcohol in four-sided plates, melting and decomposing at 229°–231° (Willstatter), while *trimethylbutyrobetaine*

$$(CH_3)_3N{<}\begin{matrix}CH_2-CH_2-CH_2\\O\end{matrix}{>}CO$$

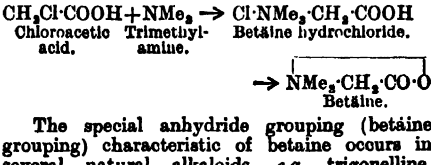
crystallises in colourless plates with $3H_2O$; in the anhydrous state it softens at 130° and decomposes at 222° (Willstatter).

The betaines are isomeric with the esters of amino- acids; thus, ordinary betaine is isomeric with methyldimethylaminoacetate $(CH_3)_2N\cdot CH_2\cdot CO\cdot OCH_3$, a volatile oily liquid, b.p. 135°, while trimethylbutyrobetaine is isomeric with methyl-γ-dimethylaminobutyrate $(CH_3)_2:N\cdot CH_2\cdot CH_2\cdot CH_2\cdot COO\cdot CH_3$, b.p. 171°–173°.

(For betaines of the pyridine series, *see* Kirpal, Monatsh. 1908, 29, 471).

According to Schulze and Trier (Zeitsch. physiol. Chem. 1910, 67, 46), the three betaines which have been isolated from plant tissues are: betaine, trigonelline [found in fenugreek by Jahns (Ber. 1885, 18, 2518) associated with choline], and stachydrine, found in the tubers of *Stachys tuberifera* and in the leaves of *Citrus aurantium* (*v.* TRIGONELLINE and STACHYDRINE).

Betäine $C_5H_{11}O_2N$ (*lycine, oxynevrine*) occurs in sugar-beet and in numerous other plants. Crystalline, m.p. 293° (dry), optically inactive. Sweet taste. The hydrochloride has been used in medicine. It is formed by the oxidation of choline and by the action of trimethylamine on chloroacetic acid



$$\underset{\text{Chloroacetic acid.}}{CH_2Cl\cdot COOH}+\underset{\text{Trimethylamine.}}{NMe_3}\rightarrow\underset{\text{Betäine hydrochloride.}}{Cl\cdot NMe_3\cdot CH_2\cdot COOH}$$

$$\rightarrow\underset{\text{Betäine.}}{\overbrace{NMe_3\cdot CH_2\cdot CO\cdot O}}$$

The special anhydride grouping (betäine grouping) characteristic of betaine occurs in several natural alkaloids, *e.g.* trigonelline. Naturally occurring betäines of other amino-acids are betonicine, ergothioneine, hypaphorine, trimethylhistidine, trigonelline, and stachydrine. *See* Barger, The Simpler Natural Bases, chap iii., Longmans, 1914. H. I.

BETAINES are completely methylated amino-acids with quinquevalent nitrogen. Bases of this type derived from several of the amino-acids of protein occur naturally in plants and animals. *Betaine* par excellence

$$(\mathrm{CH_3})_3\mathrm{N}<\begin{matrix}\mathrm{CH_2}\\ \mathrm{O}\end{matrix}>\mathrm{CO}$$

is the most important and the simplest, being trimethylglycine, and later gave its name to the whole class (for the nomenclature and general properties of which, *see* Willstatter, Ber. 1902, 35, 584, and S. Komatsu, Mem. Coll. Sci. Kyoto, 1916, 1, 369). Betaine (acetobetaine, oxyneurine, lycine) occurs in *Beta vulgaris*, the sugar-beet, and in all other *Chenopodiaceæ* examined, sporadically in a number of other plants, in mussels, cuttle fish, crayfish, &c. For localisation and migration of betaine in plants, *see* Stanék (Zeitsch. physiol. Chem. 1911, 72, 402 and Zeit. Zuckerind, Böhm. 1916, 40, 300). Young sugar beets contain more than older ones. Crude beet-sugar may contain 0·375 p.c. of betaine (Waller and Plimmer, Proc. Roy. Soc. 1903, 72, 345). The only practical natural source is the final mother liquor left after desaccharification of the molasses by strontium, which liquor, with 20 p.c. of water, may contain 115 grams of betaine per kilo. The extraction of betaine is apparently best carried out by vigorous agitation with 96 p.c. alcohol. After evaporation of the alcohol the betaine is converted into chloride and crystallised as such. Yield of the liquor of pure chloride 10–12 p.c. of the liquor employed (Ehrlich, Ber. 1912, 45, 2409; D. R. P. 157173; *cf.* Stoltzenberg, Ber. 1912, 45, 2248; D. R. P. 243332; and Chem. Zentr. 1914, i. 22; Urban, Zeit. Zuckerind. Böhm. 1913, 37, 339; Andrlik, *ibid.* 1915, 39, 387).

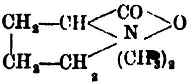
Betaine is also obtained by the oxidation of choline ('oxyneurine,' Liebreich, 1869), by the methylation of glycine and, as chloride, by the action of trimethylamine on chloracetic acid. A synthesis by heating methyldimethylaminoacetate with methyl halides and subsequent hydrolysis of the betaine ester with acids is stated to give a quantitative yield, and has been patented (D. R. P. 269338). For the isolation from plant extracts (Schulze) and estimation (Stanék), *see* the article on Choline.

Betaine crystallises from alcohol in deliquescent crystals, which lose one molecule of water at 100°, presumably changing from the ammonium hydroxide to the cyclic anhydride. It melts at 293° with partial isomerisation to methyldimethylaminoacetate (Willstatter, *l.c.*). It is a very feeble base, and neutral to litmus. The *chloride* $\mathrm{Cl(CH_3)_3N{\cdot}CH_2{\cdot}COOH}$ forms leaflets very soluble in water, and peculiar among the chlorides of organic bases in being hardly soluble in alcohol (1 part in 365 c.c. at room temperatures; separation from choline and other bases). This salt has a strongly acid reaction and has been used as a solid substitute for hydrochloric acid under the name 'acidol' in the preparation of tablets, &c. (*c.f.* acid pepsin tablets, D. R. P. 172862). When pure it is a convenient standard for alkalimetry. The *aurichloride* $\mathrm{C_5H_{11}O_2N{\cdot}HAuCl_4}$ is the most characteristic derivative, and is dimorphous; regular, m.p. 209°, and rhombic, m.p. 248°–250° (Fischer, Ber. 1902, 35, 1593; Willstätter, *ibid.* 2700). The *platinichloride*

$$(\mathrm{C_5H_{11}O_2N})_2\mathrm{H_2PtCl_6},$$

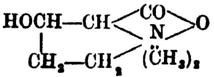
m.p. 242°, crystallises from hot water in anhydrous needles, which in contact with the aqueous mother liquor form four-sided tables with $4\mathrm{H_2O}$ (Trier, Zeitsch. physiol. Chem. 1913, 85, 372), who recommends this as a test for betaine). The *picrate*, m.p. 180°, may also be used for the separation from mixtures. A large number of other salts have been described by Stoltzenberg (Zeitsch. physiol. Chem. 1914, 92, 445). Betaine is not a nitrogenous food; it has no appreciable action on animals, and the part played by it in plant economy is obscure.

Other betaines occurring naturally, are: *Stachydrine*



the betaine of α-pyrrolidine carboxylic acid (proline) was discovered in the edible tubers of *Stachys tubifera* (Von Planta, Ber. 1890, 23, 1699), and occurs in a few other plants. According to Yoshimura and Trier (Zeitsch. physiol. Chem. 1912, 77, 290), the alkaloid chrysanthemine described by Marino-Zuco as occurring in Dalmatian insect powder (*Chrysanthemum cinerariaefolium*) is a mixture of stachydrine and choline. Stachydrine has been obtained synthetically by methylating proline (Engeland, Ber. 1909, 42, 2962), and from the methyl ester of hygric acid (Trier, Zeitsch. physiol. Chem. 1910, 67, 324).

Betonicine

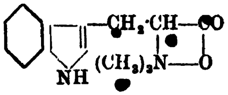


is dextro rotatory oxyproline betaine and *turicine* its stereoisomer. Both occur in *Betonica officinalis* and have been obtained by methylating natural oxyproline (Küng, Zeitsch. physiol. Chem. 1913, 85, 217), and natural 4-hydrohygric acid (Goodson and Clewer, Trans. Chem. Soc. 1919, 115, 923).

Trimethylhistidine

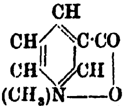
the betaine of histidine, has been obtained from fungi (Kutscher, Zentralbl. f. Physiol. 1910, 24, 775; Reuter, Zeitsch. physiol. Chem. 1912, 78, 167), and by the oxidation of *ergothioneine* (Barger and Ewins, Biochem. J. 1913, 7, 204). The latter base contains an additional sulphur atom in the glyoxaline ring and occurs in ergot (*q.v.*).

Hypaphorine



the betaine of tryptophane, occurs in the seeds of *Erythrina Hypaphorus* of Java (Greshoff, Mededeelingen uit's Lands Plantentuin, 1898). For constitution and synthesis, *see* Van Romburgh and Barger, Chem. Soc. Trans. 1911, 99, 2068.

All the above are derived from α-amino-acids. The next three are not. *Trigonelline*



the betaine of nicotinic acid, has been found in quite a number of plants, but generally only in very small amount. It probably occurs in many more species. It was discovered in the fenugreek (*Trigonella fœnum græcum*) by Jahns (Ber. 1885, 18, 2518), who later showed it to be identical with the 'methylbetain' of nicotinic acid, already synthesised by Hantzsch (Ber. 1886, 19, 3140).

γ-Butyrobetaine

$$(CH_3)_3:N<\begin{matrix}O—CO\\ CH_2\cdot CH_2\end{matrix}>CH_2$$

was obtained by Takeda (Pfluger's Archiv. 1910, 133, 365) from dog's urine after phosphorus poisoning (which interferes with the deaminating action of the liver). It is almost certainly identical with one, if not with three, of Brieger's putrefaction bases (Untersuch. über Ptomaine, i. p. 27, Berlin, 1886), and was first synthesised by Willstätter (Ber. 1902, 35, 584).

Carnitine, α-hydroxy-γ-butyrobetaine

$$(CH_3)_3:N<\begin{matrix}O——CO\\ CH_2—CH_2\end{matrix}>CHOH$$

is a hydroxy derivative of the foregoing, and was isolated from meat extract (yield 1.3 p.c.) by Gulewitsch and Krimberg (Zeitsch. physiol. Chem. 1905, 45, 326), and by Kutscher (Zeit. Unters. Nahr. Genussm. 1905, 10, 528; 'novain'). According to the latter, it is identical with a base $C_7H_{15}O_3N$, isolated from human urine by Dombrowski (Compt. rend. 1902, 135, 244). Heating with baryta yields trimethylamine and crotonic acid; phosphorus and hydriodic acid reduce to γ-butyrobetaine. Racemic carnitine was probably synthesised by Fischer and Göddertz (Ber. 1910, 43, 3272). The small differences from natural carnitine were probably connected with the optical activity of the latter substance.

Myokynine, isolated by Ackermann (Zeit. Biol. 1912, 59, 433) from the muscles of horses and dogs, is probably *l*-hexamethyl-ornithine $(CH_3)_3N(OH)\cdot CH_2\cdot CH_2\cdot CH_2\cdot CH\cdot(COOH)\cdot N\cdot(CH_3)_3OH$

All the above bases, or at least all the α-betaines, are without marked physiological activity.

For a fuller account of betaines, *see* Barger, The Simpler Natural Bases, Longmans, 1914.

G. B.

BETEL. A mixture of the leaf of the betel-pepper, *Piper Betle* (Linn.) with the fruit of *Areca catechu* (Linn.) or betel nut and *chunam* (lime obtained by calcining shells), universally used by the people of Central and Tropical Asia as a masticatory.

BETEL-NUT. The fruit of *Areca catechu* (Linn.) *v.* Areca Nut.

BETH-A-BARRA WOOD. A wood imported from the West Coast of Africa, much valued for its toughness and capability of receiving a high polish. The interstices of the fibres are filled with a yellow crystalline substance which can be extracted from the sawdust by heating with distilled water containing a little sodium carbonate, and precipitating the resulting claret-coloured solution with acetic acid. It is purified by repeated crystallisations from 80 p.c. alcohol. By precipitating the red solution with hydrochloric acid and washing the resulting precipitate with ether, Greene and Hooker (Amer. Chem. J. 11, 267) found the crystals to be identical in all respects with lapachic acid.

It differs from chrysophanic acid by melting at 135° and in not forming a compound with alum (Sadtler a. Rowland, Amer. Chem. J. 1881, 22). (For tables showing the difference in the reactions of brasilin, hæmatoxylin, santalin, and beth-a-barra, *v.* Amer. Chem. J. 11, 49, and Wagner's Jahr. 28, 537.)

BETOL β-NAPHTHOL SALICYLATE *v.* Synthetic drugs.

BETONICINE *v.* Betaines.

BETORCIN or **β-ORCIN** $C_8H_{10}O_2$. A substance obtained by the decomposition of barbatic acid, found in the lichen *Usnea barbata.* It is less soluble in water than orcin, and gives a deeper crimson colour with hypochlorites. Kostanecki has obtained it by the action of nitrous acid on *m*-amino-*p*-xylenol, thus showing that it is a dihydroxy-xylene (dimethylresorcinol) having the substituting groups in the positions CH_3, CH_3, OH, OH=1, 4, 3, 5 (Stenhouse a. Groves, Chem. Soc. Trans. 37, 396; Lampartie, Annalen, 134, 248; Menschutkin, Bull. Soc. chim. 2, 428; Kostanecki, Ber. 19, 2321).

BETULA RESIN *v.* Resins.

BETULOL $C_{15}H_{24}O$, a bicyclic sesquiterpene alcohol of the terbene type found in birch oil, B.P. 157–°158°/13 mm., D^{16}0·9777, $n\cdot{}^{16}_{D}$1·5150, $a^{16}_{D}-26\cdot5°$. Slowly absorbs hydrogen in presence of platinum yielding *tetrahydrobetrol*, b.p. 153°–158°/14 mm., D^{18} 0·9415, n^{18}_{D} 1·4908, $a^{18}_{D}-6.8°$, and bicyclic *tetrahydrobetulene* $C_{15}H_{28}$, b.p. 118°–120°/11 mm.; D^{18} 0·8737, n^{18}_{D} 1·4744, $a^{18}_{D}-3°$. For other derivatives *see* Semmler, (Jonas and Richter, Ber. 1918, 51, 417).

BEZETTA. *Tournesol en drapeaux. Schminklappchen. Bezetta rubra et cœrulea.* A dye or pigment prepared by dipping linen rags in solutions of certain colouring matters. Red bezetta is coloured with cochineal, and is used as a cosmetic.

Blue bezetta (*Tournesol en drapeaux*), which is chiefly used for colouring the rind of Dutch cheeses, is prepared at Gallargues, near Nîmes, in the department of Gard, from a euphorbiaceous plant, *Chrozophora tinctoria* (A. Juss.) [*Croton tinctorius*]. The fruits and the tops of the plants are gathered, and, the juice being expressed, rags of coarse cloth are dipped into it, then dried, and afterwards exposed to the fumes of mules' or horses' dung. This last operation is called *aluminadou.* The cloths are turned from time to time, to ensure uniform colouration and prevent any part from being exposed too long to the fumes of the dung, which would turn them yellow. They are then dried a second time, again soaked in the juice, mixed this time with urine, and lastly exposed for some time to the action of the sun and wind. The quantity thus manufactured amounts to about 50 tons yearly. The blue of bezetta is reddened by acids like litmus, though not so quickly, but differs from the latter in not being restored by alkalis. According to Joly, the same dye may be obtained from other euphorbiaceous plants, *Chrozorphora oblongata* [*obliqua* (A. Juss.) ?], *C. plicata* (A. Juss.), *Argithamnia tricuspidata* (Muell.), *Mercurialis perennis* (Linn.), and *M. tomentosa* (Linn.). The juice exists in all these plants in the colourless state, and turns blue only on exposure to the air (Handw. d. Chem. 2, [1] 1030; Gerh. Traité, 3, 820).

BEZOAR. This name, which is derived from a Persian word signifying an antidote to poison, was given to a concretion found in the stomach or intestines of an animal of the goat kind, *Capra aegragus*, which was once very highly valued for this imaginary quality, and has thence been extended to all concretions found in animals.

According to Taylor (Phil. Mag. No. 186, 36, and No. 188, 192), bezoars may be divided into nine varieties: 1. Phosphate of calcium, which forms concretions in the intestines of many mammalia. 2. Phosphate of magnesium; semi-transparent and yellowish, and of sp.gr. 2·160. 3. Phosphate of ammonium and magnesium; a concretion of a grey or brown colour, composed of radiations from a centre. 4. Oxalate of calcium. 5. Vegetable fibres. 6. Animal hair. 7. Ambergris. 8. Lithofellic acid. 9. Ellagic or bezoardic acid.

Of true bezoars there are three kinds: Oriental, Occidental, and German. The true Oriental bezoars found in the *Capra ægragus*, the gazelle (*Gazella dorcas*), and other ruminant animals, are spherical or oval masses, varying from the size of a pea to that of the fist, and composed of concentric layers of resinous matter with a nucleus of some foreign substance, such as pieces of bark or other hard vegetable matter which the animal has swallowed. They have a shining resinous fracture, are destitute of taste and odour, nearly insoluble in water and aqueous hydrochloric acid, but soluble for the greater part in potash lye. These characters suffice to distinguish the Oriental bezoars from those varieties which contain a considerable quantity of inorganic matter. There are two kinds of them, the one consisting of ellagic, the other of lithofellic acid. The latter have a more waxy lustre and greener colour than the former, and are also distinguished by their lower sp.gr., viz. 1·1, whilst that of the ellagic acid stones is 1·6. They contain, besides lithofellic acid, a substance resembling the colouring matter of bile, and are perhaps biliary calculi. Oriental bezoars are greatly prized in Persia and other countries of the East for their supposed medical properties. The Shah of Persia sent one in 1808 as a present to Napoleon. The Occidental bezoars are found in the lama (*Auchenia glama*) and in *A. vicugna.* They resemble the Oriental in external appearance, but differ totally in their chemical characters, inasmuch as they consist chiefly of calcium phosphate, with but little organic matter. German bezoars, which are chiefly obtained from the chamois or gemsbock (*Rupicapra tragus*), consist chiefly of interlaced vegetable fibres or animal hairs bound together by a leathery coating.

BICUHYBA FAT. *See* MYRISTICA FAT GROUP.

BIDRY. An Indian alloy of zinc, copper, and lead, and occasionally tin. Articles of this alloy, after being turned in a lathe and engraved, are blackened by immersion in a solution of sal ammoniac, nitre, common salt, and copper sulphate. Known also as *Vidry.*

BIEBRICH ACID RED, PATENT BLACKS, SCARLET PONCEAU *v.* AZO- COLOURING MATTERS.

BIGNONIA TECOMA.[1] **TECOMIN.** The *Bignonia tecoma* is a somewhat common tree in the uplands of Minas, Brazil, which when fully grown is about 30 feet high and in September is covered with brilliant yellow flowers. The natives mix the sawdust and shavings of this tree with slaked lime, heat the mass with water and employ the resulting bath to dye cotton cloth. A paste made of the sawdust mixed with lime is also used to stain lighter-coloured woods a deep brown. By exhausting the sawdust with boiling 85 p.c. alcohol and concentrating the extract, Lee (Chem. Soc. Trans. 1901, 79, 284) isolated the colouring matter *tecomin.* This, which has apparently not been submitted to analysis, forms shining chrome-yellow crystals possessing a nacreous lustre, soluble in alkalis with a rose-red colouration.

A further quantity of this compound could be isolated from the alcoholic filtrate, the total amount thus given by the wood being approximately 5 p.c.

The sawdust extracted with alcohol still contains a deep brown dye which may now be removed from it by alkalis, and by acidification this is deposited as an amorphous brown powder. Nothing is at present known as regards the relationship, if such exists, between tecomin and the colouring matter of chica red or carajura, which originates from the Bignonia chica. A. G. P.

BIKHACONITINE *v.* ACOTININE.

BILBERRY. *Vaccinium Myrtillus* (Linn.). König gives as the average composition of the fruit:

Water	Protein	Free acid	Sugar	Other carbo-hydrates	Crude fibre	Ash
78·4	0 8	1·7	5·0	0·9	12·3	1·0

According to Otto (Bied. Zentr. 1899, 28, 284), Silesian bilberries contain from 3·5 to 7·0 p.c. of sugar and acid corresponding to from 0·9 to 1·5 p.c. of tartaric acid. He found that fermentation of the juice with ordinary yeast was very slow unless some nitrogenous matter (*e.g.* ammonium chloride or, better, asparagine (about 0·6 gram per litre)) were added. Bilberries contain a small quantity of a wax melting at 71° (Seifert, Landw. Versuchs-Stat. 1894, 45, 29).

The juice of bilberries contains from 4 to 9·5 p.c. of total solids, 0·25 to 0·31 p.c. ash, and acidity corresponding to from 15·5 to 19·6 c.c. N/1 alkali. The juice contains some substance which gives a blue colouration when heated with hydrochloric acid. This colouration is apparently not connected with the red colouring matter of the berries and appears to be characteristic of the *Vacciniaceæ* for cranberries, *Vaccinium vitis Idæa* also yield the same reaction (Plahl, Zeitsch. Nahr. Genussm. 1907, 13, 1).

---

[1] According to Holmes the name *Bignonia tecoma* does not appear in the Kew Index, but only *Bignonia tecomoides*, which is, however, a shrubby species.

The sugar in bilberries is entirely invert sugar (Windisch and Boehm, Zeitsch Nahr. Genussm. 1908, 8, 347). The ash contains:

K_2O	Na_2O	CaO	MgO	Fe_2O_3	Mn_3O_4	P_2O_5	SO_3	SiO_2
57·1	5·2	8·0	6·1	1·1	2·1	17·4	3·1	0·9

(Borggreve and Homberger, Bied. Zentr. 1886, 487).

Bilberries contain a red-brown dye, insoluble in acidified water and a soluble dye which, when boiled with acid, yields sugar and the insoluble colouring matter (Weigert, Bied. Zentr. 1896, 25, 58).

The juice of this berry (Ger. *Heidelbeere*) is used for colouring wines. The colouring matters of grapes and of bilberries behave in an almost identical way with most reagents (Andrée, Arch. Pharm. [3] 13, 90; Ber. 13, 582; Plahl, Chem. Zentr. 1907, i. 837).

To detect bilberry juice in wine, 50 c.c. of the wine is made faintly alkaline with sodium hydroxide, and evaporated to half its volume. After cooling it is made up to the original volume and precipitated with lead acetate. The filtrate is then precipitated with sodium sulphate and after filtration the solution is acidified with hydrochloric acid. If any vegetable colouring matter is still present, the solution at once becomes red, but the blue colour given by bilberry only appears on heating the solution in a boiling water-bath. In this way 2 p.c. of bilberry juice can be detected (Plahl, Chem. Zentr. 1908, i. 1482).

According to Vogel (Ber. 21, 1746), the colouring matter of grapes and of bilberries can be readily distinguished by their absorption spectra, providing the wine is not too concentrated, and after adding a trace of alum solution, it is carefully neutralised with ammonia. After long keeping, however, the colouring matters cannot be distinguished in this way.

The colouring matter of the juice can be extracted by neutralising it with caustic soda and then treating it with hide powder. After two days the hide powder containing the colouring matter is filtered off, washed with water, and treated with dilute hydrochloric acid, after which it is precipitated with dilute soda. The colouring substance, probably $C_{10}H_{12}O_3$, is soluble in mineral and organic acids, but insoluble in water, alcohol, ether, chloroform, or benzene. It reduces Fehling's solution, and is decomposed by hot conc. sulphuric acid, a compound $C_{14}H_{14}O_7$ being thrown down when water is added to the red solution thus obtained. The colouring matter is oxidised by nitric acid to oxalic and picric acids. It slowly decomposes on standing, evolving carbon dioxide, and its solution when treated with copper sulphate or zinc chloride, turns violet; with lead acetate it turns blue, and with ferric chloride dark-brown (Nachen, Chem. Zentr. 1895, 66, 1084).

Considerable quantities of citric and malic acids are present in the juice, which also contains hydrocarbons, glucoses, pentoses, and inositol (Nachen, *l.c.*). Ammonia turns bilberry juice a brownish-green; nitric acid in the cold blue, changing to red and becoming orange on boiling; lead acetate gives a blue precipitate, copper sulphate a violet colour, sodium carbonate a blue-black, and borax an amaranth red (Griessmayer, Chem. Zentr. 8, 381).

When chlorine is passed into the juice, a bright-grey amorphous precipitate is obtained (Nachen, *l.c.*).

(For quantitative analysis of the juice, compare Mathes, Muller, and Ramstedt (Chem. Zentr. 1905, i. 407); Lühring, Bohrisch, and Hepner (*ibid.* 1907, ii. 1755); Shamm and Jegin (*ibid.* 1907, i. 983); Behre, Grosse, and Schmidt (*ibid.* 1909, i. 456).)

When the juice is fermented, the products include aldehyde, and capric, propionic, valeric, and butyric acids (Nachen, *l.c.*).

Wine has been prepared from bilberry juice by allowing it to ferment spontaneously when mixed with a third its weight of honey. The wine thus prepared bears prolonged storage, is rich in alcohol and tannin, is of a rich clear colour, and has an agreeable flavour (Graftien, Bl. Assoc. Belge des chim. 12, [3] 107; Otto, Bied. Zentr. 1899, 28, 284).

When bilberries are extracted with chloroform, the solution evaporated, and the residue extracted with light petroleum, the soluble portion yields a wax, m.p. 71°, and a crystalline compound, probably *vitin*, m.p. 255°–260° $[\alpha]_D + 60{\cdot}72°$ (Seifert, Landw. Versuchs-Stat. 45, 29).

BILE. Bile is the secretion of the liver which is poured into the duodenum (the first part of the small intestine). It can be collected in animals by means of a biliary fistula; the same operation has occasionally been performed in human beings. After death, the gall bladder yields a good supply of bile, which is more concentrated than that obtained from a fistula. The amount of bile secreted is differently estimated by different observers; in man it probably varies from 500 to 1000 c.c. per diem.

Its constituents are the bile salts proper (sodium glycocholate and taurocholate), the bile pigments (bilirubin and biliverdin), a mucinoid substance, small quantities of fats, soap, cholesterol, lecithin, urea, and mineral salts, of which sodium chloride and the phosphates of calcium and iron are the most important.

Bile is a yellowish, reddish-brown, or green fluid, according to the relative preponderance of its two chief pigments. It has a musk-like odour, a bitter-sweet taste, and is alkaline to litmus. The specific gravity of human bile is 1·026 to 1·032 from the gall bladder, and about 1·011 when derived from a fistula. The greater concentration of gall-bladder bile is partly explained by the addition to it from the wall of that cavity of the mucinoid material it secretes. The following table will, however, show that the low percentage of solids in fistula bile is due mainly to paucity of bile salts. This is accounted for in the way first suggested by Schiff—that there is normally a bile circulation going on in the body, a large quantity of the bile salts that pass into the intestine being first split up, then re-absorbed and again synthesised and secreted. This would obviously be impossible in cases where all the bile is discharged to the exterior through a fistula. The following is the table in question, the results being the mean of several analyses of human bile:—

Constituents	Fistula bile	Gall-bladder bile
Bile salts	0·42	9·14
Cholesterol, lecithin, fat	0·07	1·18
Mucinoid material	0·17	2·98
Pigment	0·07	
Ash	0 66	0·78
Total solids	1·39	14·08
Water (by difference)	98 61	85·92

For methods of analysing human bile, *see* v. Czyhlarz, Fuchs and v. Furth, Biochem. Zeitsch. 1913, 49, 120; Analyst, 1913, 208.

The *Fel bovinum purificatum* of the pharmacopœia is made by mixing ox bile with twice its volume of rectified spirit: this is set aside for 12 hours until the sediment subsides; the clear solution is decanted and evaporated on the water-bath until it acquires a consistence suitable for forming pills. The material so obtained consists mainly of bile salts, cholesterol, fats, salts, and a certain amount of the mucinoid material. Its yellowish-green colour is due to bile pigment. It is given in doses of 5 to 10 grains, usually as pills coated with keratin to obviate its deleterious action on gastric digestion. It is given mainly in cases where the natural secretion is absent or scanty, as in jaundice. But for a full description of its medicinal uses, and also for a description of the action of drugs (cholagogues) which stimulate the liver either to secrete more bile or to cause a discharge of bile already formed, the reader is referred to any standard text-book on Pharmacology.

Plattner's crystallised bile. The bile salts are soluble in water and in alcohol, but not in ether. Their solution in alcohol is therefore precipitated by ether, and this precipitate gives, with proper precautions in technique, rosettes or balls of fine needles, or 4–6 sided prisms composed of the bile salts. This preparation is known as Plattner's crystallised bile; it is usually made from ox bile, in which case the main constituent is sodium glycocholate.

The bile salts. The sodium salts of glycocholic and taurocholic acids are those most frequently found. The former is more abundant in the bile of man and herbivora, the latter in carnivora. *Glycocholic acid* ($C_{26}H_{43}NO_6$) *is* by the action of dilute alkalis and acids, and also in the intestine, hydrolysed and split into glycine (amino-acetic acid), and cholalic (cholic) acid

$$C_{26}H_{43}NO_6+H_2O=C_2H_5NO_2+C_{24}H_{40}O_5$$

Its sodium salt has the formula $C_{26}H_{42}NaNO_6$. Taurocholic acid ($C_{26}H_{45}NO_7S$) similarly splits into taurine (amino-ethyl sulphonic acid) and cholalic acid

$$C_{26}H_{45}NO_7S+H_2O=C_2H_4\cdot NH_2\,HSO_3+C_{24}H_{40}O_5$$

Its sodium salt has the formula $C_{26}H_{44}NaNO_7S$. These substances usually are detected by Pettenkofer's reaction; small quantities of cane sugar and sulphuric acid added to the bile produce a brilliant purple colour. This is due to the interaction of furfuraldehyde (produced from the sugar and sulphuric acid) and cholalic acid.

Throughout the animal kingdom considerable variations are found in the bile salts. Thus in many fishes potassium instead of sodium salts are present. There are also variations in the bile acids themselves; for instance, in the pig hyoglycocholic acid ($C_{27}H_{43}NO_5$) takes the place of ordinary glycocholic acid, and in the goose chenotaurocholic acid ($C_{29}H_{49}NSO_6$) of ordinary taurocholic acid.

A good deal of work has been expended on the constitution of cholalic acid, but much yet remains to be done. According to Mylius, it is a monobasic alcohol acid with a secondary and two primary alcohol groups. Its formula may therefore be written $C_{20}H_{31}\left\{\begin{matrix}CHOH\\(CH_2OH)_2\\COOH\end{matrix}\right.$. On oxidation it yields other acids, which have been named dehydrocholalic acid ($C_{24}H_{34}O_5$), bilianic acid ($C_{24}H_{34}O_8$), cilianic acid ($C_{20}H_{30}O_8$): on reduction desoxycholalic acid ($C_{24}H_{40}O_4$) is obtained.

Choleic acid is another cholalic acid, with the formula $C_{24}H_{40}O_4$, found in small quantities in the bile of ox and man. It is probably identical with desoxycholalic acid. Fellic acid ($C_{23}H_{40}O_4$) is still another acid obtainable from human bile along with the ordinary acid. The principal cholalic acid in bear's bile is termed ursocholeic acid ($C_{18}H_{28}O_4$ or $C_{19}H_{30}O_4$) by Hammarsten. The same investigator finds in the walrus that the principal bile acids are *α*-phocætaurocholic acid, the cholalic acid from which has the formula $C_{22}H_{30}O_5$; and *β*-phocætaurocholic acid, the cholalic acid from which differs in certain particulars from ordinary cholalic acid, although it has the same empirical formula; he terms it *iso*cholalic acid.

The bile pigments. Bilirubin has the formula $C_{32}H_{36}N_4O_6$, and biliverdin contains more oxygen $(C_{16}H_{18}N_2O_4)n$; in bile exposed to the air, bilirubin is fairly rapidly oxidised to biliverdin. It has been proved by physiological experiment that the bile pigment is an iron-free derivative of the blood pigment; it is, in fact, identical with the substance termed hæmatoidin, which occurs usually in crystalline form in extravasations of blood in the body, as in a bruise. The bile pigment shows no absorption bands with the spectroscope, and is detected by various colour reactions, of which the most familiar is Gmelin's test; this consists in the play of colours—green, blue, red, and finally yellow—produced by the oxidising action of fuming nitric acid. The end or yellow product is called choletelin ($C_{32}H_{36}N_4O_{12}$). By reduction outside the body, a product called hydrobilirubin ($C_{32}H_{40}N_4O_7$) is obtained. A similar but not identical reduction product containing less nitrogen than hydrobilirubin is formed in the intestine, and constitutes stercobilin, the pigment of the fæces. Some of this is absorbed and ultimately leaves the body in the urine, where it is termed urobilin. A small quantity of urobilin is sometimes found preformed in the bile.

Bile mucin. The viscous material in the bile of some animals (*e.g.* man) is true mucin; in other (*e.g.* the ox) it is a nucleoprotein.

Cholesterol. Of the other constituents of the bile, cholesterol or cholesterin is the most interesting; although normally present in traces only, it may occur in excess and form the concretions known as gall stones, which are usually more or less tinged with bile pigment. It is a monatomic unsaturated alcohol, with the empirical formula $C_{27}H_{45}{\cdot}OH$. Windaus and others have shown that it is a member of the terpene series, which had hitherto only been found as excretory products of plant life.

The physiological uses of bile.—Bile is doubtless to some extent an excretion. Some state that it has a slight lipolytic action; and in some animals it certainly has a feeble diastatic power. Its main action, however, is to assist pancreatic digestion; this it does not only because its alkalinity is useful in helping to neutralise the acid mixture which leaves the stomach (chyme), but it also acts as a coadjutor to the enzymes of pancreatic juice. This is true for the proteolytic enzyme (trypsin), and the amylolytic enzyme (amylopsin), but is especially so in the case of pancreatic lipase; some go so far as to speak of the bile salts as the co-enzyme of this ferment.

In virtue of the properties which the bile salts possess of lowering surface tension, the products of fat-cleavage pass more rapidly through membranes moistened with bile than through these which are not. There is a good deal of evidence that the same holds *intra vitam*, and thus the presence of bile aids the absorption of fats by the mucous membrane which lines the intestinal wall. Bile also is a solvent of fatty acids.

When the bile meets the chyme, the turbidity of the latter is increased owing to the precipitation of unpeptonised protein. This action of the bile salts is probably useful, as it converts the chyme into a more viscid mass, and somewhat hinders its progress along the first part of the intestine, so allowing digestion and absorption to occur there.

Bile is said to be a natural antiseptic, but it is very doubtful if it is really efficient in reducing the putrefactive processes in the bowel. The bile salts are *in vitro* very feeble germicides, and the bile itself is readily putrescible; any power it may have in lessening putrescence in the intestine is due chiefly to the fact that by increasing absorption it lessens the amount of putrescible material in the intestinal tract. It is stated also that bile increases the peristaltic action of the large intestine.

Industrial and commercial uses of bile.—Apart from a somewhat limited use as a therapeutic agent, to which allusion has already been made, bile has but little commercial importance. It is, however, employed for cleansing woollen goods, and, as housekeepers know, is specially useful in cleaning carpets. This is probably connected with its power of lowering surface tension. Bile is also used by artists to ensure the uniform spreading of water colours on paper.

No attempt has been made in the foregoing article to allude to the very extensive literature of bile. This relates almost exclusively to the physiology and pathology of bile, and the important references can be best obtained from some standard work on Physiological Chemistry.

W. D. H.

BIOGEN or **MAGNESIUM PERHYDROL.** Trade name for a mixture of magnesia and magnesium peroxide.

BIOTITE *v.* Mica.

BIRCH BARK. *Betula.* (*Birke*, Ger.; *Bouleau*, Fr.) The inner bark is used in India as a substitute for paper and for lining the roofs of houses (Dymock, Pharm. J. [3] 10, 661).

It contains good tanning materials, yielding bright-yellow leather (Wagner's Jahr. 30, 1206; Trotman and Hackford, J. Soc. Chem. Ind. 1905, 1096; Bögh, Chem. Zentr. 1906, i. 1915).

The dry distillation of birch bark yields a tar and an acid aqueous solution (Kuriloff, J. Russ. Phys. Chem. Soc. 23, 98). The chief constituents of birchwood tar creosote are guaiacol and 1 : 3 : 4-creosol, together with traces of phenol, cresol, and 1 : 3 : 4-xylenol (Pfreager, Arch. Pharm. 228, 713). According to Hirschsohn (Pharm. Centr. H, 1903, 44, 845) birch tar is often adulterated with crude naphtha or naphtha residues, but the adulterated can be distinguished from the pure product by the fact that the former is only partially soluble in acetone, whereas the latter is wholly soluble.

When warm birch tar is treated with air, oxygen, or ozonised air, a pleasant-smelling solid product is obtained, soluble in alkalis, but almost insoluble in alcohol, benzene, and ether. It and its salts can be employed in medicine, pharmacy, and technically. At the same time, readily condensible liquid products distil over, which can also be used medicinally and technically, as antiseptics and in perfumery (Friedländer's Fortschr. der Teerfabr. 1905–7, 930).

A colouring substance employed in pharmaceutical and cosmetic preparations is obtained when the bark of young birch trees is soaked in water containing about $\frac{1}{20}$ of its weight of bicarbonate of soda or other carbonate. It is then boiled and filtered. Hydrochloric acid is added to the red-brown filtrate until a precipitate is formed which is filtered, washed, and dried at a gentle heat. It should be kept in well-stoppered vessels (Friedländer's Fortschr. der Teerfabr. 1897–00, 661).

The bark contains a crystalline substance termed *betulin* $C_{32}H_{60}O_3$, m.p. 257·8°, sublimes in a current of air, readily yields an anhydride at 130°, and is tasteless and odourless. It does not combine with acids or alkalis, is insoluble in water, sparingly soluble in alcohol, readily in ether and turpentine.

It is prepared by mixing the powdered epidermis of *Betula alba* with 1–8 p.c. of potassium nitrate, pressing the mixture into small tablets, and burning them in closed chambers without flame, and with the introduction of a regulated supply of air. The betulin so formed is used as films for certain substances in which it acts as an antiseptic, as a protection against damp or against corrosive acids (Wheeler, Pharm. J. 1899, 494).

The films can be deposited direct on various substances by allowing the vapours to play upon them. By a slight modification the films can be made to have a greater or less degree of transparency and porosity (Wheeler, Chem. Zentr. 1900, ii. 798).

According to Wheeler (J. Soc. Chem. Ind. 1899, 606), when birch bark or materials made from the latter, containing betulin are heated in a closed chamber and in a current of air, substances termed *pyrobetulin* and *pyrobetulin anhydride* are produced in forms other than films.

Gaultherine $C_{14}H_{18}O_8{,}H_2O$, a glucoside, is obtained by extracting the bark of *Betula lenta* with alcoholic lead acetate, precipitating by ether, and recrystallising from alcohol. The aqueous solution has a bitter flavour, is lævo-rotatory, and reduces Fehling's solution when boiled. It is hydrolysed by mineral acids, baryta, and by water when heated to 130°–140°, giving a sugar and methyl salicylate (Schaugans and Geroch, Arch. Pharm. 232, 437).

A gum of probable formula $C_4H_4O_3$ has been isolated from American birch wood (*Betula alba*) (Johnson, Amer. Chem. J. 1896, 214).

Birchbark oil is obtained by distilling birch bark (*Betula alba*) in steam. It is brown, and has a similar odour to birch bud oil. On cooling, crystals separate. It contains palmitic acid (Haensel, Chem. Zentr. 1907, ii. 1620; Ziegelmann, Pharm. Review, 1905, 23, 83).

The birch bark oil prepared from the bark of *Betula alba* by Haensel (Chem. Zentr. 1908, ii. 1436), had sp.gr. 0·9003 at 20° and $[\alpha]_D -12{\cdot}08°$; a colourless monocyclic sesquiterpene was isolated from it, having b.p. 255°–256°/744 mm., sp.gr. 0·8844 at 20°, and $[\alpha]_D -0{\cdot}5°$. The terpene yields a hydrochloride, sp.gr. 0·9753 at 20°, and a hydrocarbon, b.p. 258°–260°/747 mm., and sp.gr. 0·8898 at 20°.

Birch oil, or the wintergreen oil of commerce, is obtained from the twigs of North American birches, especially the *Betula lenta*, but the pure genuine oil is prepared from *Gaultheria procumbens* (J. Soc. Chem. Ind. Abstr. 1893, 174). It consists of methylsalicylate, a hydrocarbon $C_{15}H_{24}$, and small quantities of benzoic acid and ethyl alcohol (Schroeter, Amer. J. Pharm. Aug. 1889; Trimble and Schroeter, Pharm. J. 20, 166; Ziegelmann, *l.c.*).

Oil of *Gaultheria procumbens* contains 99 p.c. methylsalicylate, together with some paraffin —$C_{30}H_{62}$—probably triacontane; an aldehyde or ketone; a secondary alcohol $C_8H_{16}O$, and an ester $C_{14}H_{24}O_2$, and is lævo-rotatory, sp.gr. 1·180; that obtained from the birch contains 99·8 p.c. methylsalicylate, together with the above constituents except the alcohol $C_8H_{16}O$, which is absent. It is optically inactive; sp.gr. 1·187 (Pharm. J. 1895, 307, 328).

Birch bud oil is obtained by the distillation of birch buds with steam. It is yellow, and has a pleasant aromatic odour. Crystals separate out at ordinary temperatures, and it becomes wholly crystalline at −45° (J. Soc. Chem. Ind. 1903, 228). It is soluble in alcohol and in ether, but not in alkalis, carbon disulphide, or glacial acetic acid. It is lævo-rotatory, its rotation and specific gravity varying with different preparations. That obtained by Schimmel (Chem. Zentr. 1909, ii. 2156) had sp.gr. 0·9730 at 15° and $\alpha_D -5°\ 34'$.

It contains a paraffin, m.p. 50°, an ester, and a sesquiterpene alcohol, *betulol*, probably $C_{15}H_{23}OH$, which is very much like amyrol (obtained from sandalwood oil), has a bitter taste, an odour like incense, b.p. 284°–288°/743 mm., 138°–140°/4 mm.; sp.gr. 0·975; $[\alpha]_D -35°$ (von Soden and Elze, Ber. 38, 1636; Haensel, Chem. Zentr. 1909, ii. 1156. Compare also Pharm. Zeit. 47, 818; Schimmel, Chem. Zentr. 1905, i. 1340).

The leaves of *Betula alba* yield an olive-green oil, which is solid at ordinary temperature, but fluid at 35°, has sp.gr. 0·9074 at 35°, and is optically inactive (Haensel, Chem. Zentr. 1904, ii. 1737).

Haensel (Chem. Zentr. 1908, i. 1837) has isolated a crystalline paraffin, m.p. 49·5°–50°, from the oil of birch leaves.

According to Grasser and Purkert (Chem. Zentr. 1910, i. 489), products $C_{41}H_{70}O_7$, $C_{39}H_{68}O_8$, readily soluble in water, and of which the potassium salt $C_{41}H_{67}K_3O_7$ can be used therapeutically as a diuretic, can be obtained by extracting birch leaves with alcohol, treating the warm extract with potassium hydroxide, and then saturating the solution with dry carbon dioxide. Water is now added and the insoluble products filtered off. The filtrate is concentrated, the soluble products precipitated with a mineral acid, and separated from one another by conversion into their di- and trialkali derivatives.

Birch juice obtained from birch trees contains lævulose, a large quantity of malates, and basic constituents. When fermented with dextrose and milk of almonds, it forms 'birch wine' (Lenz, Ber. Deut. Pharm. Ges. 19, 332).

BIRD-LIME. (*Glu*, Fr.; *Vogelleim*, Ger.) Bird-lime, from *Ilex aquifolium* (Linn.), was found by Personne to consist, in addition to vegetable *débris* and water, of calcium oxalate, caoutchouc, and ethereal salts of a solid crystalline substance, *ilicic alcohol* $C_{25}H_{44}O$, m.p. 175°, with undetermined fatty acids.

According to Divers and Kawakita, Japanese bird-lime, made from *I. integra*, contains ethereal salts of palmitic acid, and in very small quantity a semi-solid acid, the calcium salt of which is soluble in ether and in alcohol. Japanese bird-lime also yields two very similar alcohols by hydrolysis, one differing only slightly from ilicic alcohol, and termed *ilicylic alcohol* $C_{22}H_{38}O$, m.p. 172°, and another named *mochylic alcohol* $C_{26}H_{46}O$, m.p. 231°, from *mochi*, the Japanese word for bird-lime.

Caoutchouc is also present in Japanese bird-lime to the extent of about 6 p.c., but only minute quantities of oxalates. By distillation, bird-lime yields much palmitic acid and a thick oily hydrocarbon $C_{26}H_{44}$ (Divers and Kawakita, Chem. Soc. Trans. 1888, 268).

BIREEZ. Persian name for gum galbanum (Dymock, Pharm. J. [3] 9, 1016).

BISABOL *v.* Myrrh, art GUM RESINS.

BISCINIOD. Trade name for a combination of cinchonidine hydriodide and bismuth iodide.

BISDIAZONIUM SALTS *v.* DIAZO COMPOUNDS.

BISMAL. Bismuth methylene digallate (*v.* BISMUTH, Organic compounds of; also SYNTHETIC DRUGS).

BISMARCK BROWN *v.* AZO- COLOURING MATTERS.

BISMITE or **BISMUTH-OCHRE.** Native bismuth oxide, Bi_2O_3, occurring as a yellow earthy powder, or as minute rhombohedral scales. Analysis of various bismuth-ochres from the tourmaline mines of San Diego Co., California, show these to be either bismuth hydroxide, $Bi(OH)_3$, or pucherite, $BiVO_4$, or mixtures of these; and doubt has been expressed as to the occurrence of the pure oxide Bi_2O_3 in nature (W. T. Schaller, 1911). L. J. S.

BISMON *v.* SYNTHETIC DRUGS.

BISMUTH. *Bismuth.* (*Etain de glace*, Fr.; *Wismuth*, Ger.) Symbol Bi. At. wt. 208·5 (De Coninck and Gérard).

Occurrence.—Metallic bismuth occurs in small quantities in widely distributed localities, usually with other ores, such as those of cobalt, nickel, copper, silver, lead, and tin. It is found massive, granulated, reticulated or arborescent, associated with arsenic and silver, and occasionally iron.

The principal sources are Bolivia, South Australia, Altenberg, Schneeberg, Annaberg, Marienberg, Joachimsthal, Johanngeorgenstadt, Lölling in Carinthia, Fahlun, Sweden, and New South Wales. In small quantities it occurs at Huel Sparnon, Cornwall, Carrick Fells, Alva, Stirlingshire. Alloyed with 64 p.c. gold it occurs at Maldon, Victoria. Alloyed with tellurium it occurs as *tetradymite* in Cumberland. An alloy of bismuth with 3 p.c. arsenic occurs at Palmbaum near Marienberg.

Bismuth sulphide is widely distributed in small quantities, being found in Saxony, Sweden, South Australia, America, and Cumberland. A sulphide of bismuth, copper, and lead occurs as *needle ore*, *aciculite* or *patrinite*.

As oxide, or *bismuth ochre*, it is found as a yellow substance, frequently as a coating on other minerals, associated with iron and other impurities, at Schneeberg, Joachimsthal, Beresof in Siberia, and in New South Wales. The principal ore in Bolivia, which is stated by Domeyko to be the richest country in bismuth, is a compact earthy hydrated oxide.

Bismuth occurs as carbonate or *bismuthite*, usually containing carbonates of iron and copper, at Meymac, with antimony, arsenic, lead, iron, and lime; in Mexico, whence it is imported to this country; in North Carolina, and other localities. Of late years considerable deposits of bismuth ores have been found in many places in America, but they have been very little worked.

Extraction.—At Schneeberg in Saxony the ore worked is principally metallic bismuth occurring in ores which contain silver, lead, tin, and arsenic in gneiss and clay-slate.

The ore, which contains from 7 to 12 p.c. bismuth, is sorted by hand as far as possible from the gangue before treatment. The old method of *liquation* or 'sweating' is still used, but has now been largely superseded by smelting processes, in which the metal is much more perfectly extracted.

Liquation.—In this process the metal is separated as far as possible from the gangue by melting at a low temperature. The picked ore is broken into pieces as large as a hazel nut, and placed in inclined iron tubes in charges of about 12 cwts., sufficient space being left in the tube for stirring the ore from the upper end (Figs. 1, 2, 3). The tubes are closed at the upper ends by plates of iron, and at the lower ends by similar plates containing circular apertures through which the molten metal may run. The ends of the tubes project slightly beyond the walls of the furnace, the upper over a tank and the lower ends over iron crucibles which contain powdered charcoal, and which are gently heated from below by a small charcoal furnace. The tubes are heated so as to cause the metal to flow easily, and in about 10 minutes the bismuth commences to pass out into the crucibles, being there covered by the charcoal and thus protected from oxidation. The ore is occasionally stirred with an iron rod from the upper end, and in from 30 to 60 minutes the operation is completed. The residues, *graupen* or *bismuth barley*, are raked from the upper end into the tank, and at once replaced by fresh ore. In this manner only about two-thirds of the bismuth is extracted. 20 cwts. of ore require 63 cubic feet of wood. The contents of the pots are removed by ladles to moulds and cast into ingots of 25 to 50 lbs. weight.

Sulphurous ores are usually roasted to remove sulphur, and then smelted with iron (to remove the last traces of sulphur), carbon, slag, sodium carbonate, limestone, and sometimes fluor-spar. The regulus of bismuth thus obtained is fused on an inclined iron plate and run down, leaving a dross containing much of the impurity. Bismuth ores are sent from Joachimsthal, and worked by this process at Schneeberg.

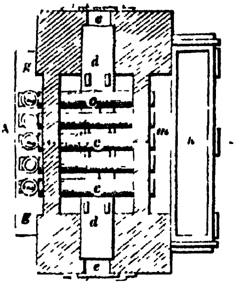


Fig. 1.

The following analyses of two typical samples show the composition of commercial bismuth: From Saxony—Bismuth, 99·77 p.c.; copper, 0·08; silver, 0·05; sulphur, 0·10; iron, trace From Joachimsthal—Bismuth, 99·32 p.c.; lead, 0·30; silver, 0·38; iron and copper, traces; sulphur, none

At Joachimsthal a method devised by R Vogel is used (Dingl. poly. J. 167, 187) for extracting bismuth from ores free from lead. The ores, which usually contain from 10 to 30 p.c. bismuth, are mixed, according to their richness, with 23 to 30 p.c. iron turnings, 15 to 50 p.c. sodium carbonate (according to the amount of gangue present), 5 p.c. lime, and 5 p.c. fluor-spar. The mixture is introduced in charges of about 1 cwt. into clay crucibles, 23 inches high and 16 inches wide at the mouth, covered and heated in a wind furnace to tranquil fusion, and poured into conical moulds. The liquid separates into three layers, the upper consisting of slag, the second of a speiss containing the arsenic, sulphur, nickel, cobalt, and iron, and most of the other impurities, with about 2 p.c. of bismuth, and the lower consisting of a regulus of nearly pure bismuth. The metal is again fused and remoulded (*see* Kerl, Handb. der Met. Hüttenkunde).

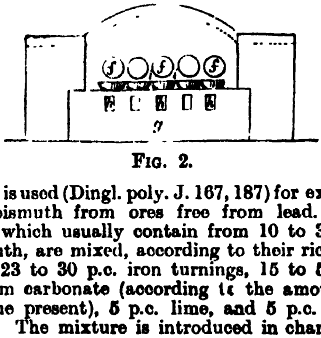

Fig. 2.

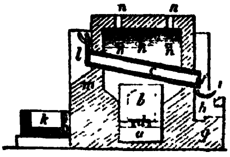

Fig. 3.

A similar process has been adopted by Patera (J. 1862, 646) for the extraction of bismuth from refinery residues.

In France the carbonate of bismuth imported from Meymac is dissolved in the minimum quantity of hydrochloric acid and pieces of iron inserted in the slightly acid liquid. The bismuth is thus precipitated as a black powder, which is well washed and fused in a plumbago crucible under a layer of charcoal at as low a temperature as possible (Ad. Carnot, Ann. Chem. Phys. [5] 1, 405; and Bull. Soc. chim. 21, 114).

Ores of bismuth averaging 60 p.c. bismuth are imported into England, principally from Adelaide, South Australia, and from Mexico. They are usually fused in plumbago pots with borax, sodium carbonate, and a little crude tartar.

For the extraction of bismuth for pharmaceutical purposes from sulphurous ores, Valenciennes roasts the ore on the level bed of a reverberatory furnace for 24 hours with the occasional addition of charcoal and frequent stirring with an iron rabble. When the sulphur has thus been evolved, the ore is mixed with about 30 p.c. charcoal, and a mixture of chalk, salt, and fluor-spar, and again fused in a reverberatory furnace. From 5 to 8 p.c. of the bismuth is lost by this process, but this is compensated by the extra purity of the product. By subsequent fusion with nitre, the antimony, arsenic, and sulphur are removed, and by the ordinary wet methods the lead, copper, and silver are eliminated (M. A. Valenciennes, Ann. Chim. Phys. [5] 1, 397).

H. Tamm (Chem. News, 25, 85) states that bismuth can be separated from ores containing much copper by fusion with an alkaline flux containing free sulphur, in which case the copper remains unreduced. He recommends a mixture of 5 parts sodium carbonate, 2 salt, 1 sulphur, 1 carbon, to be mixed in about equal proportions with the ore. The bismuth produced is stated to be much more free than usual from arsenic, antimony, and lead, but about 8 p.c. of the total bismuth is lost.

The bismuth present in small quantities in lead, copper, and silver ores frequently becomes concentrated in the secondary products of the metallurgical processes and may then be profitably extracted. In the oxidation of silver-lead containing bismuth, the lead oxidises much more rapidly than the bismuth, and at the close of the cupellation a blackish litharge rich in bismuth is obtained, from which that metal may be extracted by further concentration and acid treatment (J. 12, 711). In this manner bismuth becomes concentrated in the *blicksilber* in the treatment of silver ores at Freiberg, and passes into the hearth bottoms, as much as 25 p.c. being sometimes so absorbed. When the hearths contain sufficient bismuth to be profitably extracted, they are finely ground and treated with hydrochloric acid, with the formation of bismuth chloride. Water is added to the solution to precipitate the metal as oxychloride, and the precipitate is collected, washed, dried, and reduced to metal by fusion with charcoal, sodium carbonate, and powdered glass (*v.* Phillips's Metallurgy).

Several proposals have been made for the extraction of bismuth by wet methods. Becker (Fr. Pat. 366439, 1906) suggests the treatment of sulphide ores with a solution of an alkali or alkaline earth hyposulphite. The solution thus obtained is treated with alkali sulphides, and the resulting precipitate of bismuth sulphide is dried and smelted as described above.

Both Becker (*ibid.*) and Ranald (Eng. Pat. 16622, 1898) have patented the use of a solution of ferric chloride as a solvent for bismuth sulphide and the subsequent precipitation of metallic bismuth from the solution by means of iron or zinc, or by electrolysis.

Eulert (Rev. Prod. Chim. 4, 164) employs a mixture of sulphuric acid, water, common salt, and potassium nitrate as the extracting liquor, and the process can be made continuous. The bismuth is finally obtained as the oxychloride, which can be sold or smelted for the metal.

On the extraction of bismuth from its ores, *v.* also Winckler (Ber. Entwick. Chem. Ind. 1, 953).

Purification.—The crude bismuth produced by the above methods contains a variety of impurities, from which it is important in many cases to separate it. These impurities are sulphur, arsenic, antimony, copper, nickel, cobalt, silver, gold, lead, and iron.

Sulphur and arsenic may be removed by fusion with $\frac{1}{10}$ of its weight of potassium nitrate, with constant stirring at a temperature slightly above the temperature of fusion; the nitre soon oxidises the impurities and a little of the bismuth, forming with them a slag which rises and solidifies at the surface. For the complete removal of these impurities a second fusion is frequently necessary.

C. Méhu (Pharm. J. [3] 4, 341) recommends the following process for the removal of sulphur and arsenic. The metal is heated considerably above the melting-point in a vessel so as to expose a large surface, and the oxide is removed to the sides as fast as it forms until about one-fourth of the metal has become oxidised; the greater part of the sulphur and arsenic will then have passed off as oxides. The mass is cooled, pulverised, and mixed with charcoal, dried soap, and potassium carbonate (free from sulphate), about one-fourth of the original weight of the metal, in a crucible, covered with charcoal, and heated to redness for one hour. Arsenic may also be mostly removed by fusion for a considerable time under a layer of charcoal. Arsenic, sulphur, and most of the antimony may be eliminated by fusion at a bright-red heat under borax, stirring with a rod of iron until the action ceases. The iron combines with the impurities and rises as a difficultly fusible slag to the surface from beneath which the still liquid metal may be poured after partial cooling.

For the complete removal of *antimony*, 2 or 3 parts of bismuth oxide for each part of antimony supposed present are fused with the metal. The oxide of bismuth then gives up its oxygen to the antimony, becoming itself reduced and the antimonious oxide floats on the surface.

Hugo Tamm (Chem. News, 25, 85) recommends for the removal of *copper* the fusion of the metal at a low temperature under 1 part of a mixture of 8 potassium cyanide and 3 sulphur. When the action has ceased the mass is stirred with a clay (not iron) rod, cooled until the flux has set, and the metal poured out from beneath. If impure cyanide is used, a relatively larger quantity is required.

Iron may be completely removed, according to H. Türach (J. pr Chem. [2] 14, 309), by fusion under a layer of potassium chlorate containing from 2 to 5 p.c. sodium carbonate.

From *silver* bismuth may be separated by cupellation and subsequent reduction of the bismuth oxide so produced, or the metal may be dissolved in nitric acid, the silver precipitated with hydrochloric acid, the solution filtered, and the basic salt of bismuth precipitated by excess of water, and reduced to metal.

Silver can be partially removed from bismuth by a process resembling Pattinson's process for lead (Schneider, J. pr. Chem. [2] 23, 75).

Lead may be precipitated from a nitric acid solution of the metal by the addition of sulphuric acid, and the bismuth recovered as already described. A method commonly used is to fuse the impure metal with bismuth oxychloride, from which the lead liberates bismuth, itself becoming combined with oxygen and chlorine.

A number of investigations on the refining of bismuth have been conducted by E. Matthey, and the methods he proposes are given separately below, inasmuch as they possess the merit of simplicity and have been thoroughly tested on a large scale.

Arsenic is removed completely by maintaining molten bismuth at a temperature of 510°–520° for some time. There is only a very slight loss due to oxidation (E. Matthey, Chem. News, 67, 63).

Antimony is separated by melting the metal and maintaining the temperature at 350°. An alloy of bismuth and antimony, containing over 30 p.c. of the latter, rises to the surface of the metal, giving it an 'oily' appearance, and can be skimmed off. A complete removal of the antimony is thus effected (E. Matthey, *l.c.*).

Copper. For the separation of copper from bismuth which has been previously freed from arsenic, antimony, lead, &c., E. Matthey (Roy. Soc. Proc. 43, 172) recommends its fusion with bismuth sulphide. The pure metal obtained amounts to 90 p.c. of the crude material, while the remaining bismuth sulphide, containing copper sulphide, may be resmelted.

Alkali sulphides may be substituted for the bismuth sulphide in the above operation (E. Matthey, Proc. Roy. Soc. 49, 78).

Lead may be separated from the fused metal by repeated crystallisations, the alloy of bismuth and lead melting at lower temperatures than the purer bismuth. E. Matthey has thus by four crystallisations reduced the percentage of lead from 12 to 0·4 p.c. (Proc. Roy. Soc. 42, 93).

For the separation of *gold* and *silver*, E. Matthey (Proc. Roy. Soc. 42, 89, 94) recommends the addition of 2 p.c. zinc to the molten metal. The mass is gradually cooled and the surface crust removed. This operation is repeated, whereby the whole of the precious metals are concentrated in the skimmings. On fusing these in a crucible with borax, the gold and silver are freed from impurities by the action of the oxide of bismuth, and sink to the bottom. To separate the last traces of these metals from the slag, it is again fused with bismuth.

A. Mohr states (Elektrochem. u. Met. Ind. 1907, 5, 314) that an electrolytic method has been used with success for the purification of a Mexican lead-bismuth alloy containing 81·1 p.c. lead and 14·5 p.c. bismuth, together with small amounts of antimony, iron, zinc, arsenic, silver, and gold. First the metal is made the anode in an electrolyte containing 6 p.c. lead fluosilicate and 14 p.c. hydrofluosilicic acid. The lead is deposited on a cathode of pure lead, and contains only 0·01 p.c. bismuth. The anode slimes are fused with sodium hydroxide and carbonate, and the metal, containing 94 p.c. bismuth, cast into anodes, which are then used in a second electrolysis, using a solution of bismuth chloride (about 10 p.c.) and free hydrochloric acid (about 10 p.c.). The cathodes are of Acheson graphite, and are placed on the floor of the cell. The current used is 20 amp. per sq. ft. at the cathode, and 60 amp. per sq. ft. at the anode, with a P. D. at the terminals of 1·2 volts. The resulting bismuth is 99·8 p.c. pure, the remaining 0·2 p.c. consisting chiefly of silver. (*See* also Zahorski, Hurter and Brock, Eng. Pat. 22251, 1895.)

Chemically pure bismuth is best prepared by dissolving the commercial metal in nitric acid, decanting from any residue, and adding excess of water, whereby the bismuth is precipitated as basic nitrate, leaving the impurities in solution. The precipitate is well washed by decantation, dried, mixed with black flux or other reducing agent which produces a readily fusible flux, and reduced at a gentle heat in a crucible.

Properties.—Bismuth is a greyish-white crystalline metal of distinctly red tinge when compared with whiter metals such as zinc or antimony. It is very brittle and easily powdered, and a bad conductor of heat and electricity. Its tenacity is very small, a rod 2 mm. in diameter will just support a weight of 14·19 kilos. (Muschenbroeck). It forms fine obtuse rhombohedral crystals, which approach very closely to the form of cubes. It has also been obtained in the form of acicular needles, which are really elongated hexagonal prisms (Heberdey, Ber. Akad. Wien. 104, i. 254). Bismuth melts at 271° (Mylius and Groschuff), and boils at a temperature between the melting-point of copper and nickel, *i.e.* between 1084° and 1450° (Carnelley and Carlton Williams), condensing in laminæ. The vapour density at temperatures between 1600° and 1700° is 11, which corresponds to that calculated for a mixture of monatomic and diatomic molecules (Meyer, Ber. 1889, 22, 726). Its sp.gr. at 12° is 9·823. W. Spring has shown that by the exposure of bismuth of density 9·804 to a pressure of 20,000 atmospheres, the density was raised to 9·856: a second compression still further increased the density to 9·863 (Ber. 16, 2724). It is stated that by careful hammering its density may be raised to 9·88.

Bismuth expands in cooling. Tribe (Chem. Soc. Trans.) has shown that this expansion does not take place until after solidification.

According to Cohen and Moesveld, bismuth exists in two enantiotropic modifications, the transition temperature being 75°/760 mm. The transformation of the form stable below this temperature (α) into the other modification (β) is accompanied by considerable increase in volume. The β-variety can exist in the metastable condition below the transition point.

Exposed to dry air, bismuth remains unaltered at the ordinary temperature, but in moist air or in contact with water it becomes coated with oxide. When heated in air it burns with a bluish flame, evolving yellowish fumes of oxide. At high temperatures it decomposes water.

Cold sulphuric acid has no action, but the hot concentrated acid dissolves bismuth. Hydrochloric acid acts but slowly, and Ditte and Metzner have shown (Compt. rend. 115, 1303) that this action can only take place in presence of oxygen. Nitric acid, dilute or strong, dissolves it readily, with the formation of nitrate. Powdered bismuth thrown into chlorine gas ignites with the formation of trichloride. It also unites directly with bromine, iodine, and sulphur.

When comparatively pure, bismuth crystallises readily. To obtain it in the form of fine crystals it is melted and allowed to cool until a crust has formed; the crust is pierced on opposite sides with a hot iron, and the still liquid portion poured through one of the openings. On careful removal of the crust the sides of the vessel are found covered with crystals, frequently resembling hollow pyramidal cubes like those of salt, but which are in reality obtuse rhombohedra. Their iridescent lustre is due to a very thin film of oxide which shows the colour characteristic of thin plates.

Bismuth can be obtained in the colloidal state by reducing a solution of the nitrate with stannous chloride, or by the action of hypophosphorus acid on bismuth oxychloride (Gutbier and Hofmeyer, Zeitsch. anorg. Chem. 44, 225).

Bismuth is the most diamagnetic substance known, a bar of the metal placing itself equatorially between the poles of a magnet, *i.e.* at right angles to the position taken up by a bar of iron. Bismuth also occupies an extreme place in the thermo-electric series, being used with antimony in the preparation of the most delicate thermopiles.

Analysis.—All compounds of bismuth, when mixed with carbon or other reducing agent and fused before the blowpipe, give a *brittle* white bead of metal and a yellow incrustation on the charcoal, darker than that of oxide of lead.

A very good dry test for bismuth is that due to von Kobell. The substance is heated on charcoal with a mixture of potassium iodide and sulphur, when, if bismuth is present, a brilliant scarlet incrustation is obtained.

Salts of bismuth in solution give, on addition of excess of water, a white precipitate of basic salt, which is insoluble in tartaric acid, and blackens with sulphuretted hydrogen (distinction from antimony).

Metallic iron, copper, lead, and tin precipitate metallic bismuth from solutions.

A qualitative test for bismuth proposed by Reichard (Chem. Zeit. 28, 1024) is the addition of a brucine salt, or, better, brucine itself to the solution. In presence of bismuth a deep-red colour is produced which is distinguished from that given by nitric acid by the fact that it becomes deeper on heating, whereas the colour given by nitric acid turns to yellow.

Estimation.—Bismuth may be separated from copper, cadmium, mercury, and silver, lead having been removed previously by precipitation as sulphate, by the following method, due to Stähler and Scharfenberg (Ber. 38, 3862).

The solution, which may contain hydrochloric acid, and should contain about 0·1–0·2 gram of bismuth, is diluted to 300–400 c.c., and any precipitate redissolved by the cautious addition of nitric acid. This solution is heated to boiling, and treated with a boiling 10 p.c. solution of trisodium phosphate Na_3PO_4 (obtained by mixing equivalent amounts of sodium hydrogen phosphate and caustic soda). In presence of much hydrochloric acid, a considerable excess of the phosphate must be used, but, should the solution become alkaline, nitric acid must be added. After boiling the whole for some time, the precipitate is allowed to settle, and the supernatant liquid is tested with sodium phosphate. If precipitation is complete, the precipitate is collected hot on a Gooch crucible, washed with 1 p.c. nitric acid, containing ammonium nitrate, dried at 120°, and finally heated over a bunsen burner, and weighed as bismuth phosphate $BiPO_4$. The precipitate is very hygroscopic: suitable precautions must therefore be taken in weighing it.

A modification of this method, which renders it suitable for the separation of bismuth from considerable amounts of mercury, has been described by Stähler (Chem. Zeit. 31, 615).

A volumetric method for the estimation of bismuth, for which considerable accuracy is claimed, is the chromate method of Löwe as modified by Rupp and Schaumann (J. Soc. Chem. Ind. 1902, 1558).

H. W. Rowell has published a method (J. Soc. Chem. Ind. 1908, 102) for the estimation of small quantities of bismuth in ores, &c. The method is colorimetric, depending on the yellow colour produced when potassium iodide is added to a solution of the bismuth compound in sulphuric acid (*see* also Eng. and Mining Jour. 1901, 459).

An account of other methods used for the estimation of bismuth will be found in the article on ANALYSIS.

For the dry assay of bismuth ores the fluxes used must depend on the composition of the ore. Thus with ores containing metallic bismuth or that metal as oxide, sulphide, carbonate, &c., a flux consisting of a mixture of 2 parts potassium or sodium carbonate, 1 part sodium chloride, and a proper quantity of argol or potassium cyanide or charcoal powder, will be useful (Tamm); with the addition, where much earthy matter is present, of borax. Where much *copper* is present, Tamm advises the use of one part of the ore mixed with one part or less of a mixture of sodium carbonate 1, salt 2, sulphur 2, charcoal powder 1 part. The exact proportions in which these fluxes are most useful must be learned by experience.

Alloys of Bismuth.

Bismuth unites readily with most metals, forming alloys which, with few exceptions, are not of commercial importance.

Tin and Lead. The alloys of bismuth with these two metals are of special interest. They are extremely fusible, and on account of their expansion on cooling they take a very fine impression, being largely used for electrotype moulds, &c.

An alloy of 1 bismuth, 2 tin, 1 lead is used as a soft solder by pewterers, and for the cake moulds for toilet soap. An expensive but effective alloy for stereotype clichés and metallic writing pencils contains 5 bismuth, 2 tin, 3 lead; it melts at 91·66°.

A thorough physico-chemical investigation of these ternary alloys has been made by Charpy (Compt. rend. 126, 1569), whose memoir should be consulted for details. He finds that the eutectic mixture contains 32 p.c. lead, 16 p.c. tin, and 52 p.c. bismuth, and has m.p. 96°. Such alloys are used to a considerable extent in safety plugs for boilers and for automatic sprinklers.

The varieties of *fusible metal* contain these three metals, with the addition sometimes of cadmium, which still further lowers the melting-point. A table of the most important of these alloys is given below:

Name of alloy	Bismuth	Lead	Tin	Cadmium	Melting-point	Temperature of maximum density
Newton's . .	50	31·25	18·75	—	94·5°	—
Rose's . . .	50	28·10	24·1	—	95°	55° (Spring)
D'Arcet's . .	50	25·0	25·0	—	94°	—
Lichtenberg's . .	50	30·0	20·0	—	—	—
Wood's . .	50	25·0	12·5	12·5	65°	25° (Spring)
Lipowitz's . .	50	26·9	12·78	10·4	65°	38·5° („)
Guthrie's 'Eutectic'	50	20·55	21·10	14·03	—	—

The action of heat on fusible metal is somewhat anomalous. Taking Lipowitz's alloy as a typical example, we find (from Spring's table of densities at different temperatures) that this alloy whilst cooling contracts very rapidly at the solidifying point (65°), contracts slowly from that temperature to 38·5°, expands thence to about 25°, and again contracts, occupying at 0° the same volume as at 46°.

For this reason, in taking a cast or impression with fusible metal, it is advisable to allow the alloy to cool to a pasty mass before placing in the mould (*v.* further, Godefroy, Fremy's Encycl. Chimique, art. 'Bismuth,' 1888, 24–30).

Mercury dissolves a considerable amount of bismuth without solidifying. The amalgam containing 1 bismuth and 4 mercury adheres strongly to smooth surfaces such as glass. One part bismuth and 2 parts mercury forms a pasty amalgam. The alloy consisting of D'Arcet's alloy and mercury, for which 250 parts of mercury are used for 100 parts of D'Arcet's alloy, is used, on account of its low melting-point, for taking casts of anatomical preparations. The alloy is introduced in the liquid state, allowed to solidify, and the fleshy parts dissolved by solution of caustic soda. This alloy is also used for silvering glass tubes, &c.

Bismuth alloys with the *alkali metals*; Johannis (Compt. rend. 114, 585) has obtained an alloy of bismuth and sodium, of the formula $BiNa_3$, by the action of a solution of sodium in liquid ammonia on bismuth. The compound forms small, dark-grey crystalline laminæ, m.p. 775°, and takes fire in the air. It may easily be prepared by slowly adding bismuth to sodium melted beneath paraffin heated to 300°–310° when the crystals separate out. An alloy with potassium, K_3Bi, may be prepared in a similar manner (Vournasos, Ber. 1911, 44, 3266). The alkali bismuthides are readily oxidised in the air, turning black, and burn easily, giving a red residue of alkali bismuthate. They absorb hydrogen at 350°, forming a product which is decomposed by water, evolving hydrogen. They decompose water slowly at the ordinary temperature, and more rapidly on boiling, and reduce copper salts in solution to metallic copper.

A. H. Gallatin (Phil. Mag. [4] 38, 57) has prepared an alloy of bismuth with *ammonium* (?). He scattered ammonium chloride over bismuth sodium alloy, and added water. The alloy swelled and then contracted. On plunging in water or heating, a mixture of hydrogen and ammonia was evolved. After drying *in vacuô* over sulphuric acid, it evolved 27 volumes of gas on heating.

COMPOUNDS OF BISMUTH.

Bismuth forms two well-defined classes of compounds, in which it is a diad and a triad respectively. There are indications of the existence of some more highly oxidised compounds, but, assuming their existence to be proved, their constitution can be more easily explained by the assumption of a higher valency for oxygen than by assuming bismuth to be a pentad.

Hydride. A gaseous hydride of bismuth appears to be formed by the solution of an alloy of bismuth and magnesium with thorium-C or radium-C in 0·2 N hydrochloric acid. It is fairly stable at ordinary temperatures, but is decomposed at a red heat and forms a mirror in the Marsh apparatus similar to antimony (Paneth, Ber. 1918, 51, 1704; Paneth and Winternitz, *idem.* 51, 1728).

Oxides. Only two oxides of bismuth, the dioxide and the trioxide, are definitely known. The statements of Deichler, Hauser, and Vanino and Treubert, that bismuthic acid and tetroxide exist, have been controverted by Gutbier and Bunz (Zeitsch. anorg. Chem. 48, 162; 49, 432; 50, 210; 52, 124); Moser (Zeitsch. anorg. Chem. 50, 33) states that the addition of hydrogen peroxide to a bismuth salt precipitates only bismuth trioxide. According to Hollard (Compt. rend. 136, 229) a peroxide of the formula Bi_2O_7 is formed during the electrolysis of a solution of bismuth sulphate, but this observation has not been confirmed. It is doubtful whether a suboxide exists.

The trioxide and the compounds derived from it are the only ones of commercial importance.

Bismuth trioxide Bi_2O_3 occurs in nature as *bismuth ochre*. It is best prepared by heating the subnitrate of bismuth until red fumes cease to be evolved. It may also be prepared by exposing the metal to a red-white heat in a muffle. The metal then burns and forms the oxide, which condenses as a yellow powder. Bismuth oxide thus obtained is a pale-yellow amorphous substance, which melts at a red heat to a glass without change of weight. Its sp.gr. is 8·21. Heated in sulphur dioxide it is ultimately converted into a basic sulphate $4Bi_2O_3,3SO_3$.

The oxide can be obtained crystalline, and has been shown to be isodimorphous with antimony trioxide (Muir and Hutchinson, Chem. Soc. Trans. 1889, 143).

It is used for glass and porcelain staining; as an addition to certain fluxes to prevent the production of colour; and in gilding porcelain, being mixed in the proportion of 1 part oxide to 15 parts of the gold.

The darkening of the commercial substance on exposure to light is due to the presence of a trace of silver.

A **hydrated bismuth oxide** Bi_2O_3,H_2O is precipitated as a white powder on addition of caustic alkali to a bismuthous salt, such as the nitrate; but Thibault (J. Pharm. Chim. 12, 559) has shown that under these conditions the product contains appreciable quantities of oxy- acid salts. By precipitating the hydroxide from an alkaline solution by the addition of acid, a pure product is obtained which on drying yields the pure oxide. It dissolves in alkali in presence of glycerol. On addition of sugar to the solution, metallic bismuth is precipitated, whilst arsenic, if present, remains in solution. Lowe (Zeitsch. anal. Chem. 22, 498–505) recommends this method for the preparation of pure bismuth for pharmaceutical purposes.

Bismuth carbonate $CO(O{\cdot}BiO)_2$ is best prepared by triturating powdered bismuth nitrate with mannitol under water until solution is obtained, when a strong solution of potassium carbonate is added. Bismuth carbonate separates as a fine heavy powder which is washed with water, alcohol and ether, and dried in the air (Vaning, Pharm. Zentr-h. 1911, 52, 761).

Bismuth nitrate $Bi(NO_3)_3,5H_2O$ is prepared by dissolving bismuth or its oxide or carbonate in moderately strong nitric acid. The concentrated solution is filtered, if necessary, through asbestos, and deposits on cooling large deliquescent crystals, which are caustic and melt in their water of crystallisation when gently heated.

When the bismuth used for the preparation contains arsenic, excess of nitric acid should be used for the solution; the arsenic is then oxidised to arsenic acid, and combines with its equivalent of bismuth, being precipitated as arsenate of bismuth. R. Schneider (J. pr. Chem. 20, 418–434) recommends the following proportions: 2 kilos. bismuth, 10 kilos. *hot* nitric acid (75° to 90°); when the action is finished the liquid is decanted from the sediment, which contains all the arsenic. On addition of water to the solution a white precipitate of basic nitrate falls, the constitution of which varies with the amount of water used. This was formerly known as *magistery of bismuth*, and is now called *flake* or *pearl white*, the latter name being also applied to the oxychloride of bismuth.

For pharmaceutical purposes the subnitrate is prepared as follows: Dissolve 2 parts of bismuth in 4 parts nitric acid of sp.gr. 1·42, diluted with 3 parts water, pour from deposit, if any, evaporate to one-third the bulk, and pour into 80 parts of water, filter, wash and dry the precipitate at a temperature not above 55°.

It is a pearly-white powder consisting of minute crystalline scales. It is employed as a flux for certain enamels, augmenting their fusibility without imparting any colour, and on this account is used as a vehicle for metallic oxides. For the colourless iridescent glaze on porcelain the basic nitrate is rubbed with resin and gently heated with lavender oil; by the addition of coloured oxides, yellow and other colours are produced. It is also used like the oxide and in the same proportions for gilding porcelain, and to some extent as a cosmetic under the names *blanc de fard* and *blanc d'Espagne*. It is largely used in medicine.

When prepared from impure metal it is liable to contain arsenic, lead, and silver; tellurium has also been suspected (Pharm. J. 3, No. 287). To test for arsenic, heat a little of the nitrate in a tube until brown fumes cease to be evolved. Add a small crystal of potassium acetate, and again heat; in presence of a trace of arsenic the odour of kakodyl is observed (A. Glenard, J. de Pharm. [4] 1, 217).

Bismuth chloride $BiCl_3$. This compound is produced when finely powdered bismuth is thrown into chlorine gas or when chlorine is passed over the heated metal. It is also formed by the solution of bismuth in *aqua regia* and evaporation of the liquid; or by distilling a solution of the oxide in hydrochloric acid, changing the receiver when all the water has distilled over.

It is a white, easily fusible solid, which absorbs moisture from the air, forming a crystalline hydrate. By the addition of water a white precipitate of basic chloride or oxychloride is produced corresponding to BiOCl, though its composition varies considerably.

The **oxychloride of bismuth** is, however, usually prepared by pouring a solution of the normal nitrate into a dilute solution of common salt, forming oxychloride of bismuth and sodium nitrate.

It is a white pearly powder known as *pearl white*, and is used as a pigment, and in the preparation of a very fine yellow pigment known as Merimée's antimony yellow (*v.* ANTIMONY). For double salts of bismuth chloride and chlorides of bivalent metals, *see* Weinland, Alber and Schweiger, Arch. Pharm. 1916, 254, 521.

Bismuth chromate *v.* under Chromium.

Bismuth sulphite, produced by the action of sulphurous acid on bismuth carbonate, or by double decomposition between a bismuth salt and an alkali sulphite, is a white crystalline powder, and is used in medical practice to check intestinal fermentation, and in cases of worms.

The **organic compounds** of bismuth have found many applications in medicine and surgery.

Bismuth salicylate is prepared, according to Causse (Compt. rend. 112, 1220), by adding a solution of a neutral salicylate to a solution of bismuth nitrate in a minimum amount of hydrochloric acid. Considerable quantities of ammonium chloride are added to the solutions before they are mixed. Hydrated bismuth salicylate $Bi(C_7H_5O_3)_3,4H_2O$ is thus obtained as a white crystalline powder, insoluble in cold water.

A better method of preparation, due to

Thibault (Bull. Soc. chim. 25, 794), consists in treating the bismuth oxide obtained by precipitation from 15 parts of bismuth nitrate with a solution of 10 parts of salicylic acid in 200 parts of water and heating on the water-bath till the action is complete. The product is decanted, washed with cold alcohol, and dried at 100°. It is thus obtained in rose-grey crystals, which are soluble without decomposition in cold alcohol, ether, or in a saturated aqueous solution of salicylic acid.

Martinotti and Cornelio (Bull. Chim. Pharm. 40, 141) point out that commercial preparations of the salt vary very much in composition, the amount of acid ranging from 5 to 67 p.c., and that of bismuth oxide from 37 to 79 p.c.

Kebler, however, has shown (Pharm. J. 64, 591) that the alcoholic test of the British Pharmacopœia is too stringent, as hot alcohol decomposes the salt. A more trustworthy method of testing of bismuth salicylate for free acid consists in extracting it with 90 p.c. benzene and filtering the extract into dilute ferric chloride solution (1 in 3000), when a violet ring is produced at the junction of the two liquids if free acid is present.

Basic bismuth gallate, known commercially as '*dermatol,*' is prepared as follows: 306 grams of basic bismuth nitrate is dissolved in 328 grams nitric acid of strength 38°B., diluted with 200 grams water. The solution is filtered through glass-wool, evaporated down to 600 grams, and allowed to crystallise. The product is dissolved in 980 grams glacial acetic acid, diluted with 8 litres of water, and then mixed with a solution of 188 grams crystallised gallic acid in 8 litres of water. The precipitate of bismuth gallate thus produced is washed five or six times with water, pressed, and dried (Hartz, Pharm. Rundsch. 12, 182).

Another method consists in treating a solution of bismuth nitrate in nitric acid with a solution of gallic acid in 70 p.c. alcohol, nearly neutralising with sodium hydroxide or sodium carbonate, and finally adding considerable quantities of sodium acetate or diluting largely with water. The compound is thus obtained as a yellow precipitate, which is collected and dried (Eng. Pat. 6234, 1891).

The empirical formula of the substance is $BiC_7H_7O_7$, and Thibault (J. Pharm. Chim. 14, 487) considers that it is really bismuthogallic acid, adducing in favour of this view the fact that with alkalis it forms salts of which potassium bismuthogallate $K_3BiC_7H_5O_7$ is a type.

A general method for the preparation of bismuth salts of organic acids is the solution of freshly precipitated bismuth hydroxide in a solution of the acid (Fischer and Grützner, Arch. Pharm. 1894, 232, 460; *v.* also Telle, *ibid.* 1908, 246, 484, for the preparation of *bismuth lactate* by this method).

Basic bismuth dibromohydroxynaphthoate, which has been suggested as a substitute for iodoform in surgical dressings (G. Richter, Apoth. Zeit. 1908, 23, 600), is obtained by a similar method. β-hydroxynaphthoic acid is brominated in acetic acid solution, and the recrystallised product heated with bismuth hydroxide. The salt is a finely crystalline, yellow, odourless, insoluble powder, which is unaffected by heating to 110°.

Bismuth chrysophanate ('*Dermol*')

$$Bi(C_{15}H_9O_4)_3 \cdot Bi_2O_3(?)$$

a yellowish-brown powder, is, according to Merck, a mixture of impure chrysarobin and bismuth hydrate.

Compounds of bismuth with phenols are obtained by double decomposition between an alkaline salt of the phenol and a salt of bismuth, such as the nitrate. Among those that have been made commercially may be mentioned:

orphol (the β-naphthol compound)

$$C_{10}H_7OBi(OH)_2+Bi_2O_3+H_2O\,;$$

xeroform (the tribromophenol compound)

$$(C_6H_2Br_3O)_2Bi \cdot OH+Bi_2O_3\,;$$

helcosol (the pyrogallate)

$$[C_6H_3(OH)_2O]_2 \cdot Bi \cdot OH.$$

An important pathological application of bismuth salts is their administration internally in order to outline parts of the body in Röntgen ray work.

Bismuth oxyiodosubgallate $C_6H_2(OH)_3 \cdot CO_2 \cdot BiI(OH)$, '*airol,*' is prepared by heating together in 50 parts of water 35 parts bismuth oxyiodide, and 18·8 parts gallic acid until the product is a greyish-green powder. It is used as a substitute for iodoform.

Other compounds of bismuth to which trade names have been given are:

Bismal, bismuth methylenedigallate, obtained by the general method from the hydroxide and methylenedigallic acid.

Markasol, bismuth borophenate.

Thioform, bismuth dithiosalicylate, used as a substitute for iodoform (*v.* SYNTHETIC DRUGS).

Tertiary aromatic bismuthines and their halogen derivatives have been prepared by Challenger (Chem. Soc. Trans. 1914, 105, 2210). Other organo-bismuth compounds have been described by Löwig, Annalen, 1850, 75, 355; Breed, *ibid.* 1852, 82, 106; Dunhaupt, *ibid.* 1854, 92, 371; Michaelis and collaborators, Ber. 1887, 20, 52, 54, 1516; 1888, 21, 2035; Gillmeister, Ber. 1897, 30, 2843; Pfeifler and Pietsch, *ibid.* 1904, 37, 4620; Hilpert and Grüttner, *ibid.* 1913, 46, 1685; Hilpert and Ditmar, *ibid.* 3741; Ehrlich and Karret, *ibid.* 3564; Vanino and Mussgnug, Ber. 1917, 50, 21.

BISMUTHINITE or **BISMUTH-GLANCE.** Native bismuth sulphide, Bi_2S_3, occurring as acicular or bladed orthorhombic crystals or lamellar masses, very like stibnite (Sb_2S_3) in appearance. In Queensland and Bolivia it is found in sufficient abundance to be mined as an ore of bismuth. L. J. S.

BISMUTITE. Basic bismuth carbonate, containing about 90 p.c. Bi_2O_3; formula perhaps $Bi_2O_3 \cdot CO_2 \cdot H_2O$. It is a yellowish earthy material, and presenting such an appearance is surprisingly heavy (sp.gr. variously given as 6·9 and 7·6). It occurs as an alteration product of native bismuth, and in Bolivia is an important ore of this metal. L. J. S.

BISMUTOSE *v.* SYNTHETIC DRUGS.

BISTRE *v.* PIGMENTS.

BISULPHIDE OF CARBON *v.* *Carbon disulphide*, art. CARBON.

BITTER ALMOND OIL *v.* BENZALDEHYDE, and OILS, ESSENTIAL.

BITTER APPLE *v.* COLOCYNTH.

BITTER SWEET *v.* DULCAMARA.

BITTER WOOD *v.* QUASSIA.

BITTERN. The mother liquor which remains after the crystallisation of common salt from sea-water, or the water from salt springs. It contains soluble magnesium salts, bromides, and iodides.

The same term is also applied to a mixture of equal parts of quassia extract and sulphate of iron, 2 parts extract of *Cocculus indicus*, 4 parts Spanish liquorice, and 8 parts treacle, used to sophisticate beers.

BITUMEN. This term includes a considerable number of inflammable mineral substances consisting mainly of hydrocarbons. They are of various consistence, from thin fluid to solid, but the solid bitumens are for the most part liquefiable at a moderate heat. The purest kind of fluid bitumen, called naphtha or rock oil, is a colourless liquid of sp.gr. 0·7–0·84, and with a bituminous odour. It often occurs in nature with asphalt and other solid bitumens. Petroleum is a dark-coloured fluid variety containing much naphtha. Maltha or mineral tar is a more viscid variety. The solid bitumens are *asphalt* (*q.v.*); *mineral tallow* or *hatchetin*; *elastic bitumen*, *mineral caoutchouc* or *elaterite*; *ozokerite*, &c.

An abundance of bitumen is found in the island of Trinidad at the Pitch Lakes, and in Mexico. It is supposed to be a product of the decomposition of vegetable matter, and consists chiefly of hydrocarbons with variable quantities of oxygen and nitrogen (*v.* PITCH).

BITUMINOUS COAL *v.* FUEL.

BIXEIN, BIXIN. Colouring matters of annatto (*v.* ANNATTO).

BLACK BAND IRONSTONE *v.* IRON, ORES OF.

BLACKBERRIES. The fruit of the bramble, *Rubus fruticosus*. König gives, as the average composition:

Water	Protein	Free acid	Sugar	Other carbohydrates	Fibre	Ash
86·4	0·5	1·2	4·4	1·8	5·2	0·5

The seeds contain about 12·6 p.c. of a drying oil, sp.gr. at 15° 0·9256, iodine number 147·8, the liquid fatty acids—about 91 p.c. of the oil, contain about 80 p.c. of linolic acid, 17 p.c. of oleic acid, and 3 p.c. of linolenic acid, whilst the solid acids, chiefly palmitic acid, amount to about 4·7 p.c.; volatile acids are not present in the oil. A small quantity of phytosterol is present (Krzizan, Chem. Rev. Fett u. Harz, Ind. 1908, 15, 7). For a study of the colouring matter of the fruit, *see* Vecchi (Chem. Zeit. 1914, i. 1209). H. I.

BLACK BOY GUM *v.* BALSAMS.

BLACK CHALK. A kind of clay containing carbon, found in Carnarvonshire and in the Isle of Islay.

BLACK COPPER *v.* COPPER.

BLACK EARTHY COBALT *v.* COBALT.

BLACK FLUX *v.* ASSAYING.

BLACK HAW. The dried bark of *Viburnum prunifolium* (Linn.).

BLACK HELLEBORE ROOT. *Radix Hellebori nigri.* (*Racine d'Ellebore noir*, Fr.; *Schwarze Nieswurzel*, Ger.).

The root of the *Helleborus niger* (Linn.) or Christmas Rose (Woodville, Med. Bot. 169; Bentl. a. Trim. 2). Black hellebore and the nearly related green hellebore, *Helleborus viridis* (Linn.), are seldom employed in England except in veterinary medicine. They are both powerful intestinal irritants. (*Veratrum viride* and *V. album*, also known as green and white hellebore respectively, are very different plants, and contain alkaloids.)

According to Husemann and Marmé (Annalen, 133, 55), both species of *Helleborus* contain a glucoside *helleborein*, and a smaller quantity of a second glucoside *helleborin*. The former is, according to Sieburg (Arch. Pharm. 1913, 251, 154), an amorphous saponin $(C_{21}H_{34}O_{10})x$, and is hydrolysed by boiling dilute sulphuric acid to 2 mols. each of dextrose and arabinose, [illegible] mol. of acetic acid, *acid helleboretin* $C_{21}H_{36}O_7$ (a lactone ?), and *neutral helleboretin* $C_{15}H_{24}O_3$, a greenish-black mass. Helleboreïn is not a suitable substitute for digitalis (*cf.* also Thaeter, Arch. Pharm. 1897, 235, 414). Helleborin melts with decomposition at 150°, dissolves easily in boiling alcohol or chloroform and gives a deep red solution with sulphuric acid.

BLACKING. Blacking for shoes is mentioned as early as 1598, but it was not introduced into England until the reign of Charles II. It consists of (1) black bone charcoal (free from calcium phosphate, otherwise it is subsequently treated with dilute sulphuric acid) and black colouring matter; (2) a mixture of sugar and oil, which, on rubbing, imparts the gloss; and (3) fatty matter for preservation purposes.

Carnauba wax with its hardness and high melting-point is the basis of modern friction polishes. The cheaper candelilla wax may, to a certain extent, replace the carnauba with but little difference in the quality of the polish.

There are two chief methods for working these waxes into polish: The wax is emulsified by boiling in a solution of borax. The product is known as white stock. If polish is to be in the form of paste, the white stock while hot is mixed with a hot solution of ordinary laundry soap and sufficient nigrosin to give the desired depth of colour. The mixture cools as a soft paste that may readily be applied by means of a brush or sponge. If the polish is desired in the liquid form, the best grade of Castille soap is used; a solution of this variety of soap does not gelatinise. Numerous trials have shown that no matter how dilute the soap solution, a satisfactory liquid cannot be obtained unless Castille soap is used. Both the paste and liquid forms are widely used. With a moderate friction, the hard waxes held upon the leather by the soap, give a beautiful and very desirable polish.

The second method of dealing with the hard waxes is as follows: Carnauba or candelilla or a mixture of the two with beeswax and ceresin or paraffin is dissolved in hot turpentine and mixed with very finely pulverised bone charcoal. When properly cooled there results a firm paste that spreads rapidly under a brush or sponge. When this mixture is poured into boxes it must be properly cooled, otherwise there is a separation of the harder waxes from the solvent, the result being a granular sloppy mass instead of the firm paste desired. If the harder waxes alone were used it would be difficult to prevent separation from the turpentine on cooling, hence the admixture of softer waxes. Beeswax gives also a toughness or lack of shortness to the paste, and a smooth finish that cannot be obtained without it. These softer waxes reduce the gloss available from the carnauba or candelilla. The use of bone black as a colouring agent is an attempt to overcome the weakness inherent in the use of the softer waxes, and to add to the gloss obtainable from the waxes that obtained by friction of the bone carbon.

For tan leathers the same goods are used, except that a brown or yellow dye and pigment replace the nigrosin and bone char. The application of the tan polish is frequently preceded by the use of a cleaning solution to remove stains and discolouration (J. T. Donald, J. Soc. Chem. Ind. 1913, 32, 459).

A liquid blacking can be prepared from 120 parts of ivory black, 90 parts brown sugar, 15 parts olive oil, and 500 parts stale beer. The ivory black, sugar, and olive oil are mixed into a smooth paste, and the beer added under constant stirring (Hiscox, 1907).

A German recipe is as follows: 25 parts Marseilles soap are dissolved in 375 parts of warm spirit (25 p.c.) and 40 parts of glycerol added; this is shaken and added to a solution of 200 parts of shellac dissolved in 1000 parts of spirit (95 p.c.) and 5 parts nigrosine in 125 parts of spirit added. The mixture is well shaken in a closed vessel and left for a fortnight.

Liquid polish. 4 oz. asphaltum, 8 fl. oz. turpentine, 3 fl. oz. of gold size. ¼ oz. nigrosine, and 3 fl. oz. linseed oil. The mixture is heated until uniform and thinned down to desired consistence with oil of turpentine (Phot. J. Dec. 1908, 738).

Day and Martin's chief blacking is obtained by mixing ground animal charcoal, sperm oil, raw sugar or treacle, and a small portion of vinegar. Dilute sulphuric acid is then added to the mass until intumescence ceases, and the product is thinned by the addition of vinegar.

Bryant and James's indiarubber blacking is prepared by triturating thoroughly 18 oz. very fine shreds of indiarubber, 9 lbs. hot rapeseed oil, 60 lbs. finely powdered animal charcoal, 45 lbs. treacle, 1 lb. gum arabic previously dissolved in 20 gall. vinegar. The whole is placed in a wooden vessel, and 12 lbs. sulphuric acid added in small quantities at a time, and stirred for ¼ hour daily for 14 days, 3 lbs. of finely ground gum arabic added, and stirring continued for 14 days. If required in the paste form, only 12 gall. vinegar added and 6 or 7 days' stirring is sufficient.

Brunner makes a blacking by stirring 10 parts of bone black with 100 parts of glucose syrup, and 5 parts sulphuric acid added with rapid stirring until the mass is homogeneous. 2 parts of soda are dissolved in 4 parts water, and 20 parts train oil added and boiled with constant stirring until a thick liquid is formed: the other mixture is then added with repeated stirring.

A cheap and good shoe blacking may be prepared by mixing 1 lb. of ivory black, 1 lb. molasses, 8 tablespoonfuls sweet oil, and 1 oz. of gum arabic, dissolved in 2 quarts of vinegar and ½ lb. of oil of vitriol.

Paste blacking. Mix 16 oz. ivory black, 16 oz. lampblack, 6 oz. treacle, 5 oz. vinegar, and 4 oz. sperm oil. Mix and add gradually 4 oz. sulphuric acid. When intumescence ceases, add ½ oz. of iron sulphate, 6 oz. gum arabic, and 5 oz. water (Pharm. Formulæ, 1908, 378).

Sticks of blacking of plastic consistence are made from the following: 5 oz. stearin, 5 oz. paraffin wax, 2½ oz. carnauba wax, 2½ oz. lustrous pitch, and 7 oz. turpentine (Pharm. J. Pat. 2564, 1908).

Hiscox describes the following paste: 122 parts Marseilles soap, 61 parts potassium carbonate, 500 parts beeswax, and 2000 parts water are mixed with constant stirring and 153 parts rock candy (powdered), 61 parts gum arabic, and 1000 parts ivory black are added with constant stirring.

Boot polish. 5½ oz. ozokerite, 2 lbs. cerasin, 5½ oz. carnauba wax, 1¾ oz. beeswax, 4 pints turpentine, 2 lbs. lampblack, 20 grams black aniline dye, and perfume added if desired (Pharm. J. 1908, 506).

Self-shining blacking. Dissolve 4 oz. gum arabic, 1½ oz. coarse sugar, ¼ pint good black ink, and 1 oz. sweet oil, rub in a mortar, add 2 oz. strong vinegar, and add lastly 1 oz. rectified spirits (Scientific Amer. 1903, 39).

French shoe dressing. 32 oz. vinegar, 8 oz. logwood, and ¼ oz. potassium dichromate are boiled and strained whilst hot into a mixture of 4 oz. gelatine, 4 oz. tragacanth, 4 oz. glycerol and 15 oz. water. The mixture is allowed to stand for some hours: 2 oz. indigo are then added, and the whole triturated in a mortar (Pharm. Form. 1908)

Boot-top liquid. 1 oz. oxalic acid, 1 oz. zinc sulphate, dissolved in 30 oz. water. Apply with a sponge to the leather, which has been previously washed with water, then wash off with water, and dry (Workshop Receipts, 1909, 123).

For kid shoes. 2 oz. gum shellac, 1 oz. aqueous ammonia, 8 oz. water, and aniline black enough to colour. The first two ingredients are heated almost to boiling, and water is added to make the whole measure 16 oz. (Scien. Amer. 1903, 39).

Waterproof blacking. 6 oz. caoutchouc and 3 lbs. hot rape oil are added to 20 lbs. ivory black, 15 lbs. molasses, and 6 or 7 gall. vinegar in which 6 oz. ground gum arabic has been dissolved; then add 4 lbs. sulphuric acid and stir constantly. Allow to stand for 2 weeks, then add 1 lb. fine gum arabic. Stir daily during 2 weeks, and bottle (Workshop Receipts, 1909, 124).

For *dress boots.* 8 oz. gum arabic and 2 oz. molasses dissolved in 2 oz. ink and ¼ pt. vinegar. This is strained, and 2 oz. spirits of wine added.

BLACK-JACK. A miner's term for blende, or zinc sulphide (*v.* ZINC). *V.* ZINCBLENDE.

BLACK LEAD. The common name of plumbago or graphite (*v.* CARBON).

BLACKLEY BLUE *v.* INDULINES.

BLACK LIQUOR. Ferrous acetate (*v.* ACETIC ACID).

BLACK MUSTARD SEED OIL *v.* RAPE OIL; OILS and FATS.

BLACK TELLURIUM *v.* TELLURIUM.

BLACK TIN *v.* TIN.

BLACK VARNISH or **BLACK JAPAN** *v.* VARNISH.

BLACK WAD *v.* MANGANESE.

BLACK, WOOL. *v.* AZO- COLOURING MATTERS.

BLANK FIXE. Trade name for ground barium sulphate used as a pigment (*v.* BARYTES).

BLANKIT. A trade or factory term for sodium hydrosulphite.

BLANQUETTE. A kind of crude soda, less caustic than barilla, obtained at Aigues-Mortes by the incineration of *Salsola kali*.

BLAST FURNACE GAS *v.* FUEL.

BLASTING GELATINE AND POWDER *v.* EXPLOSIVES.

BLAU or **BLUE GAS.** A mixture of volatile hydrocarbons, *e.g.* propane, butane, the pentanes, &c., containing hydrogen and methane, &c., in solution under pressure. The pressure solution is filled into steel cylinders, and is thus available for transport. Used for illuminating, heating, and power purposes (Hallock, J. Soc. Chem. Ind. 1908, 550).

BLEACHING. This term signifies the art of destroying the natural colour of vegetable and animal products in such a manner as to leave them unimpaired with as white an appearance as possible. The removal of certain other natural or artificial impurities usually accompanies the bleaching proper. The art acquires its greatest importance in connection with the textile fibres, cotton, linen, wool, and silk; hence special reference will be made to the modern methods of bleaching these materials.

Cotton bleaching. Cotton is usually bleached in the form of yarn, thread, and fabric, seldom as loose cotton-wool. The natural impurities occurring in raw cotton amount to about 5 p.c., and consist chiefly of pectic matters; other substances present are brown colouring matter and very minute quantities of a fatty acid, cotton wax, and albuminous matter. The soiled grey appearance of raw cotton-wool, yarn, and thread is almost entirely due to the presence of these natural impurities. Cotton cloth or calico, however, is still further contaminated with flour or starch, fatty matter, China clay, and other mineral substances, all of which, to the amount of 30–50 p.c., have been introduced during the sizing of the warp.

Cotton yarn and thread bleaching. If the cotton yarn is in the form of 'warps,' these are loosely plaited by hand or machine in order to reduce their inconvenient length; if in the form of 'hanks,' these are bleached separately or linked together in chain form; weft yarn is sometimes bleached in the form of 'cops,' *i.e.* ready for the spool of the weaver's shuttle.

The several operations of the bleaching process for 1500 kilos. yarn, employing low pressure kiers, are as follows:—

1. *Ley-boil.* 300 litres caustic soda (sp.gr. 1·16), 2000 litres water, boil 6 hours; wash in kier 1 hour.
2. *Chemicking.* Bleaching-powder solution (sp.gr. 1·005), steep under sieve 2 hours; wash under sieve half an hour.
3. *Souring.* Sulphuric acid (sp.gr. 1·005), steep under sieve half an hour; wash under sieve half an hour and afterwards in washing machine.
4. *Soaping and blueing.* Soap solution about 6 grams per litre, with addition of small quantity of indigo-purple (indigotin monosulphonate of soda), steep 2 hours under sieve.
5. *Dumping.* Pass through dumping machine containing soap solution and indigo-purple, as in operation No. 4; wash, squeeze or hydro-extract, and dry.

The first, second, and third operations are repeated in the case of thread because of its closer texture. For the second ley-boil, 30 litres caustic soda (sp.gr. 1·16) and 15 kilos. soap are used; the chemicking and souring are exact repetitions.

The *ley-boil* takes place in large iron boilers or 'kiers,' a representation of which is shown in Fig. 1.

The boiler A has a central puffer pipe, B, furnished with a bonnet or spreader, M, at the top.

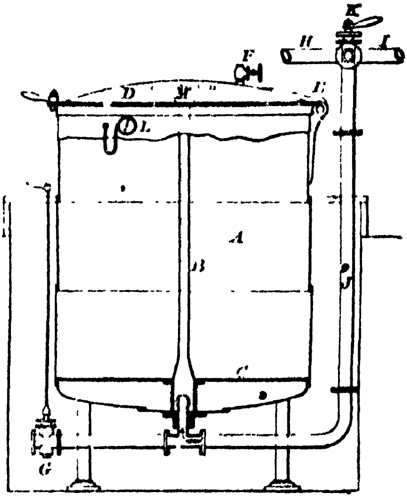

FIG. 1.

C is a perforated false bottom; D is the lid hinged at E and capable of being readily lifted by means of a chain and counterweight; F is an air valve, L a steam pressure gauge; H and I are the steam and liquor pipes connected by the two-way valve K with the pipe J, which enters the kier immediately below the puffer pipe; G is the let-off valve.

When such a kier has been charged with yarn and caustic soda solution, the lid is fastened down and steam is admitted. The liquor below the false bottom soon begins to boil, and as the pressure of steam increases, a portion of the boiling liquor is forcibly ejected up the puffer pipe and spread over the yarn. The liquor drains through the yarn, soon to be ejected as before. In this intermittent manner the circulation of the boiling liquor is maintained.

The apparatus for chemicking, souring, washing under sieve, soaping and blueing, shown in Fig. 2, consists of a stone tank, E, with perforated false bottom F, and communicating by the valve G with the stone tank D below. The chain of yarn is drawn from the kier and led into the tank E by means of the winch A. When E is suitably filled with yarn, the liquor in tank D is raised by the pump C to the sieve F', whence it drains through the yarn into the well below, again to be pumped up as before; B is the eccentric wheel on revolving shaft by which the pump is worked.

The 'dumping' machine referred to consists of a pair of heavy wooden rollers placed over a large wooden tank containing the soap solution. The upper roller is covered with cotton rope and rests loosely on the lower one. The yarn is first passed through the soap solution and then between the squeezing rollers; the irregularities caused by the linking or plaiting impart to the upper roller a constant jumping motion, which thus effectually cleanses the yarn and presses the soap and blue into the fibres.

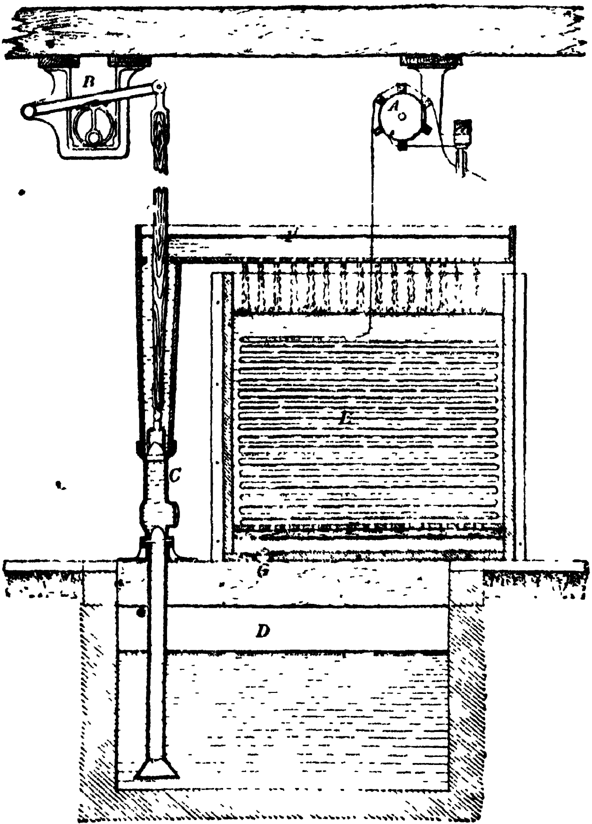

FIG. 2.

When hank yarn is not linked to form a chain, but treated as separate hanks, 'wash stocks' in which the yarn is subjected to the beating action of heavy wooden hammers replace the dumping machine.

Bleaching of yarn in the form of 'cops' or 'cross-wound spools' ('cheeses'). The cops may be packed in wicker baskets or in linen bags and boiled in an ordinary kier, or they are treated in special cop-dyeing apparatus. It is preferable to use a solution of sodium hypochlorite in place of a bleaching-powder solution.

Cotton-cloth or calico bleaching. According to the purpose for which the bleached material is intended, we may distinguish between the *madder bleach*, the *market bleach*, and the *Turkey-red bleach*.

The madder bleach. This, the most thorough kind of calico bleaching, is in general use with calico-printers. It aims at entirely removing every impurity which will attract colouring matter in the madder or other dye-bath, so that the finished print may have a pure white ground.

Before proceeding to the actual bleaching process the preliminary operations of *stamping*, *stitching*, and *singeing* have to be performed.

To recognise each piece of cloth and to trace damages, the ends are stamped with numbers and letters, usually with thick gas tar, occasionally with aniline black. The pieces are then stitched together by machine.

The *singeing* operation is for the purpose of burning off the loose fibres on the surface of the calico, since they interfere with the production of fine impressions, and are apt to give rise to certain defects during the printing process. It is performed by rapidly passing the cloth in the open width over red-hot copper plates or cylinders, or over a row of Bunsen gas flames. We may distinguish, therefore, between *plate singeing* and *gas singeing*, the former being generally preferred for thick heavy cloth, the latter for light thin cloth, muslins, &c.

In plate singeing it is important that the plates be kept at a uniform strong red heat sufficiently high to overcome the cooling action of the rapidly moving cloth. The best results are obtained by means of the 'singeing roller,' which consists of a slowly revolving copper cylinder through which a furnace flame is conducted. In this case the cloth presses continually against a different portion of the red-hot surface of the roller; the cooling action is thus reduced to a minimum, and a regular even singe is the result.

All singeing machines are provided with lever arrangements for immediately removing the cloth from the hot plate, or the gas flame from the cloth, in case of necessity; further danger from fire is avoided by causing the singed cloth to pass at once between a pair of rollers moistened with water, or through a small steam chamber, in order to extinguish sparks adhering to the cloth.

The above preliminary operations are now succeeded by those of the bleaching proper. The following is an outline of the process at present in use for 24,000 kilos. cloth, employing ow-pressure kiers :—

1. Wash after singeing.
2. *Lime-boil.* 1000 kilos. lime, water about 37,000 litres ; boil 12 hours ; wash.
3. *Lime sour or grey-sour.* Pass through hydrochloric acid (sp.gr. 1·01) ; wash.
4. *Ley-boils.* 1st. 340 kilos. soda ash, water about 37,000 litres ; boil 3 hours.
   2nd. 860 kilos. soda ash, 380 kilos. resin, 190 kilos. caustic soda (solid), water 37,000 litres ; boil 12 hours.
   3rd. 380 kilos. soda ash, water 37,000 litres ; boil 3 hours ; wash.
5. *Chemicking.* Pass through bleaching-powder solution (sp.gr. 1·0025) ; pile 2–12 hours ; wash.
6. *White-sour.* Pass through hydrochloric or sulphuric acid (sp.gr. 1·01) ; pile 1–3 hours.
7. Wash, squeeze, open out, and dry.

1. *Wash after singeing.* From the singeing house the cloth is passed through the washing machine in rope form, then plaited down on the floor and allowed to lie 'in pile' for some hours to soften. By this operation the cloth is well soaked with water, and is thus better prepared to absorb the liquors used in the subsequent operations. Should the cloth be heavily sized, much of the adventitious matter is also removed at this stage.

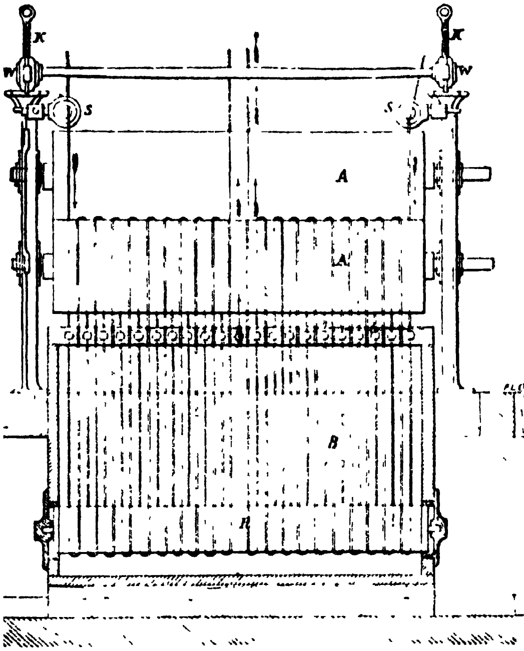

FIG. 3.

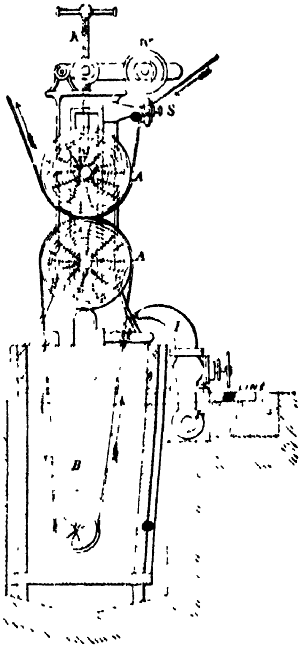

FIG. 4.

The form of washing machine generally employed is shown in Figs. 3 and 4. It consists of a water trough, B, above which a pair of heavy wooden squeezing rollers, A, A, are supported. Two strands of cloth are washed simultaneously ; they enter the machine at the ends, pass between the squeezing rollers, then round the roller R in the water trough, again between the rollers A, A, and thus travel spirally towards the centre of the machine, whence they are drawn out by a winch and piled on the floor. A constant stream of water from the main D enters at the centre of the trough by the tap E, the dirty water flowing out at both ends ; C, C are wooden guide pegs to separate the several strands of cloth ; S, S are strong brass rings or 'pot eyes' through which the cloth enters the machine, and which can be set at any angle to regulate its tension ; K and W are the screws, levers, and weights for regulating the pressure of the squeezing rollers against each other. The action of this machine is such that the cloth is continuously being soaked with water and then squeezed, thus causing a vigorous stream of water to flow down the upward-moving strands of cloth.

2. *Lime-boil* (lime-bowk, bucking, bowking). The pieces are run through milk of lime supplied to a washing machine of small dimensions—generally termed the 'liming machine'—and are at once drawn by winches into the lime kiers, carrying with them the lime they have absorbed. The cloth is plaited in regular folds and well tramped down by boys, who enter the kiers.

After adding the necessary amount of water, the boiling and circulation of the liquor takes place as already described in the case of the ley-boil of cotton-yarn bleaching.

The lime-boil has for its object the decomposition of the fatty, waxy, and resinous impurities present in the cloth. Though not removed, but adhering still to the fabric in the form of lime-soaps, their altered condition facilitates their removal by the subsequent processes. The starch of the size is removed, and the colouring matter of the fibre is modified. Lime is preferred to caustic soda because it is cheaper, and much more effective in saponifying neutral fatty matter than the caustic or carbonated alkalis; indeed, with the exception of barium hydroxide, it seems to be the most energetic saponifying agent which could be used in cotton bleaching.

It is very essential to have a sufficiency of water in the kier, so that it stands at least about 2 feet above the false bottom; otherwise the cloth, either at the top or bottom of the kier, is very apt to be tendered, probably because it becomes oxidised by the action of the steam upon the cloth in its limed condition. On the other hand, an excess of water in the kier is to be avoided, since then the cloth is apt to float and become entangled, or damaged by rubbing against the sides of the kier during the boiling. When closed high-pressure kiers and live steam are employed, the increase in volume of liquor by the condensation of the steam must be taken into account, and, if necessary, a little liquor must be allowed to escape.

Of the several varieties of kier which have from time to time been introduced in practice, mention may be made of '*Barlow's kiers*.' These are always worked in pairs, and so arranged that the top of one kier is connected by a pipe with the bottom of the other; the pipes which enter at the top and centre of each kier are continued as perforated pipes or 'distributors' to a little above the false bottom, and then to the bottom of the kier as a stay. Both kiers having been charged with cloth, the necessary amount of water is run into one kier only; high-pressure steam is then admitted at the top, and the liquor forced out below enters the distributor of the other kier at the top and permeates the cloth. When all the liquor has been thus transferred, the taps are reversed so that the steam forces the liquor in a similar manner back into the first kier. This alternating process and circulation of the liquor is continued for about seven hours.

Pendlebury's arrangement of kiers is precisely similar to that of Barlow, the only difference being that one kier is smaller and serves only to hold the liquor each time it is forced through the cloth contained in the larger kier. The arrangement is cheaper, more economical as regards space required, and is suitable for small requirements.

In the *vacuum kier* of Mason and others, the circulation of the liquors is effected by means of a pump. After filling the kier with cloth, the air is pumped out and the boiling liquor is then admitted; in this manner a more perfect penetration of the material by the liquor is obtained.

The *injector kier* of Mather and Platt is shown in Fig. 5. A is the kier filled with cloth; B, B are the steam pipes; C is the injector; and D the circulating pipe; F is the liquor pipe by which water or other liquor is admitted; E, E is the draw-off valve and waste pipe. When the kier has been suitably filled with cloth and liquor, steam is turned on, and, by the action of the injector C, the liquid is withdrawn from the kier below, forced up the pipe D, and spread over the cloth at G. Temporarily collecting at H, the liquor is gradually drawn through the cloth, and in this manner a continual circulation of liquor is maintained.

3. *Lime-sour* (grey-sour). After the lime-boil the pieces are washed, then passed through a washing machine fed with dilute hydrochloric acid, and, if convenient, at once washed.

The object of the lime-sour is to decompose the insoluble lime-soaps fixed on the cloth during the lime-boil, and to dissolve and remove the lime, also any iron or other metallic oxides present. Experiments by A. Scheurer show also that the use of the lime-sour makes it less essential that complete saponification of the fatty matter should take place during the lime-boil than would be the case if it were omitted. This is so because the free fatty acid liberated during the lime-sour greatly facilitates the saponification of any undecomposed neutral fat during the succeeding ley-boil, since the soap which the fatty acid then forms emulsifies the neutral fat and exposes it to the action of the alkali employed. Hence the adoption of the lime-sour is equivalent to shortening the time of the lime-boil. A continual flow of fresh dilute acid into the machine must be maintained, and, since it is rapidly neutralised by the lime, it is well to ensure a constant slight acidity of the liquor by occasionally making acidimetrical tests. Hydrochloric acid is preferred to sulphuric acid, because it gives the more soluble calcium chloride. The soured cloth should never be permitted to remain long exposed to air, especially air currents, otherwise the acid is apt to concentrate in the exposed portions and thus tender the fibre.

4. *Ley-boil.* This operation takes place in the same kind of kiers as are used for the lime-boil. The fatty acids resulting from the decomposition of the lime-soaps during the grey-sour, also the brown colouring matters, are removed during this operation. Its special feature is the use of resin-soap, which greatly facilitates the removal of fatty matter by exercising a purely mechanical emulsive action, the alkali present being then able more readily to saponify the emulsified fats, particularly those neutral fats which perchance have escaped the action of the lime-boil. Ordinary soft-soap acts in a similar manner, but resin-soap is cheaper and better. A. Scheurer finds by experiment that, after caustic lime, the most rapid saponification of a neutral fat spotted on a piece of calico is effected when boiling under pressure at 120° C., by a solution containing 10 grams anhydrous caustic soda and 2½ grams resin per litre. Increasing the amount of resin does not hasten saponification, though this is done by increasing the velocity of the circulation of the solution. Indeed, *with circulation* even a more rapid saponification is effected with caustic soda and resin than with lime.

The preliminary short boiling with soda ash, which is sometimes replaced by merely soaking the cloth in a weak solution of soda ('sweetening'), prevents tendering of the cloth by neutralising any traces of acid left in by reason of insufficient washing after souring. The boiling with soda-ash after the resin-boil is for the purpose of completing the removal of fatty matters and any undissolved resin, which otherwise give rise to brown stains. Immediate removal of the cloth from the kier and washing is necessary to prevent the production of iron stains.

5. *Chemicking.* The application of the bleaching-powder solution takes place in washing machines of the ordinary kind, but provided with stone instead of wooden troughs, because of their greater durability. The bleaching action takes place essentially during the lying-in-pile or exposure to air of the cloth saturated with the solution of bleaching powder, the carbonic acid of the air liberates hypochlorous acid, and this, in the presence of the fibre, at once decomposes, yielding hydrochloric acid and oxygen: in the moment of its production the oxygen oxidises and destroys the traces of colouring matter present in the fibre, thus giving it the highest degree of whiteness.

It is necessary to avoid the use of strong solutions of bleaching powder, otherwise the fibre itself is attacked, oxycellulose being produced; and even if the cotton is not tendered thereby it is still apt to acquire brown stains during subsequent operations employed by the calico-printer, *e.g.* steaming, or to produce uneven shades in dyeing.

6. *White-sour.* This operation is similar to the lime-sour already described, except that sulphuric acid is usually employed instead of hydrochloric acid, chiefly because of its lower cost. Its object is to decompose and remove traces of undecomposed bleaching powder, lime, iron, and the oxidised colouring matter.

7. The *final washing* must be as thorough as possible in order to ensure the removal of all traces of acid, which, if left in the cloth, would inevitably tender portions of it during the drying process. After washing, the cloth is specially squeezed by passing through a pair of heavy wooden rollers, or through the modern grooved brass roller and disc machine of W. Birch. The chain of cloth then passes in a horizontal, loosely hanging position, between a pair of rapidly revolving, double-armed winches or scutchers, which effectually shake out the twist from the strand. Thus opened out to the full width, the cloth is dried by passing over steam-heated copper cylinders, and folded. The time usually required to complete the madder bleach is four to five days.

The market bleach. In market bleaching the object is simply to give a brilliant white appearance to the calico or other similar material, to fit them for immediate sale in the market as finished white goods. It is not necessary to have the calico 'well bottomed'—*i.e.* cleansed from all colour-attracting impurities, since no subsequent dyeing or printing is intended. The operations are for the most part identical with those of the madder bleaching process. The modifications introduced are shown in the following outline of the process, intended for 24,000 kilos cloth, employing open or low-pressure kiers:—

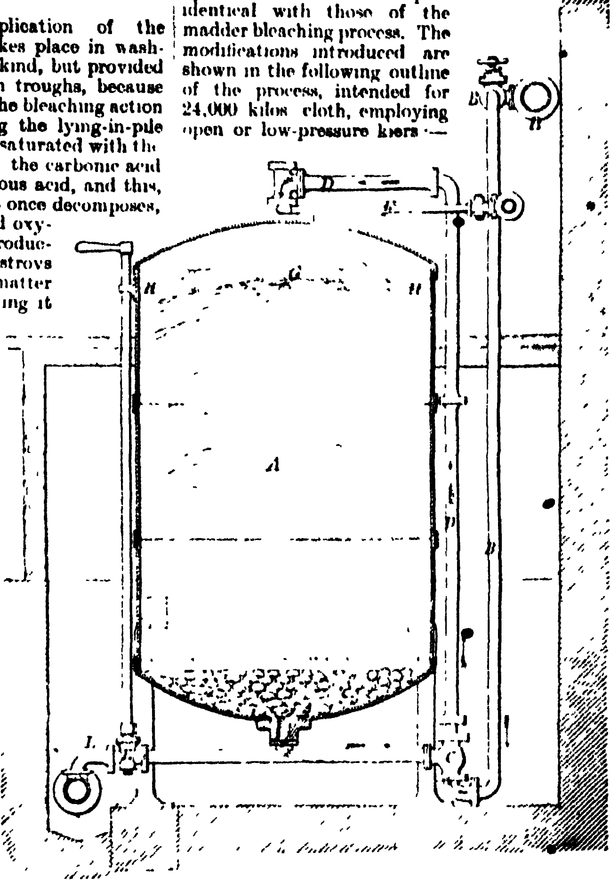

Fig 5

1. *Lime-boil.* 1440 kilos lime, water about 37,000 litres, boil 12 hours; wash.
2. *Lime-sour.* Hydrochloric acid (sp gr. 1·01); steep 2-4 hours; wash.
3. *First ley-boil or grey-boil.* 240 kilos. caustic soda (solid), about 37,000 litres water; boil 12 hours; wash.
4. *Chemicking.* Bleaching powder solution (sp.gr. 1·005); steep 2-4 hours; wash.
5. *Second ley-boil or white-boil.* 240 kilos. soda ash, about 37,000 litres water; boil 12 hours; wash.

6. *White-sour.* Sulphuric acid (sp.gr. 1·01); steep 2–4 hours; wash.
7. *Tint* with blue; squeeze dry.

More or less elaborate finishing operations follow—*e.g.* starching, calendering, beetling, stentering, &c. Some bleachers introduce a white-sour between operations 4 and 5, and a second chemicking between operations 5 and 6. The absence of resin-soap in the ley-boils is characteristic.

The Turkey-red bleach. This is merely a curtailment of the foregoing processes, and is specially intended for yarn or cloth to be subsequently dyed plain alizarin-red or Turkey-red. In it the operation of singeing and the application of bleaching powder are omitted, since they diminish the fulness and brilliancy of the Turkey-red dye; the use of the latter is to be avoided, because it gives rise to the production of oxycellulose. The use of resin-soap is unnecessary, and the process is limited to the following operations:—

1. Wash.
2. Boil in water 2 hours; wash.
3. *Ley-boils.*
   1st. 90 litres caustic soda (sp.gr. 1·35), about 3000 litres water; boil 10 hours; wash.
   2nd. 70 litres caustic soda (sp. gr. 1·35); ditto, ditto.
4. *Sour.* Sulphuric acid (sp.gr. 1·01); steep 2 hours.
5. Wash well and dry.

The above quantities of materials are intended for 2000 kilos. cloth, with low-pressure kier

The steamer-kier bleaching process. The bleaching processes previously described have been in vogue with little change during the last forty years; minor modifications have certainly been introduced, but the chief improvements have always been in respect of the mechanical appliances employed.

In 1883 Thompson patented a bleaching process in which the goods contained in an air-tight kier are submitted to the action of bleaching-powder solution and of carbonic acid alternately.

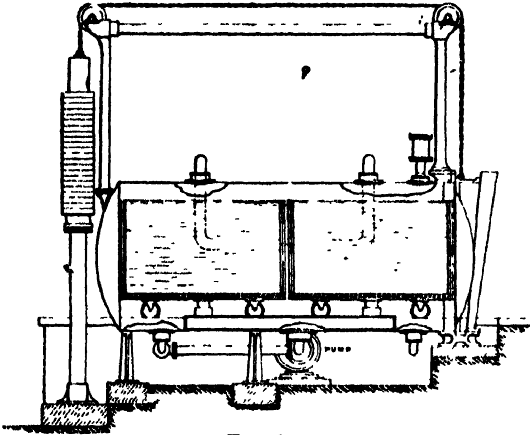

FIG. 6.

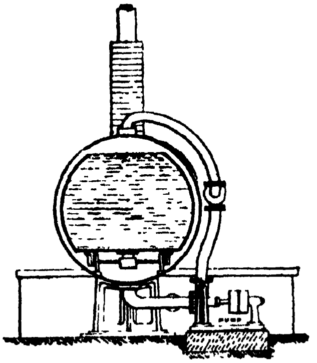

FIG. 7.

In 1884 W. Mather, of the firm of Mather & Platt, Manchester, devised an improved arrangement in which the calico could be passed continuously through chambers or tanks containing the two necessary agents mentioned.

The so-called *Mather-Thompson* process results from a combination of the two processes here indicated. With regard to the principles of the process there is nothing new, for the application of carbonic acid in connection with bleaching-powder solution was patented by P. F. Didot in 1855, while the steaming of goods impregnated with alkali was patented as far back as 1800 by J. Turnbull.

The novelty consists essentially in the machinery employed, by which the duration of the bleaching process is very much shortened, and other material advantages are gained.

In the following year Mather introduced the so-called *steamer-kier*, in which the goods, previously impregnated with dilute caustic soda, were submitted to the action of low-pressure steam.

The steamer-kier consists of a strong wrought-iron horizontal boiler, one end of which can be closed by a specially constructed sliding door. At the side of the kier stands a centrifugal pump connected with the top and bottom of the kier, and also with liquor tanks beneath, so that either boiling water or dilute caustic alkali solution can be sprinkled on and circulated through the goods. Figs. 6 and 7 show the general disposition of the steamer-kier.

Two waggons of cloth having been run into the kier, and the door closed, steam is admitted till the pressure reaches a maximum of 4–5 lbs. During the steaming or boiling process, a continual sprinkling of the cloth with dilute caustic soda (sp.gr. 1·01–1·02) is maintained, in order to keep the cloth well saturated with liquid, and thus prevent oxidation and consequent tendering of the fibre by the action of the steam. The excellent circulation of the liquors in the steamer-kier is a noteworthy and most important feature, since it greatly facilitates the saponification of the fatty matters on the cotton.

After steaming, the liquor is run off, the kier is almost filled with hot water, and this is circulated through the cloth by means of the centrifugal pump for one hour. A similar washing with fresh hot water takes place during another hour.

Each kier is provided with two pairs of waggons, so that while the goods in one pair are being steamed, the other pair can be emptied and refilled with cloth ready to be steamed. In this manner the operation of steaming is rendered as continuous as possible and a very great saving of time is effected.

The following details have been furnished by H. Koechlin, of the Loerrach Printworks:—

To effect the *madder bleach* by the *steamer-kier* process, the continuous bleach with the application of carbonic acid, &c., is omitted, the older method of chemicking and souring being preferred. Those who consider the lime-boil as essential may apply it equally well by means of the steamer-kier.

The operations in this case are as follows:—

1. *Lime-boil* (*or steam*). Run through milk of lime, 50 grams per litre, and pile in steamer-waggon; boil in steamer-kier 5 hours at 10 lbs. pressure, circulating 2000 litres water. Wash in kier with hot water.
2. *Sour.* Sour as usual with dilute HCl (sp.gr. 1·015); pile 2–3 hours, and wash.
3. *Ley prepare* Pass through NaOH solution (sp.gr 1·005-1·01), heated to 70° C, and pile in steamer-waggon.
4. *Ley-boil* (*or steam*). Boil 6 hours in steamer-kier at 10 lbs. pressure, with circulation of resin-soap liquor: 40 kilos. soda ash, 20 kilos. resin, 1000 litres water. Wash four times (½–1 hour each time) with boiling water, and finally with cold water, in kier.
5. *Chemicking.* Pass as usual through dilute bleaching-powder solution (sp gr. 1·0025); wash.
6. *Sour.* Pass as usual through dilute sulphuric acid (sp gr. 1·01); wash and dry.

Perfectly satisfactory results, however, are obtained by even *omitting* the lime-boil and proceeding as follows:—

1. *Sour.* Pass as usual through dilute H_2SO_4 (sp.gr. 1·015); pile 2–3 hours; wash and squeeze.
2. *Ley-prepare.* Pass through following solution at 70° C.: 20 litres bisulphite of soda (sp.gr. 1·3), 20 kilos. NaOH (solid 72 p.c.), 1800 litres water; pile in steamer-waggons.
3. *Ley-boil* (*or steam*). Boil in steamer-kier 6–8 hours at 10 lbs. pressure, with circulation of resin-soap liquor: 20 kilos. NaOH (solid 72 p.c.), 40 kilos. soda ash, 20 kilos. resin, 2000 litres water; wash 4 times (½–1 hour each time) with boiling water, and once with cold water in kier.
4. *Chemicking.* As above.
5. *Sour.* As above; wash and dry.

With the exception of the employment of the steamer-kier and the use of bisulphite of soda, this process is essentially the same as that employed for many years with success by Messrs. Guillaume Frères of St. Denis.

The preliminary souring process effects the decomposition of any insoluble fatty acid compounds present in the grey cloth; it removes calcareous or other mineral matter soluble in acids, and modifies any starchy matter present, probably rendering it more soluble. The addition of the small proportion of the reducing agent bisulphite of soda, along with the caustic soda in the preparing process, is intended to prevent any oxidation and consequent tendering of the cotton during the steaming process. The use of resin-soap along with the caustic soda, combined with the perfect circulation of the liquor, is very material to the success of this method of madder bleaching, for reasons already stated.

According to H. Koechlin, this method gives a perfectly satisfactory bleach. The white is not permanently stained in an alizarin dye-bath, and does not become yellow on steaming.

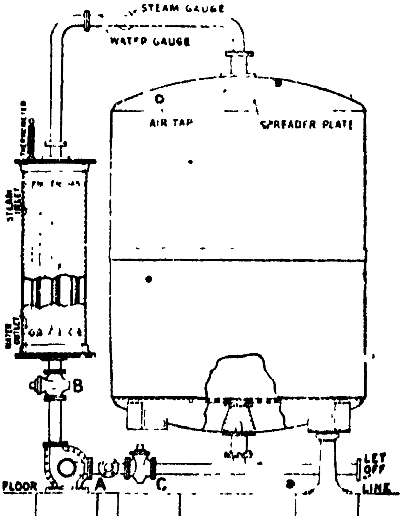

FIG. 8.

A noteworthy invention of Dr. G. Lunge is the application of acetic acid in connection with bleaching powder, in place of mineral acids or carbonic acid. It can be applied immediately before or after, or even along with, the solution of bleaching powder. It liberates hypochlorous acid with formation of soluble calcium acetate. When the hypochlorous acid exercises its bleaching power, it gives up oxygen and produces hydrochloric acid, which immediately acts upon the calcium acetate. In this manner the acetic acid is reproduced, and is thus ready to decompose fresh portions of calcium hypochlorite.

Hadfield and Sumner patented a process in which the cloth, after having been impregnated with a solution of bleaching powder, is passed through a box containing acetic acid vapour.

A solution of sulphurous acid has been used by some bleachers for the final souring process in place of sulphuric acid, over which it possesses the advantage of being an antichlor, in consequence of its reducing action.

The Walsh kier. In this kier, shown in Figs.

8 and 9, wh [illegible] gely used, the boiling liquor is circulated by means of a centrifugal pump, and it is heated in a special heating arrangement outside the boiling kier.

In the *Bentz-Edmeston* and in the *Tagliani-Rigamonti* kiers the boiling operation is a continuous process. Low pressure is usually employed, and the impregnation of the pieces with the boiling liquor in the lower part of the kiers is followed by steaming in the upper part. After the boiling is completed the pieces are plaited into wooden boxes, in which they are allowed to lie for some hours.

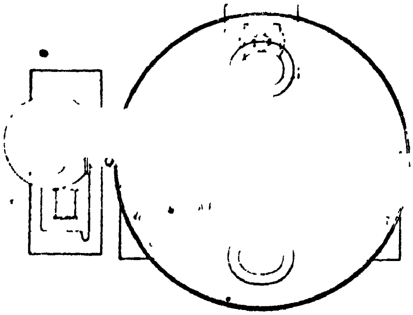

FIG. 9.

Piece goods, such as heavy twills, &c., which are frequently damaged (creased) in ordinary bleaching in the rope form, are treated in the open width. Special kiers have been constructed for this purpose, the principal one being the *Jackson-Hunt* kier (Fig. 10).

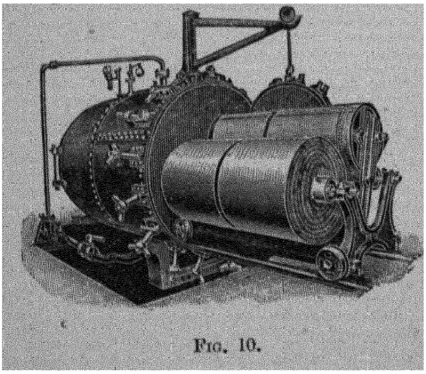

FIG. 10.

Previous to boiling in this kier the cloth is impregnated with caustic soda ley, which has been used in a former boiling, in a special [illegible] machine. In this the cloth travels [illegible] forated drum, and the soda ley is [illegible] ough it by means of steam, which is blown against it whilst it travels over the drum. Ultimately, the cloth is wound tightly and evenly into a batch.

This batch is now placed on a waggon, which is transferred to the horizontal boiling kier.

Special driving gear is provided, by means of which the cloth is wound off the batch on to another batching roller, passing over a heavy perforated drum which rests on both batches. The caustic soda liquor is circulated by means of a centrifugal pump, and is showered over the cloth during its passage over the perforated drum.

In this kier the cloth is usually boiled under high pressure (about 45 lbs.).

In the preparation of *sodium hypochlorite* solution, by electrolysing a solution of common salt two types of processes are employed, one in which the products of electrolysis, viz. sodium and chlorine, are not allowed to combine, and the other in which they are allowed to combine to form sodium hypochlorite

$$2NaOH + Cl_2 = NaOCl + NaCl + H_2O.$$

The latter process comes chiefly into consideration as regards the bleaching of textile materials.

The apparatus used may be divided into two classes, the one in which electrodes made of platinum-iridium are used, and the other in which carbon electrodes (highly compressed graphite) are employed.

In the Kellner electrolyser, which belongs to the former kind, a centrifugal pump is employed by means of which the salt solution is repeatedly passed through the apparatus until it contains from 3 to 5 grams of active chlorine per litre.

In the Haas and Oettel electrolyser, which belongs to the latter kind, the salt solution is electrolysed until it contains from 10 to 15 grams of active chlorine per litre.

Powerful circulation of the salt solution is obtained by means of the hydrogen gas evolved during electrolysing.

Bleaching by means of electrolytically prepared hypochlorite solution, although employed with advantage in special cases, such as the bleaching of cops, is not commonly practised, because it is more expensive in its application than bleaching powder.

The statement that an electrolytically prepared bleaching solution is more effective than a solution of bleaching powder containing the same amount of active chlorine, cannot be confirmed in practice.

Permanganate of potash, *sodium peroxide*, and *hydrogen peroxide* give excellent results in bleaching. Their price, as compared with bleaching powder, is, however, in most instances, prohibitive.

The history of cotton bleaching may be briefly said to comprise the following noteworthy improvements:—

1. The use of chlorine gas by Berthollet in 1787, and of hypochlorite of lime in 1799 by Tennant.
2. The boiling with carbonate of soda instead of caustic soda, after the lime-boil, introduced from America about 1837. A more effectual decomposition of the lime-soaps was thus obtained.
3. The adoption of the lime-sour, as proposed by A. Scheurer-Rott in 1837.
4. The use of resin-soap in the ley-boils about the same period.
5. The introduction of high-pressure boiling kiers about 1844.
6. The use of caustic alkali and resin-soap in conjunction with the steamer-kier, to the exclusion of the lime-boil, in 1883–84.

Linen bleaching. Since the retted flax fibre contains a much larger proportion of natural impurities than cotton, *e.g.* 25–30 p.c. of pectic acid, beside fatty matter, &c., linen is not so readily bleached as cotton. In the main, however, the methods adopted for the two fibres are the same. Linen is bleached in the form of yarn, thread, or cloth.

Linen-yarn bleaching. Very frequently linen yarn is only partially bleached, the process being completed, if necessary, when the yarn has been woven into cloth.

The following operations are employed in order to obtain 'half-white' or cream, with 1500 kilos. yarn, using low-pressure kiers:

1. *Ley-boil.* Boil 3–4 hours in a solution of 150 kilos. soda ash; wash and squeeze.
2. *Chemick* (*reel*). Reel 1 hour in bleaching-powder solution, sp.gr. 1·0025; wash.
3. *Sour.* Steep 1 hour in dilute sulphuric acid, sp.gr. 1·005; wash.
4. *Ley-boil* (*scald*). Boil 1 hour in a solution of 30–75 kilos. soda ash; wash.
5. *Chemick.* Reel in a dilute solution of bleaching powder, sp.gr. 1·0025; wash.
6. *Sour.* Steep 1 hour in dilute sulphuric acid, sp.gr. 1·005; wash well and dry.

If the yarn should be bleached more completely, then operations 4, 5, and 6 are repeated two or three times, as may be found necessary, with this difference, that between 4 and 5 the yarn is 'grassed,' *i.e.* exposed in the field to the action of the air, light, and moisture, for several days. By introducing this very gentle method of bleaching, the full strength of the fibre is better maintained.

The various operations are conducted in apparatus precisely similar to that employed in the bleaching of cotton yarn, except in the operation of chemicking. Although steeping under the sieve in dilute bleaching-powder solution might well be employed, it is usual to suspend the hanks of linen yarn on reels in such a manner that they are only partially immersed in the solution contained in a shallow tank. As the reels revolve the yarn becomes thus alternately impregnated with the solution and exposed to the air. The liberation of hypochlorous acid by the carbonic acid of the air is advantageous, and the bleach is more effective and regular.

The application of acetic acid, as proposed by Lunge, instead of this exposure to air, may here be strongly recommended, since then no insoluble lime salt is fixed on the fibre, and the subsequent souring is reduced to a minimum.

To avoid the presence of caustic lime, some bleachers use hypochlorite of magnesia, as proposed by Hodge, instead of bleaching powder.

Linen-cloth bleaching. The old method of bleaching linen cloth consisted in alternately boiling the fabric with solutions of sodium carbonate and exposing on the grass, succeeded by souring, and rubbing with solutions of soap. The modern method, adapted from that employed for calico, is given in the following *résumé*. It is intended for 1500 kilos. brown linen, using low-pressure kiers.—

1. *Lime-boil.* Boil 14 hours with 125 kilos. lime, 2000 litres water; wash.
2. *Sour.* Steep 2–6 hours in dilute hydrochloric acid, sp.gr. 1·0025; wash in stocks, *turn-hank*, wash.
3. *Ley-boils.* First, boil 8–10 hours with 2000 litres water containing resin-soap; 30 kilos. caustic soda (solid), 30 kilos. resin, previously boiled together with water; secondly, boil 6–7 hours with 2000 litres water, 15 kilos. caustic soda (solid), previously dissolved; wash.
4. *Expose in field* 2–7 days according to the weather.
5. *Chemick.* Steep 4–6 hours in dilute bleaching-powder solution, sp.gr. 1·0025; wash.
6. *Sour.* Steep 2–3 hours in dilute sulphuric acid, sp.gr. 1·005; wash.
7. *Ley-boil* (*scald*). Boil 4–5 hours, with 2000 litres water, 8–13 kilos. caustic soda (solid); wash.
8. *Expose in field* 2–4 days.
9. *Chemick.* Steep 3–5 hours in dilute bleaching-powder solution, sp.gr. 1·0013; wash.

At this stage the cloth is examined; those pieces which are sufficiently bleached are soured and washed, the rest are further treated as follows:—

10. *Rub* with rubbing boards and a solution of soft soap.
11. *Expose in field* 2–4 days.
12. *Chemick.* Steep 2–4 hours in dilute bleaching-powder solution, sp.gr. 1·0006; wash.
13. *Sour.* Steep 2–3 hours in dilute sulphuric acid, sp.gr. 1·005.
14. Wash, squeeze, and dry.

If the linen is not brown, but made of yarn already partly bleached, the above process is much curtailed, and weaker liquors are employed.

The kiers, chemicking and souring machines are the same as those used in cotton-cloth bleaching. The washing is done in the so-called wash-stocks or by slack-washing machines. The latter are very similar to the cotton-washing machines, the chief difference being that the water tank is divided into compartments, each of which holds a few yards of slack cloth forming each strand, before it passes through the squeezing rollers.

The 'rubbing' referred to is for the purpose of removing mechanically any remaining brown particles of ligneous matter termed 'sprits.' It consists in passing the chain of cloth through a solution of soap, and then immediately between a pair of horizontal, corrugated, heavy boards; the upper board rests loosely upon the lower one, and moves lengthwise to and fro, while the pieces pass between them at right angles.

The operation of 'turn-hanking' consists in disentangling the pieces after they have been washed in the stocks, and then refolding them for a further wash, thus ensuring a thorough cleansing of every portion of the cloth. When slack-washing machines are employed, the operation is of course not necessary.

The chemistry of linen bleaching is essentially the same as that of bleaching cotton. The pectic acid, fatty matters, &c., are rendered soluble by the alkaline boilings, and the colouring matters still remaining are oxidised and destroyed by hypochlorites. The repetition of these operations is considered necessary by reason of the large percentage of impurities present; but it is very probable that good results would be obtained by adopting the more rational plan of first removing the whole of the pectic and fatty matters before applying the hypochlorites.

A process of boiling linen goods preparatory to the bleaching has been patented by Cross and Parkes. The pieces are first impregnated with a solution of soap, silicate of soda, caustic soda, and mineral oil. They are then wound on a batching roller in a chamber containing steam, and afterwards steamed for some hours. This is followed by boiling with a solution of silicate of soda or of soda ash. The goods are finally washed; they are now ready for the first 'dip.'

Wool scouring and bleaching. The bleaching of wool never forms a separate industry, as in the case of cotton and linen, and, although in itself of minor importance, it is necessarily preceded by the operation of 'scouring,' which is of fundamental importance both to the woollen manufacturer and the dyer.

In its natural condition the wool fibre is contaminated with 15–80 p.c. of foreign matter, consisting partly of dirt, &c., derived from without, but mainly of certain fatty matters designated as 'yolk,' secreted by the animal from which it is derived. This secretion is separable into two parts—the one, 'wool-perspiration,' is soluble in water, and consists essentially of the potassium compounds of oleic and stearic acids (potash soaps), &c.; the other portion, termed 'wool-fat,' is insoluble in water, and is composed of cholesterol and iso-cholesterol, which exists partly in the free state, but chiefly in combination with oleic acid and other fatty acids.

Loose-wool scouring. The object of scouring wool is to remove from it the yolk, &c., and thus render it more suitable for spinning, dyeing, or bleaching. Two methods of effecting it may be employed. The one generally adopted is to treat the wool with dilute alkaline solutions capable of forming emulsions with the yolk; the other mode is to submit the wool to the successive action of fat solvents, carbon disulphide, &c., and of water.

Scouring with alkaline solutions. When carried out in the most complete manner, this method comprises the following operations:—

1. *Steep* several hours in tepid water.
2. *Scour* 15–30 minutes with dilute alkaline solutions (soap, sodium carbonate, &c.) at about 50° C.
3. *Wash* with water.

The *steeping* is performed in a series of large iron tanks, in which the wool is systematically washed or rather steeped in water heated to 45° C., until it is deprived of soluble matter. As a rule, two or three steeps with fresh water are found sufficient; but it is customary to pass the wash-water through several lots of wool until it becomes well saturated with 'wool-perspiration.' It is particularly advantageous in the case of wools rich in yolk (*e.g.* Buenos Ayres wool, &c.), since it prevents too rapid soiling of the scouring bath and consequent staining of the wool, and thus it tends to ensure more complete scouring. By evaporating the waste steeping liquors to dryness, and calcining the residue, a good quality of potassium carbonate, containing very little sodium salts and suitable for glass manufacturers, is obtained.

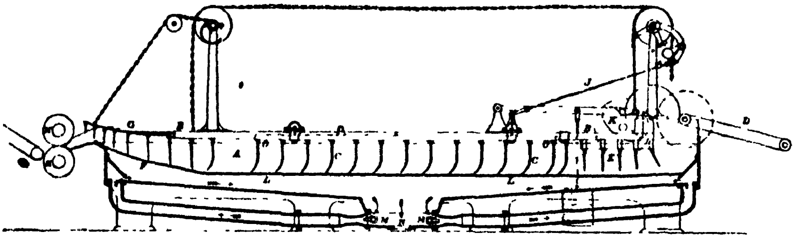

FIG. 11.

The *scouring and washing* of the wool in order to remove the remaining 'wool-fat' is best performed by the aid of so-called wool-scouring machines, one of which (J. & W. McNaught's) is shown in Fig. 11.

It consists of a large rectangular trough, A, with a light frame, B, suspended over it by chains and carrying a series of transverse, fixed, vertical rakes or combs, C.

The wool either in its raw condition or after steeping, is spread evenly on the moving endless apron or feeder D; it is thus continuously introduced at one end of the trough.

By suitable mechanism the frame is lowered, and the wool is at once pressed beneath the surface of the scouring liquor by the perforated tray or sieve E. When the frame is sufficiently lowered, it moves forward, the rakes gently carrying the wool towards the other end of the trough. When the forward stroke is completed, the frame is lifted up, the rakes rise vertically out of the liquid, and the frame returns to its original position. By these successive movements the wool is slowly passed through the scouring liquor. At the delivery end it is carried up the inclined plane F by the rakes fixed on the small frame G, which is hinged to the larger one. Having been pushed over the ridge, the wool slips down between the squeezing rollers H, H, ready to be passed through a second similar machine.

The working of the machine as above described, is suitable for Botany and other fine classes of wool. When washing low Cape, River Plate, and similar wools, which contain much dirt and sand, an additional movement is given to the rakes while in the liquor. This is effected by having the rakes fixed in a second frame, OO, which receives a slight backward-and-forward movement by means of the rod O and the cam K during the inward movement of the main frame BB, to which it is attached. By this means the wool is slightly opened out and agitated, and the sand and dirt fall through the perforated grating LL. When the scouring liquor becomes too soiled for further use, the steam injectors MM are brought into action in order to stir up all sediment, and the dirty liquor is run off by the plug-hole N.

For a complete arrangement there should be at least three such machines placed in line, so that the wool passes automatically from one to the other. The first contains more or less soiled scouring liquid which has been previously used in the second trough; the second contains fresh scouring liquid; and the third a continual flow of clean, cold, or preferably tepid water.

The choice of scouring agents depends upon the character and quality of the wool. For fine lustrous wools and such as are poor in yolk, a mild scouring agent should be selected, *e.g.* soap, ammonia, ammonium carbonate, 'lant,' &c., that is to say, agents which are capable of removing the yolk with the least injury to the fibre. The best soaps to use are those which are most soluble and least likely to contain any trace of caustic or carbonated potash or soda. Should these injurious constituents be present, the soap solution may be de-alkalised by the addition of a small quantity of boracic acid or ammonium chloride, thus yielding the less injurious alkali borates and ammonia, respectively.

Potash soaps, being very apt to contain excess of alkali, should be critically examined. An excellent and very soluble soap may be readily made from oleic acid and caustic soda.

Although a perfectly neutral soap does not always effect a rapid and complete removal of yolk, still it is better to adopt it, since one can always add the proper quantity of other agents, *e.g.* sodium carbonate, ammonia, &c., when necessary.

For low-class wools containing a large proportion of yolk, and when cheapness is a desideratum, sufficiently satisfactory results are obtained by the proper use of sodium carbonate free from caustic soda or other injurious impurity. Suitable sodium carbonates are sold under such commercial names as refined soda ash, Solvay soda, concentrated crystal soda (Brunner, Mond, & Co.), crystal carbonate (Gaskell, Deacon, & Co.), &c.

It is impossible to give precise data with respect to the concentration and temperature of the scouring solution to be employed, since these vary somewhat according to the character of the wool operated upon. If the best results are to be obtained, the solutions must always be applied as dilute and at as low a temperature (not above 50° C.) as is consistent with the complete removal of the yolk.

The waste scouring liquors are collected in large tanks and neutralised with sulphuric acid; the liberated fatty acids are sold to oil refiners, who by distillation obtain purer products, suitable for making soap.

Scouring with volatile liquids. This method is still only in an experimental stage. Mechanical difficulties, the fear of fire and explosions, the first cost of the scouring agent, &c., seem to have prevented the general adoption of this process. Its advantages are that the wool-fat is more completely removed than by the emulsion method, and the wool itself is not injured. A certain degree of success has been obtained by the method proposed by T. J. Mullings, and tried on a large scale. It consists in submitting the wool to the action of carbon disulphide in a closed centrifugal machine until the whole of the wool-fat is dissolved, then expelling the solvent by means of water, and not as heretofore by heat or steam, which always leaves the wool with a yellow colour. The wool must afterwards be washed in warm water to remove wool-perspiration and other impurities. The wool cleansed in this manner is said to be stronger, capable of spinning finer yarn and with less waste and at less cost than if scoured by the ordinary method with soap.

The same principle is adopted in the process of Singer & Judell of Adelaide, who employ, however, a more elaborate and more perfect apparatus, whereby the scouring is made continuous. The raw wool is placed on a feeding apron and carried along between two broad endless bands of wire gauze, first through a succession of fourteen tanks containing carbon disulphide and then through five containing water, all suitably enclosed. The wool, still held between the wire gauze bands, then passes between hot rollers in a steam-heated drying chamber and emerges in a scoured, washed, and dried condition. Arrangements for automatically collecting the dirt which settles from the carbon disulphide, for separating the latter from the water, distilling and returning it to the scouring tanks with the least possible loss, are all provided for by ingenious devices, and the general arrangement seems eminently typical of the method of scouring wool to be adopted in the future. It is said to have been worked with success in Australia.

Woollen-yarn scouring. The object of scouring woollen yarn is to remove the oil with which wool has been impregnated by the spinner. Precisely the same agents are used as for loose wool, but the machinery employed is necessarily different.

Those yarns which have a tendency to curl up because they have been highly twisted are submitted to the preliminary operation of 'stretching'; it also prevents them from shrinking during the subsequent scouring process.

The hanks of yarn are suspended on the arms of a strong iron frame and tightly stretched by means of screws. Thus charged, the frame is immersed in boiling water for a few minutes. After changing the position of the hanks on the arms, the operation is repeated, the yarn is allowed to cool in the stretched condition, and is then removed ready for scouring.

The scouring of yarn is effected either by hand or by machine. In the first case the hanks of yarn are suspended on wooden rods placed across a rectangular steam-heated tank containing the scouring liquor. During a period of 15 to 20 minutes the rods are swayed to and fro by hand, one by one, each hank being frequently turned in order to expose every por-

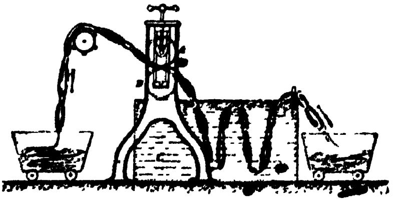

FIG. 12.

tion to the action of the liquor. The yarn is washed in another tank in the same manner.

Yarn-scouring machines are to be met with in several forms. A very effective one consists of a rectangular tank, C, having several rollers above and below, and a pair of squeezing rollers, A, B, situated at one end. The hanks of yarn, linked together by means of string loops, are passed continuously through the scouring liquor, and are then washed in a similar machine (*see* Fig. 12).

Woollen-cloth scouring. Woollen cloth is also scoured for the purpose of removing the oil with which the yarn is impregnated by the spinner. The operation consists in passing the cloth as an endless band, either in the strand form or in the open width, through the scouring liquor and then through a pair of squeezing rollers.

For thick woollen cloths, flannels, &c., scouring in the strand is preferred, since a certain amount of felting takes place and the cloth acquires a better handle. For worsted goods and such as are liable to crease, scouring in the open width is preferable.

Fig. 13 shows a section of E. Kempe's machine for this purpose. It consists of two squeezing rollers, A and B, placed above the wooden trough C containing the scouring liquor. The roller D serves to draw the cloth from the squeezing rollers, and causes it to fall in regular folds upon the inclined plane EE. This is covered with corrugated zinc, the grooves of which run longitudinally, in order to reduce the friction of the cloth, and to prevent the latter from moving to either side. The upper part of the inclined plane is hinged at F, so that the inclination of this part can be regulated to suit different qualities of cloth, and to ensure that it always slips down in regular folds without any tendency to fall over or become blocked. The perforated water-pipes G, G are for the purpose of washing the cloth after scouring.

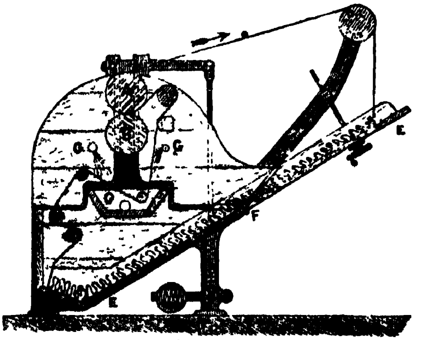

FIG. 13.

Bleaching of wool. After scouring, the wool still possesses a faint yellow tint, to remove which is the object of the bleaching proper. The agent almost universally employed is sulphur dioxide, either in the form of gas (gas-bleaching) or in solution (liquid bleaching). With hydrogen peroxide a more permanent white is obtained, but it is still too expensive to admit of extended application, but it serves as an excellent bleaching agent for certain fine materials.

Gas-bleaching, stoving, or sulphuring, consists in exposing the scoured and washed woollen material, while still wet, to the action of sulphur dioxide in a brick chamber. Yarn or thick cloth is suspended on poles, the sulphur (6–8 p.c. on the weight of wool) contained in an iron pot is ignited, the chamber door is closed, and the material is then left exposed to the action of the gas for six or eight hours, or even overnight. Thin cloth is generally passed in a continuous manner through a similar chamber provided with rollers above and below. The cloth in the open width enters through a narrow slit at one end of the chamber; it passes in a zigzag course under and over the rollers to the further end, then returns and passes out by the same slit. The sulphur dioxide is prepared in the stove itself, or it is produced in a separate furnace and led beneath the perforated floor of the chamber. According to the appearance of the fabric, it is passed through the bleaching chamber once or several times. Fig. 14 gives a sectional view of the sulphur stove for the continuous bleaching of cloth.

In **liquid-bleaching** the woollen material is immersed and moved about for several hours in a solution of sulphurous acid, or in one containing sodium bisulphite, and acidified with sulphuric acid. One may also steep the wool, first in a solution of sodium bisulphite and then in dilute sulphuric acid, and repeat the operations as often as may be necessary. The liquid-bleaching process has not met with that general acceptance to which it seems entitled.

After bleaching, the materials are well washed and tinted blue or bluish-violet, *e.g.* with refined indigo, indigo-extract, aniline-blue, methyl violet, &c., in order to counteract the yellowish tint which is so liable to return.

The bleaching action of sulphurous acid is most probably due to its reducing properties. According to this view, the sulphurous acid takes up oxygen from the water present, while the liberated hydrogen combines with the colouring matter of the wool to form a colourless leuco-compound. Another explanation, however, is that a colourless sulphurous acid compound is formed. Frequent washing of the wool with alkaline solutions restores the yellow colour. It seems evident, however, that the yellowing influence of alkalis is largely due to their further action upon the wool substance itself since they cause the wool eventually to become yellower than it was before bleaching.

Bleaching with hydrogen peroxide is effected by steeping the wool for several hours in more or less dilute solutions of this liquid, made slightly alkaline by the addition of ammonia. The simultaneous action of light accelerates and improves the bleaching. The white is very good and permanent, probably because, in this case, the colouring matter is destroyed by oxidation. Excessive bleaching by this method gives the wool a harsh feel. Lunge recommends a slight treatment with hydrogen peroxide of sulphur-bleached wool in order to oxidise and thus render innocuous traces of sulphurous acid not removed by washing. A very dilute solution of sodium hypochlorite and exposure to air will effect the same purpose.

Bleaching of wool with hydrosulphite of soda has been suggested by F. V. Kallab. It is prepared by adding zinc powder to a solution of bisulphite of soda. The zinc is precipitated by adding milk of lime.

Silk scouring and bleaching. The raw silk fibre consists essentially of two substances, *fibroïne* and *sericine*. The former constitutes the central portion of the fibre, and may be regarded as the fibre proper, while the latter resides principally in the external part and is readily removed by water and especially alkaline solutions.

Raw silk is harsh, stiff, lustreless, and more or less unsuitable for dyeing, but when the external sericine or silk-glue is removed it becomes soft and lustrous, and acquires an increased affinity for colouring matters.

The object then of scouring is to remove the silk-glue from the raw silk. It is effected by the two operations, '*stripping*' and '*boiling-off*.'

Stripping or ungumming. In order to remove calcareous or other mineral matter soluble in dilute acids, it is well first to rinse the silk in a tepid bath of dilute hydrochloric acid, and then wash. The hanks of silk are then hung on smooth wooden rods and worked, as in woollen-yarn scouring, in a soap-bath heated to about 90°–95° C. for about 20 minutes. A second and even a third bath may be used with advantage. Long working in one bath is not good, especially for silk intended to be white, since the silk (fibroïne) is apt to attract some of the colouring matter at first removed along with the silk-glue, and it is afterwards very difficult to remove. With yellow silk this point must be carefully attended to.

During the stripping operation the sericine at first swells up and makes the silk somewhat glutinous, but soon it dissolves off and leaves the fibre soft and lustrous. The waste soapy liquors, strongly impregnated with sericine, are carefully preserved and find an important use in silk-dyeing under the name of '*boiled-off liquor*.' When applying the coal-tar colours, it serves to retard their attraction by the silk, and thus ensures the production of even or level colours.

After stripping the silk is rinsed in water containing a small proportion of soap and sodium carbonate.

Boiling-off. The object of this operation is to complete the removal of the silk-glue and thus give the silk all the lustre and brilliancy of which it is capable. The hanks of silk are tied up in coarse bags of cotton or hemp, generally called 'pockets,' and these are boiled for one to three hours in open copper boilers. The silk is then well rinsed in a weak tepid solution of carbonate of soda, and finally in cold water.

During the operations above described, Japanese and Chinese silks lose 18–22 p.c. in weight, European silks lose 25–30 p.c.

Bleaching of silk. The actual bleaching of silk is effected by exposing the scoured silk, while still in the wet state, to the action of sulphur dioxide gas. The operation is precisely similar to the stoving of wool.

In certain cases, *e.g.* with so-called 'souple' silk, the stoving is preceded by a preliminary bleaching in *aqua regia*, diluted to sp.gr. 1·02 and heated to 20°–35° C. The silk is rinsed in this solution for 8–15 minutes until it acquires a greenish-grey colour, and then at once washed well in cold water. A dilute solution of the so-called 'chamber-crystals' of the sulphuric acid manufacture may replace the *aqua regia*.

The bleaching of silk with hydrogen peroxide is gradually being more and more adopted, especially for Tussur silk and other wild silks. Indeed, for these silks no other method of bleaching is so satisfactory. The silk is steeped and worked in a dilute solution of hydrogen peroxide, rendered slightly alkaline with ammonia or with silicate of soda or borax, until it is sufficiently bleached. A more rapid and effective method is to steep the silk in a somewhat stronger solution, then wring out the excess of liquid, and steam. The operations may be repeated until the silk is sufficiently bleached.

Tinting of silk. Bleached silk is finally tinted or dyed in delicate shades of blue, purplish-blue, cream colour, &c. For pure white it is usual to dye the silk in a very dilute solution of a suitable coal-tar colour. After tinting, the silk is slightly rinsed in water and dried in a moderately warm and darkened stove. J. Hü.

BLEACHING POWDER *v.* CHLORINE.

BLENAL. Carbonic acid ester of santalol

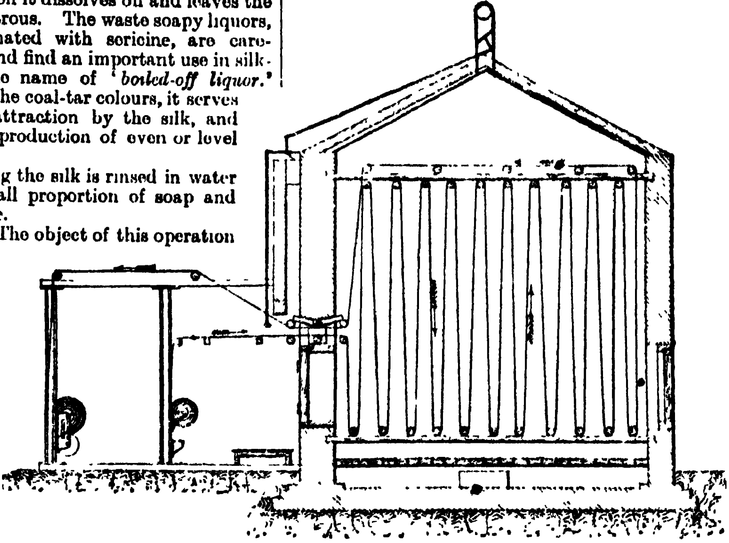

FIG. 14.

BLENDE, from *Blenden*, Ger., to dazzle. Native zinc sulphide. It usually contains iron sulphide which gives it a black colour, whence the name Black Jack applied to it. An important ore of zinc. The sulphur it contains is occasionally utilised in the manufacture of sulphuric acid. (For descriptions of burners for this purpose, *v.* J. Soc. Chem. Ind. 3, 631; 4, 54.) *V.* ZINC-BLENDE.

BLEU DIRECT or **DIPHENYLAMINE BLUE** *v.* TRIPHENYLMETHANE COLOURING MATTERS.

BLEU FLUORESCENT $C_{18}H_{6}Br_{4}N_{2}O_{5}(NH_{4})$. A colouring matter obtained by Weselsky and Benedikt in 1880 by treating diazoresorufin dissolved in potassium carbonate with bromine and precipitating by an acid. Soluble in boiling water with a red-violet colour, giving a fluorescent green solution. Dyes silk and wool blue with brownish fluorescence (Weselsky and Benedikt, Monatsh. 5, 605; Ber. 1885, 18; Ref. 76).

BLEU DE GARANCE. Artificial ultramarine (*v.* ULTRAMARINE; PIGMENTS).

BLEU LUMIÈRE *v.* TRIPHENYLMETHANE COLOURING MATTERS.

BLEU DE LYON, BLEU DE NUIT, BLEU DE PARIS *v.* TRIPHENYLMETHANE COLOURING MATTERS.

BLEU MARIN *v.* TRIPHENYLMETHANE COLOURING MATTERS.

BLEU DE SAXE *v.* COBALT.

BLEU SOLUBLE *v.* TRIPHENYLMETHANE COLOURING MATTERS.

BLIND-COAL. A Scotch term for anthracite.

BLISTER STEEL *v.* IRON.

BLOCK FUEL *v.* FUEL; also PITCH.

BLOCK TIN *v.* TIN.

BLOEDITE. A hydrated double sulphate of magnesium and sodium, $Na_2Mg(SO_4)_2 \cdot 4H_2O$, forming water-clear monoclinic crystals, often of large size and beautifully developed. They are found in the salt mines of Stassfurt and in Austria, and in the Punjab Salt Range, India. Crystals 16½ cm. in length have been found in the black mud beneath a crust of sodium sulphate on Soda Lake, San Luis Obispo Co., California. Simonyite and astrakanite (from salt lakes near Astrakan) are synonyms.

L. J. S.

BLOMSTRANDINE. A rare-earth mineral consisting of a titano-columbate of yttrium-metals, thorium, uranium, &c., occurring as orthorhombic crystals in pegmatite veins at several localities in southern Norway. The large crystals of tabular habit are found in the felspar quarries, and those from the island of Hitterö are well known in collections. They are brown on the surface, but on a fresh conchoidal fracture the colour is black with a bright pitchy lustre. The mineral is optically isotropic, owing to alteration by hydration. Sp.gr. 4·82–4·93. These crystals were provisionally referred by W. C. Brogger in 1879 to æschynite (*q.v.*), an allied species differing mainly in containing cerium-metals in place of yttrium-metals. More recently, Brögger (Die Mineralien der südnorwegischen Granit-Pegmatitgänge, Videnskabs-Selskabets Skrifter, Kristiania, 1906) has given a detailed description of this material, and he gives several other Norwegian localities for the mineral, namely, near Arendal and in Sætersdal. He interprets the complex composition as an isomorphous mixture in varying proportions of a meta-columbate with a metatitanate; and for another member of the same series from the tin gravels of Swaziland, Transvaal, shown by G. T. Prior's analysis (1899) to contain more columbium with less titanium, he proposed the name priorite. These isomorphous minerals, blomstrandine and priorite, are respectively dimorphous with polycrase and euxenite; the four minerals euxenite-polycrase and priorite-blomstrandine thus forming an isodimorphous series.

The name blomstrandine is not to be confused with the earlier name *blomstrandite* (of G. Lindstrom, 1874), which was applied to an uncrystallised hydrated titano-columbate and tantalate of uranium with some calcium and iron, from a felspar quarry at Nohl, in Sweden (*v.* BETAFITE). L. J. S.

BLOOD is a richly albuminous fluid which holds in suspension large numbers of corpuscles. The fluid medium in which the corpuscles float is called the plasma, or *liquor sanguinis.* In round figures, the plasma contains about 10 p.c. of solids, of which proteins comprise 8, extractives 1, and inorganic salts (the principal one being sodium chloride) the remaining 1. The proteins are all coagulable by heat, and are named serum albumin, serum globulin, and fibrinogen. The last-named is the least abundant (0·4 p.c.), but confers upon the blood its characteristic power to clot or coagulate when it is shed. When shed, the blood rapidly becomes viscous, and then sets into a jelly; the jelly contracts and squeezes out of the clot a straw-coloured fluid called serum, in which the shrunken clot then floats. The formation of threads of a solid protein called fibrin from fibrinogen is the essential act in coagulation; this with the corpuscles it entangles constitutes the clot, and serum is plasma *minus* the fibrin which it yields. The following scheme shows the relationships of the constituents of the blood at a glance:—

$$\text{Blood}\begin{cases}\text{plasma}\begin{cases}\text{serum}\\ \text{fibrin}\end{cases}\\ \text{corpuscles}\end{cases}\left.\begin{matrix}\\ \\ \end{matrix}\right\}\text{clot.}$$

In round figures, the blood contains 60–65 p.c. of plasma, and 35–40 p.c. of corpuscles. The corpuscles are of three kinds, the red corpuscles or erythrocytes, the white or colourless corpuscles or leucocytes, and some very small particles also colourless, which are called the blood-platelets.

The subject of blood clotting has been the battlefield of numerous opposing theories, but the view now generally held is that the conversion of fibrinogen into fibrin is due to the action of an enzyme called thrombin or fibrin-ferment. This agent takes origin from the platelets and white corpuscles; it is first shed out from them in an inactive form called thrombogen; thrombogen is converted into the active enzyme thrombin by the combined action of the calcium salts of the plasma and of an activating agent termed thrombokinase, which originates from the cells of the blood itself and of the other tissues of the body.

The transformation of fibrinogen into fibrin has been regarded as a chemical change. But the recent work of Hekma (Biochem. Zeitsch. 1916, lxxiii. and lxxiv.) and of Howell (Amer. J. Physiol. 1916, 40) shows that the change is probably a physical one. Fibrinogen is the sol, and fibrin the gelphase of the protein. Fibrin is first deposited as ultramicroscopic particles (microns), then fine needle-like crystals appear; these by agglutinating together ultimately lead to the formation of typical fibrin threads.

The white or colourless corpuscles are typical nucleated animal cells which have been differentiated into varieties by their staining reactions, the number of their nuclei, and their seat of origin (lymphoid tissue, and red bone marrow). Their most important property is their power of amœboid movement, by which they ingest and subsequently digest foreign particles. They act in this way as scavengers (phagocytes), and thus confer protection against pathogenic organisms (bacteria, &c.).

The red corpuscles are much more numerous than the white, averaging in man 5,000,000 per cubic millimetre, or 400–500 red to each white corpuscle. It is these which give the red colour to the blood. They vary in size and structure in different groups of the vertebrates. In mammals they are biconcave (except in the camel tribe, where they are biconvex) non-nucleated discs, in man $\frac{1}{3200}$ inch in diameter; during fœtal life nucleated red corpuscles are, however, found. In birds, reptiles, amphibia, and fishes, they are biconvex oval discs with a nucleus; they are largest among the amphibians. Their most important and abundant constituent is the pigment hæmoglobin. In invertebrates this respiratory pigment is usually absent, and when present is, with few exceptions, in solution in the plasma and not in special corpuscles. In other invertebrates its place is taken by other respiratory pigments, for instance, by the green pigment which contains iron and is called chlorocruorin (in certain worms), or by the blue pigment which contains copper and is termed hæmocyanin (in certain crustaceans and molluscs). The vast majority of invertebrates have colourless blood containing only colourless corpuscles. Hæmoglobin contains 0·4 p.c. of iron; it and certain of its derivatives give characteristic absorption spectra which form one of the best tests for blood. It is termed a conjugated protein, consisting of a protein (globin) in combination with the iron containing material termed hæmatin

$$(C_{32}H_{30}N_4FeO_3)$$

Hæmoglobin is crystallisable, but hæmatin has not yet been obtained in crystalline form. By boiling dried blood with a little sodium chloride and glacial acetic acid, the characteristic brown crystals of hæmatin hydrochloride or hæmin are readily obtained, and this is the best chemical test for blood; it can be performed quite readily on a microscope slide. By treatment with acid, an iron-free derivative of hæmatin is obtained called hæmatoporphyrin, and in the body certain iron-free derivatives somewhat similar to hæmatoporphyrin are formed; these constitute the pigments of the bile. By the reduction of hæmatoporphyrin, hæmopyrrol (a mixture of pyrrol derivatives) is obtained, and the same substances are obtained also from phylloporphyrin, a derivative of chlorophyll; this is an interesting fact, as it indicates a near relationship between the principal pigments of the animal and vegetable worlds.

During life the blood is in constant movement (circulation), and it is owing to this circumstance that it supplies the tissues with both nutriment and oxygen. The products of protein and carbohydrate digestion pass directly from the alimentary canal into the blood-vessels; the fat reaches the blood indirectly by the lymph-stream. The blood, however, does not, except in the spleen, actually bathe the tissue elements; the middle-man between blood and tissues is a fluid called lymph, which exudes from the blood through the thin walls of the capillary blood-vessels. The lymph thus supplies the tissues with material for their repair or for storage; it also removes from the tissues the waste products of their activity; it is collected by lymphatic vessels, which converge to the main lymphatic channel called the thoracic duct. This opens into the large veins near to their entrance into the heart, and thus the lymph is returned to the blood, and the waste products are then conveyed to the various organs (lungs, kidneys, skin) by which they are discharged from the body.

The function of blood as an oxygen carrier is dependent on the presence of hæmoglobin. Oxygen passes by diffusion into the blood of the lungs, and is then seized by the pigment, with which it forms a loose compound called oxyhæmoglobin; this bright-red arterial or oxygenated blood passes to the heart, and is thence propelled by the arteries all over the body; in the tissues, where the oxygen tension is very low, oxyhæmoglobin is dissociated, and the oxygen passes into the plasma, and again reaches the actual tissue elements *viâ* the lymph. The reduction of oxyhæmoglobin changes the colour of the blood to the darker tint which it has in the veins, by which vessels it is carried back to the heart and sent to the lungs for a fresh supply of oxygen. The venous blood is also rich in carbonic acid, which finds an exit from the blood in the lungs into the expired air. It should be noted that hæmoglobin is not the exclusive carrier of carbon dioxide; the other proteins act similarly, but the gas is carried mainly as carbonates in the blood-plasma.

The amount of respiratory oxygen carried by the blood pigment is 1·34 c.c. oxygen per gram of hæmoglobin. This can be replaced by equivalent amounts of such gases as carbon monoxide or nitric oxide. These compounds are more stable than oxyhæmoglobin, and the gas is not removable by the tissues; hence in coal-gas poisoning the colour of the blood is equally bright in arteries and veins, and the cause of death is oxygen starvation.

The foregoing outline of the composition and uses of the blood from the physiological point of view can be amplified by the study of any standard textbook of physiology or physiological chemistry.

Passing now to the technical and commercial aspect of the case, the uses of the blood come mainly under four headings: (1) as food; (2) as manure; (3) as a clarifying agent; and (4) as a drug.

(1) As *food*. Blood as such is only used as food by savages, and attempts have been made to utilise dried defibrinated blood as a commercial food product without any great success. It, however, forms an important constituent of certain articles of diet, of which Black pudding and the German Blutwurst (Blood sausage) are

the best known. In the preparation of these pig's blood is most commonly employed, and they are of high nutritive value. (For the composition of various kinds of Blutwurst, *see* König, Chemie d. menschl. Nahrungs und Genussmittel, Berlin, 1904, 525; Pott. Handb. d. Tier-Ernahrung, iii. 513, 1909; E. Schmidt, Lehrb. d. pharm. Chem. ii. 2, 1833, 1901.)

(2) *As manure.* Dried blood, the so-called Blood-meal (Blutmehl), is extensively used as manure, and may be placed directly on the land, or, more frequently, is mixed with superphosphates. It is a brown powder with a glue-like smell, and must be kept in dry places to avoid putrefaction. It is valuable on account of its high percentage of nitrogen (11·8) and of phosphorus (1·2 p.c.). Numerous patent manures contain a certain proportion of blood. (For details, *see* König, *l.c.* 496; Merck's Waren-Lexicon, 5th ed. art. 'Blut.')

(3) *As a clarifying agent.* Blood is employed in the same way as milk, gelatin, and albumin are, as a clarifying agent for wines, syrups, and similar liquids, in the proportion of 150–200 c.c. of blood per litre. The clearing action is due to the proteins present, but used in this way there is considerable danger of infection, as also is the case for milk. Dried blood or the dried blood-albumin is therefore preferable. Blood-albumin is prepared from the serum drained off from the clot; the product is really dried serum, as the proteins are mixed with the other constituents of that fluid, and the word 'albumin' is used as synonymous with 'protein,' and not in the correct chemical sense. It has the advantage of being considerably cheaper than egg-albumin, for the total blood of an ox will yield 750–800 grams of the dried product, a good-sized calf will yield 340–400 grams, and a sheep about 200 grams (*see* Merck, *l.c.* art. 'Blutalbumin').

(4) *The therapeutic uses of blood and serum.* The high nutritive value of blood makes it a valuable drug in the treatment of anæmia, and certain patent medicines sold under the name of hæmatogen consist very largely of blood mixed with suitable flavouring and preservative agents. A still larger practical use of blood products (serum therapy) has been the outcome of work on immunity, in which the names of Richet, Ehrlich, Behring, and Roux may be mentioned as those of pioneers. Those interested in problems of immunity should consult current handbooks of pathology. The following does not pretend to do more than give a sketch of the main facts, and the example selected of the usefulness of the method is that in which serum therapy has been the most successful, namely, the treatment of diphtheria. The animal body is protected against its foes by a variety of mechanisms, and against our microscopic (bacterial) enemies the most potent of these is the action of colourless blood corpuscles (phagocytosis). This, however, is assisted in certain cases by the presence in the fluid part of the blood of chemical substances which have received a variety of names; for instance, 'bacteriolysins' are substances which actually kill bacteria; 'agglutinins' are substances which clump the bacteria together and render them immobile; 'opsonins' are substances which render bacteria an easy prey to leucocytes, either by adding something to them to make them tasty or removing something from them which makes them distasteful; and 'antitoxins' are substances which neutralise the poisons or toxins which are produced by the bacteria. There is very little accurate chemical knowledge of the composition of these various materials; they are, however, as a rule, destroyed by a high temperature, and are probably protein-like in nature. The amount of these substances in the blood may be increased by certain stimuli, much in the same way as the epidermis becomes thickened as the result of manual labour. The administration, for instance, of small doses of the toxin will produce an excessive production of the antitoxin which specifically neutralises the poison. Substances which in this way stimulate the production of these natural antidotes are spoken of in general terms as antigens.

If the bacilli which produce diphtheria are grown in a suitable medium, they produce the diphtheria toxin much in the same way as yeast will produce alcohol when grown in a solution of sugar. If a certain small dose of this poison is injected into an animal, it will produce death, and that is called the lethal dose. But if the animal receives a smaller dose, it will recover; a few days later it will stand a larger dose and recover more quickly; this is continued until after many successively increasing doses, it will finally withstand without ill effects an amount equal to many lethal doses. The animal is now immune against diphtheria, for the administration of the toxin (or antigen) has called forth an excessive production of antitoxin, and the blood remains rich in antitoxin for a considerable but variable time; the serum obtained from the blood of the immunised animal is then employed for injecting into other animals or human beings suffering from diphtheria, and rapidly cures the disease. The horse is the animal selected for the preparation of antitoxin, and the success of the new treatment in reducing the death-rate from what used to be considered a terrible disease is one of the wonders of modern medicine.

(5) *Miscellaneous uses of blood.* Blood is, or has been, employed in a number of industrial processes, but it will be sufficient here just to enumerate a few of them: thus it has been used as a medium for paints (Johnson, Eng. Pat. 82, 1883), in the preparation of adhesive cements, as a precipitant of sewage in the alum, blood, and clay process, and in the manufacture of pure animal charcoal.

Tests for blood. It is often necessary, in medico-legal practice, to be able to identify blood-stains on garments and instruments. If the blood is fresh, a microscopic investigation reveals the presence of corpuscles, and an aqueous extract will show the typical absorption bands of hæmoglobin with the spectroscope. The best chemical test is the formation of hæmin crystals already described, and is given by quite small quantities of blood, even if it is old and dry. When the blood is dry, and small quantities only are present, the most delicate spectroscopic test consists in dissolving it in dilute potash with the aid of heat, and then adding a drop of a reducing agent such as ammonium sulphide; the two absorption bands of reduced hæmatin are then seen, one about half-way between the D and E lines, and the other just on the blue side of the E line.

Human blood can only be distinguished with certainty from the blood of other animals by the so-called ‘biological reaction.’ The injection in successive doses of blood of another species into an animal acts as an antigen, and causes the development in the blood of the injected animal, of a specific ‘precipitin’; the addition of the blood to the serum of the animal which furnished the injected blood causes a precipitate; and such a precipitate does not form except between the blood of the two species of animal used in the experiment. This has been applied to the case of human blood, by taking a rabbit and injecting human blood into it. The serum of this rabbit will then give a precipitate with the blood of man (and to a less extent of the higher apes), and with the blood of no other species of animal. The test is extraordinarily delicate, and will detect human blood that has been dried for months, and even when it is mixed with the blood of other animals. W. D. H.

BLOODSTONE. A popular name for the mineral heliotrope, a variety of chalcedony (SiO_2), showing bright-red spots on a dark-green ground. It is much used for the engraving of ring-stones and seals.

The same name has also been used for hæmatite (Fe_2O_3), being a translation of *αἱματίτης*, so called because the colour of the powdered mineral is like that of dried blood.

L. J. S.

BLOOM. A term given to a mass of iron after it leaves the puddling furnace (*v.* IRON).

BLOOMERY. An old term for an iron furnace.

BLOWN OILS *v.* OILS and FATS.

BLOWPIPE *v.* ANALYSIS.

BLUBBER OILS *v.* OILS and FATS.

BLUE, ACETIN, *Coupier's blue* (*v.* INDULINES)

BLUE, ALIZARIN. This name is given to *dioxyanthraquinone-quinoline* $C_{17}H_9NO_4$, and its *sodium bisulphite compound*

$$C_{17}H_{11}NO_{10}S_2Na_2$$

(*v.* ALIZARIN AND ALLIED COLOURING MATTERS).

BLUE, ALKALI, NICHOLSON'S BLUE or **SOLUBLE BLUE** *v.* TRIPHENYLMETHANE COLOURING MATTERS.

BLUE, ANILINE. GENTIAN BLUE, OPAL BLUE, NIGHT BLUE, LIGHT BLUE, or **FINE BLUE** *v.* TRIPHENYLMETHANE COLOURING MATTERS; also ANILINE BLUE.

BLUE, ANTWERP, *v.* PIGMENTS.

BLUE, AZO-, *v.* AZO- COLOURING MATTERS.

BLUE, AZODIPHENYL, ACETIN BLUE, COUPIER'S BLUE, INDULIN, FAST BLUE R. $C_{18}H_{15}N_3Cl$ (*v.* INDULINES).

BLUE, BASLE. *Tolyldimethylaminophenotolyliminonaphthazonium chloride* $C_{32}H_{29}N_4Cl$ (*v.* AZINES AND COLOURING MATTERS DERIVED FROM THEM).

BLUE, BAVARIAN, *v.* TRIPHENYLMETHANE COLOURING MATTERS.

BLUE, BENZIDINE, *v.* AZO- COLOURING MATTERS.

BLUE BLACK *v.* AZO- COLOURING MATTERS.

BLUE, BLACKLEY, *v.* INDULINES.

BLUE, BRILLIANT COTTON, METHYL BLUE, METHYL WATER BLUE. *Soda salt of triphenyl-β-rosanilinetrisulphonic acid* (*v.* TRIPHENYLMETHANE COLOURING MATTERS.

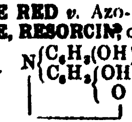
BLUE, QUINOLINE, *v.* TRIPHENYLMETHANE COLOURING MATTERS.

BLUE RED *v.* AZO- COLOURING MATTERS.

BLUE, RESORCIN, or LACMOID $C_{12}H_9NO_4$?

probably



$$N\begin{cases}C_6H_3(OH)_2\\C_6H_3\begin{cases}OH\\O\end{cases}\end{cases}$$

, a colouring matter obtained by Weselsky and Benedikt in 1880, by the action of sodium nitrite on resorcin. Blue violet powder soluble in water. Soluble in alcohol with blue colour and dark-green fluorescence. Used as an indicator in alkalimetry (*q.v.*).

BLUE, SAXON, *v.* Cobalt.

BLUE, VICTORIA, *v.* Triphenylmethane colouring matters.

BLUE COPPERAS, BLUE STONE, or **BLUE VITRIOL.** *Copper sulphate* (*v.* Copper).

BLUE GUM TREE. The *Eucalyptus globulus* (Labdll.), a tree common in Tasmania and South-Eastern Australia.

BLUE JOHN. A variety of fluor-spar found in Derbyshire, and valued for making ornamental articles (*v.* Calcium).

BLUE LEAD. A term applied to galena by miners to distinguish it from white-lead ore, or carbonate.

BLUE PIGMENTS *v.* Pigments.

BOBBINITE *v.* Explosives.

BODY VARNISH *v.* Varnish.

BOFFINITE. An explosive consisting of potassium nitrate, 62–65 pts.; charcoal, 17–19½ pts.; sulphur, 1½–2½ pts., copper sulphate and ammonium sulphate, 13–17 pts.

BOG-BUTTER or **BUTYRELLITE.** A substance resembling adipocere (*q.v.*), occasionally found in peat in Ireland and elsewhere. (For list of chemical and physical constants of a sample of bog-butter found in Tyrone, *v.* Radcliffe and Maddocks, J. Soc. Chem. Ind. 1907, 3.)

BOGHEAD COAL *v.* Paraffin.

BOGHEAD NAPHTHA *v.* Paraffin.

BOG-IRON-ORE. An impure iron hydroxide of recent formation in bogs and marshes. It is referable to the mineral species limonite ($2Fe_2O_3, 3H_2O$), and, in fact, this name (from λειμών, a meadow) was at first applied to this material, which is known in German as Raseneisenstein or Wiesenerz (meadow-ore). It is sometimes placed under the species limnite (from λίμνη, a marsh), to which the formula $Fe_2O_3,3H_2O$ is assigned. It contains 20–78 p.c. Fe_2O_3, some silica and organic matter, and often phosphates in considerable amount. The material has been deposited by the oxidation, through the agency of algæ and bacteria, of chalybeate waters. It is dug in shallow pits in the peat bogs of Ireland, the production amounting to a few thousand tons per annum, and is mainly used for the purification of coal-gas. The Swedish lake ores (sjömalm) are of the same nature L. J. S.

BOG MANGANESE, *wad*, or earthy manganese (*v.* Manganese and Wad).

BOHEMIAN BOLE. A yellow variety of bole (*q.v.*).

BOILED OIL. Linseed oil (*v.* Linseed oil).

BOILER INCRUSTATIONS AND DEPOSITS. The deposition of insoluble salts directly through boiling the water in boilers, or through concentration beyond the limit of solubility of salts in solution, or again, by interaction between otherwise soluble salts leading to the precipitation of insoluble salts, causes serious trouble in boiler practice, and lowers the efficiency of the boilers. Any incrustation or scale retards heat transmission to the water, thereby increasing fuel consumption; overheating of the plates or tubes may result in serious damage, and the removal of a hard scale by mechanical means leads to further damage, in addition to the cost of removal and the boiler being idle for some time. If the deposit remains as a soft mud, frequent use of the blow-off cock is demanded, and heat is lost in the hot water blown off; but this, of course, is preferable to the accumulation of the deposit, and its baking on the plates or tubes to a hard mass.

The question of corrosion is also closely associated in many cases with the production of deposits, and treatment on scientific lines for the removal of the latter overcomes troubles from the former.

Natural waters vary widely in composition, and some are wholly unsuited for boiler use, either by reason of the formation of deposits and scale, or of their corrosive action. For the different characters of natural waters and their composition, *see* article on Water.

It is convenient to regard deposits as the soft material which can be removed as sludge; incrustations as deposits more or less firmly adherent to the boiler; and scale as the firm hard material which can only be removed with difficulty, usually requiring chipping off. Naturally no hard-and-fast line can be drawn between these forms.

Either form is to be associated primarily with the 'hardness' of water. 'Temporary hardness,' *i.e.* hardness removable by simple boiling, is due to calcium and magnesium carbonates (to a small extent also to ferrous carbonate). These salts, although almost insoluble in pure water, dissolve in the presence of carbon dioxide, owing to the formation of soluble bicarbonates ($CaCO_3 \cdot H_2CO_3$; $MgCO_3 \cdot H_2CO_3$). One litre of water holds about 1·2 grams of calcium carbonate (as bicarbonate) in solution; after prolonged boiling about 18–20 milligrams per litre. In the presence of other soluble salts the solubility is increased, thus with calcium sulphate present the solubility may be increased to 1·8 grams of $CaCO_3$ (as bicarbonate) per litre.

When water containing calcium bicarbonate is heated to about 65° C. it begins to deposit the normal carbonate in powdery form; at a later stage the deposit becomes crystalline, and may form a fairly adherent incrustation. Calcium carbonate exists in two crystalline forms, *calcite* (rhombohedral, belonging to the hexagonal system), and *aragonite* (orthorhombic, belonging to the rhombic system). The latter is harder and denser than calcite, and is believed by some authorities to be the cause of incrustation from carbonated waters. On boiling such waters the precipitate is a mixture of calcite and aragonite; the presence of other soluble salts favours the formation of aragonite.

Magnesium carbonate behaves somewhat differently, several intermediate hydroxy-carbonates being formed, the composition of which is dependent on temperature. By continued boiling in the presence of water at high temperatures (under pressure) magnesium carbonate forms the hydroxide ($Mg(HO)_2$), with liberation of carbon dioxide, and, according to J. H. Paul, insoluble magnesium oxide may even result. W. A. Davis (J. Soc. Chem. Ind. 1906, 788) found that on heating an alkaline solution of magnesium bicarbonate to 50° in a partially closed flask, the precipitate was $MgCO_3 \cdot 3H_2O$. At 100° it lost water ($2H_2O$), and at 125° the third molecule, together with carbon dioxide.

A table of solubility of magnesium carbonate in water containing carbon dioxide at various pressures will be found under Magnesium carbonate.

Solutions of magnesium carbonate decompose much more slowly on boiling than those of calcium bicarbonate, but the precipitation is more complete. In peaty waters the deposition of both carbonates is considerably retarded and may be prevented.

Ferrous carbonate behaves similarly to calcium carbonate.

The 'permanent hardness' is due chiefly to the sulphates of calcium and magnesium; to a minor extent to the chlorides and nitrates of these metals. Boiling at ordinary pressure does not cause the deposition of any of these salts, providing the water does not become too concentrated. On the other hand, boiling at the higher pressures existing in boilers almost complete precipitation of calcium sulphate occurs, and this constitutes the most troublesome constituent in boiler waters, being very largely responsible for the formation of hard adherent scales.

Calcium sulphate ($CaSO_4$) is practically insoluble in water. It occurs naturally in the hydrated form ($CaSO_4 \cdot 2H_2O$) as *gypsum*. Two varieties of the anhydrous sulphate are recognised; insoluble and soluble *anhydrite*. The solubility of natural gypsum attains a maximum at 32° C., 100 parts of water dissolving 0·2096 part. At 10° C. the solubility is 0·1929; at 100°, 0·1620 (Hulett and Allen, J. Amer. Chem. Soc. 1902, 24, 667). Much stress has been laid on the decreasing solubility with rise of temperature as the important factor in causing deposition in practice, but since the amount of calcium sulphate is generally much below the limit of solubility at 100°, it seems impossible that it can be an important factor. According to Silchester, at low boiler pressure (28–29 lbs.) water containing the salt will concentrate like other waters without scale, but at higher pressures (40–50 lbs.) will deposit, due to the formation of a hemihydrate, $2CaSO_4 \cdot H_2O$, at a temperature of 107°. This has been recognised by Johnston in scale from boilers working at 2 atmos. Above 130° the anhydrous calcium sulphate is formed. These are salient facts in the formation of hard scales due to this salt, for it is evident that it is not a question of concentration above the limit of solubility of $CaSO_4 \cdot 2H_2O$, but the definite formation of another phase, and the material being practically insoluble in this phase is almost completely precipitated even when present in very small amount in the water. 130°, or perhaps a little lower, may be regarded as the critical point determining the precipitation of calcium sulphate.

The solubility is increased by the presence of other more soluble salts such as sodium chloride and sulphate, and calcium sulphate may concentrate to a fairly high degree in a boiler water, as is shown by the following analysis by J. C. W. Greth:—

	Grains per Imperial gallon
Volatile and organic matter .	5·04
Silica	0·66
Calcium carbonate . .	1·20
Calcium sulphate . .	94·56
Magnesium sulphate . .	7·63
Sodium chloride . . .	12·66
Sodium sulphate . .	23·77

Other constituents of natural waters, such as calcium chloride, magnesium sulphate and chloride, often play an important part in the formation of scale by interaction; thus magnesium sulphate, although so soluble that it should never form part of a scale under proper working conditions, may be almost as troublesome as calcium sulphate, since with calcium carbonate or chloride it reacts with the formation of calcium sulphate and magnesium carbonate or chloride.

Formation of scale.—Waters which are in the main temporarily hard will deposit the carbonates of calcium and magnesium (also ferrous carbonate, if present), either in the boiler or feed-water heaters by the simple dissolution of the bicarbonates. Such deposits are usually powdery; in the presence of organic matter they seldom form coherent deposits, and so may be got rid of by the sludge cock. Under some conditions, however, the deposits bake on the plates or tubes and form incrustations. Further, on concentration of the water other salts in solution, like magnesium or sodium sulphate, may react on the incrustation with the formation of calcium sulphate and produce a much harder deposit—a true scale. Similarly, an incrustation containing magnesium hydroxide may react with magnesium chloride and form a hard incrustation.

The deposition of the carbonates is a gradual process so that a temporarily hard water which deposits much of its calcium carbonate in the feed-water heaters, but less of the magnesium carbonate because of its slower rate of deposition on heating, will continue to deposit in pipes, and such deposit will, for the same reason, contain a higher proportion of magnesium carbonate. Such actions are modified by the presence of other salts; thus, according to Petit, sodium chloride reduces the proportion of lime and increases that of magnesium, whilst magnesium sulphate causes more lime to be retained in solution.

Calcium sulphate, whether present as such or formed by interactions on concentration of the water, becomes deposited in the anhydrous form as soon as the temperature is above that corresponding to the phases $CaSO_4 \cdot 2H_2O$ or $CaSO_4 \cdot H_2O$. It forms an extremely hard scale of itself. If deposited amongst the precipitated carbonates it acts as a binder, and may form hard incrustations or scales. Its deleterious action may, therefore, be far greater than the mere proportion present would indicate. Calcium sulphate is throughout the most important factor in the formation of hard incrustations and true scales.

In broad terms, whilst the carbonated waters (temporarily hard) form soft easily removed deposits or incrustations, and waters containing calcium sulphate, or salts liable to form it by interaction (permanently hard), produce hard scales, and serve to bind loose incrustations into harder masses, such a generalisation must only be accepted as broadly true, for exceptions are not infrequent under the varying composition of natural waters and conditions of practice.

Magnesium hydroxide ($Mg(HO)_2$) with magnesium chloride forms a hard material; certain covering compositions for ships' decks are made on this basis. In the presence of calcium sulphate these salts form very hard porcelain-like scales, which are extremely difficult to remove. According to J. H. Paul, the tidal waters of the Thames give such a scale, the composition being very constant between 85–87 p.c. calcium sulphate, and 10–13 p.c. magnesium hydroxide, which approximately agrees with a molecular composition $3CaSO_4 \cdot Mg(HO)_2$.

Under bad conditions of working the concentration of the water in a boiler is sometimes allowed to increase to such an extent that soluble salts are deposited along with the true incrustation-forming solids. Paul gives the composition of such a scale from a feed-water containing 20 grains of lime and magnesia, and 40 grains of sodium salts per gallon as:—

Calcium carbonate . .	3·89 p.c.
Magnesium carbonate . .	1·16 ,,
Silica	0·69 ,,
Iron oxide	0·77 ,,
Sodium chloride . . .	77·09 ,,
Sodium sulphate . . .	11·82 ,,
Sodium carbonate . .	3·62 ,,
Combined water . . .	5·96 ,,

Ninety-five p.c. of this hard tough crystalline scale was soluble in water. The removal of scales of this 'soluble' type is simple, it being only necessary to blow down the boiler and fill up with fresh water and again empty.

The formation of scale from sea water is a matter of some importance, for although the use of sea water in boilers has been almost entirely discarded in favour of the use of distilled water for the 'make up,' made in the ship's evaporating plant, yet sea water frequently finds its way into the feed from leaky condensers, or through priming in the evaporator. The scale from sea water is mainly calcium sulphate, together with magnesium hydroxide and silica. Frequently the scale can be separated into a hard and soft portion, the latter containing a considerably higher proportion of magnesium hydroxide. The calcium sulphate may be between 80–90 p.c., magnesium hydroxide 2–5 p.c., calcium carbonate is usually under 1 p.c. One ton of sea water contains about 3·5 lbs. of scale forming salts, of which a little over 3 lbs. is calcium sulphate.

With low-pressure boilers it was possible to evaporate sea water without any serious trouble, providing the density was not allowed to become excessive (according to Lewes, to a density of 1·09 without deposition of calcium sulphate), but with modern boilers working at high pressures, so that the boiling-point was raised above the critical temperature of deposition of calcium sulphate in brine solution, troubles from scaling became so developed that the use of such water in these boilers had to be abandoned.

The formation of magnesium hydroxide is probably due to the interaction of the concentrated solution of magnesium chloride on the small amount of calcium carbonate which would be the first substance to deposit, the magnesium carbonate formed later losing carbon dioxide. Such a reaction accounts for the very small quantity of calcium carbonate in the scale. Magnesium hydroxide may also partly result by direct hydrolysis of magnesium chloride which takes place readily in contact with heated iron. Hydrochloric acid is set free, and this is closely associated with corrosion of the boiler on which it acts with the production of ferrous chloride, this further reacts with magnesium hydroxide in the absence of air. Free hydrochloric acid and iron are thus not found in the water; indeed the water is slightly alkaline, due to the solubility of the excess of magnesium hydroxide.

PREVENTION OF SCALE.

The treatment of water to prevent the formation of incrustations or scale may either be preparatory to its use in the boiler, or chemicals (generally sold as 'boiler fluids') may be added from time to time to the water in the boiler. In the latter case prevention of troublesome scale may be possible, the added fluids causing precipitation in a form which can be easily removed by the sludge cock, but unless all scale-forming materials can be kept in solution, an almost unrealisable condition, it is clearly more satisfactory to remove the causes of trouble before the water enters the boiler.

There is no relationship between the amount of impurity in a water and its scale forming character, since concentration will soon increase the quantity from even a very pure water. The essential point is the character of the dissolved solids, and accurate analysis is essential both from the point of view of determining suitability for boiler use, and the correct system of treatment necessary to render a natural water suitable.

With purely carbonated waters treatment in a special form of heater, whereby the calcium and magnesium carbonates are to a considerable extent precipitated, may be satisfactory, but in general chemical processes are employed. Although a large number of reagents have been proposed and adopted with success in special cases, three only find extended use, namely, lime (as milk of lime or as clear lime-water), sodium carbonate (soda ash), and sodium hydroxide (caustic soda). The action of lime on the bicarbonates is

$$CaCO_3 \cdot H_2CO_3 + Ca(HO)_2 = 2CaCO_3 + 2H_2O$$

$$MgCO_3 \cdot H_2CO_3 + Ca(HO)_2 = CaCO_3 + MgCO_3 + 2H_2O$$

The removal of calcium carbonate is never quite complete, and the reaction is still less complete with magnesium bicarbonate.

It can be ascertained when lime has been added in the requisite slight excess by the yellowish brown colouration the water gives with silver nitrate solution.

Lime has no action on the salts which cause permanent hardness, so that it is seldom employed alone, but generally in conjunction with soda ash or caustic soda. Either or both of these reagents may be employed without lime, and will remove both temporary and permanent hardness under suitable conditions. Soda ash reacts as follows:—

$$CaCO_3 \cdot H_2CO_3 + Na_2CO_3 = CaCO_3 + 2NaHCO_3$$

At temperatures above 160° the sodium bicarbonate is converted into the normal carbonate again, and carbon dioxide is liberated.

With caustic soda the reaction is similar, so that theoretically a small amount of either reagent is capable of dealing with the temporary hardness of a large quantity of water, but there is always the liability of the water becoming unduly alkaline by concentration.

With magnesium bicarbonate it is frequently found that when the correct quantity of is no precipitation in the cold. W. A. Davis (*l.c.*) states that this is due to the formation of the soluble salts

$$MgHCO_3{\cdot}CO_3.Na \text{ or } Mg(CO_3{\cdot}Na)_2,$$

according to the proportions used. Precipitation only occurs when the liquid is heated sufficiently to decompose these soluble double salts when a mixture of magnesium hydroxide and a basic carbonate, $Mg(OH){\cdot}(HCO_3)$, is precipitated. Consequently below a certain temperature it is impossible to completely soften magnesian waters containing small quantities of the bicarbonate, sulphate or chloride by means of either sodium carbonate or hydroxide.

It follows that a water containing magnesium salts if treated by these chemicals in the cold will deposit sludge or form an incrustation in a boiler or in feed-water heaters.

The action of sodium carbonate on calcium or magnesium sulphate causes precipitation of the respective carbonates and the formation of sodium sulphate. Sodium hydroxide forms calcium hydroxide and sodium sulphate, and the calcium hydroxide may then react on the salts causing temporary hardness, if these latter have not already been acted on directly according to the equation

$$CaCO_3{\cdot}H_2CO_3+2NaOH$$
$$=CaCO_3+Na_2CO_3+2H_2O$$

With these soluble alkalis it is important to note that the water will be left with free alkali in solution if the salts causing temporary hardness are in excess of the molecular equivalent of those causing permanent hardness. With calcium sulphate, on the other hand, in excess, or in molecular proportion, the sodium will all remain as sulphate

$$CaCO_3{\cdot}H_2CO_3+Na_2CO_3=CaCO_3+2NaHCO_3$$

(Mol. Wt. 100).

Above 160° C. $2NaHCO_3=Na_2CO_3+H_2O+CO_2$

$$CaSO_4+Na_2CO_3=CaCO_3+Na_2SO_4$$

(Mol. Wt. 136).

Accumulation of free alkali in boiler waters is objectionable ; it is commonly associated with priming or foaming, and if the solution be at all concentrated, may cause attack of brass boiler fittings and even of the gauge glass. For certain industrial purposes also alkaline water is inadmissible ; for example, in affecting delicate shades of colour in dyeing, and in the preparation of tan liquors.

Caustic soda requires using with discretion. It finds most useful application with waters containing the sulphates, chlorides and nitrates of calcium and magnesium.

Other chemicals which have been employed include magnesium oxide (or hydroxide), barium hydroxide and chloride, and the oxalates of potassium and sodium, but as they offer little advantage over lime and soda, and are very much more expensive, they are but seldom employed. Aluminium sulphate, alum solution, or sodium aluminate are sometimes employed.

A most successful system, both for boiler and industrial purposes, is the *Permutite* process, and this gives an almost perfectly softened water, and the process is one requiring the minimum of plant, it being simply necessary to pass the water through vessels containing the material. This is an artificial zeolite made by fusing together silica, alumina (or China clay) and sodium carbonate, and extracting the soluble portion with water. The crystalline product is a double silicate of alumina and soda, approximating to the composition $Al_2O_3{\cdot}Na_2O{\cdot}4SiO_2{\cdot}5H_2O$. Generally a portion of the soda is replaced by a small quantity of potash (K_2O) and lime.

Water is passed through the crystalline material when the sodium is replaced quantitatively by other metals, such as lime

$$Al_2O_3{\cdot}Na_2O{\cdot}4SiO_2+CaCO_3{\cdot}H_2CO_3$$
$$=Al_2O_3{\cdot}CaO{\cdot}4SiO_2+2NaHCO_3$$
$$Al_2O_3{\cdot}Na_2O.4SiO_2+CaSO_4$$
$$=Al_2O_3{\cdot}CaO{\cdot}4SiO_2+Na_2SO_4$$

The permutite may be regenerated when exhausted by passing strong brine through it, and this therefore is practically the only softening agent consumed.

With the ordinary permutite waters containing iron cannot be treated, and a special form containing a proportion of the higher oxides of manganese is used. This causes oxidation of ferrous to ferric salts, which are precipitated.

According to Bahrdt the reactions between the alkaline earth metals and permutite are reversible, and calcium can displace magnesium from magnesium permutite if first formed, and more magnesium may at times be present in the treated than in the untreated water. Bahrdt therefore recommends prior removal of the temporary hardness by lime and confining the permutite treatment to the removal of permanent hardness. Such treatment would require to be carefully controlled, as a too highly alkaline water spoils permutite.

The point must be emphasised that whilst with lime in the correct proportion to remove temporary hardness the precipitate is wholly insoluble, and no soluble salts are formed, with practically all other reagents an insoluble and soluble salts are formed. The latter will increase by concentration in the boiler, and care must be taken that this does not become excessive. Especially is this important where the soluble salt is alkaline.

Softening plant. Numerous forms of plant are employed for carrying out the softening process ; in some the sludge is allowed to settle, two tanks being used alternately. To decrease the settling period the sludge is generally stirred up with the fresh charge, and since the upper portion of the water clarifies first considerable saving of time (and consequent reduction in size of tanks) is possible by the use of a draw-off pipe carried by a float. Many softening plants are provided with automatic means of measuring in the required reagents in the proportion determined by analysis, also with mechanically operated stirrers and suitable filtering arrangements. It has been found that the softening process is more complete when there is an accumulation of precipitated material in the filters, which suggests that the action of the sludge left in settling tanks is beneficial beyond its mere mechanical action in promoting clarification.

With waters softened by the lime-soda treatment, even with heat, the reactions are often not completed in the tanks, and deposits are found in the feed-water heaters and pipes. These incompleted reactions are primarily due to magnesium salts, the behaviour of which has already been referred to. In the Archbutt-

Deely process this trouble is overcome by passing carbon dioxide into the softened water, the gas being drawn off from a coke fire, freed from sulphur dioxide by limestone, and injected by the steam blower, which serves to draw the gases from the small producer.

Boiler Fluids.

The use of an anti-incrustation fluid in the boiler is greatly favoured by many engineers, but is not such a satisfactory method of treatment as the prior removal of the scale-forming constituents. The method has the advantage of requiring no external plant, and for one or two boilers this is an advantage; but for larger installations a proper softening plant is better and more general in practice. It is obvious that precipitation of any solids by the boiler fluid takes place in the boiler, and the sludge so formed must be blown out at intervals. Some of the compounds used are not without action on boiler plates, tubes and fittings, especially copper alloys.

Sodium carbonate and hydroxide with waters containing little of the bicarbonates of lime and magnesium, especially if the water is slightly acid, give good results. With carbonated waters the alkali will not be used up and the water may become objectionably alkaline.

Ammonium chloride reacts with calcium carbonate, producing calcium chloride and ammonium carbonate, and the latter is decomposed at boiler temperatures, ammonia escaping in the steam. With magnesium salts magnesium chloride may be formed, and this is an active corrosive agent.

Sodium phosphate ($Na_2HPO_4 \cdot 12H_2O$) is suitable for sulphated waters. Bicarbonates are also decomposed, apparently through hydrolysis of the salt in solution with the formation of a small amount of sodium hydroxide.

Sodium sulphite and silicate are also sometimes employed. The former precipitates calcium sulphite, which is slowly oxidised to sulphate, in a non-crystalline form so that it can be blown off. Sulphites are, however, likely to cause corrosion, especially in the presence of nitrates, which become reduced to nitrites, and as these decompose active corrosion may result. The objection to sodium silicate is its liability to harden otherwise soft incrustations.

Many organic substances of the most varied character, starchy, albuminous and gelatinous materials, are used. The general action appears to be due to their colloidal character, which prevents the formation of crystalline deposits.

Tannic acid, or sodium tannate, have been widely employed. The free acid decomposes the carbonates with the formation of insoluble tannates. Tannic acid may act on the iron, and should only be used with alkaline waters, and then under careful chemical supervision. Alkaline solutions containing more or less sodium tannate are frequently employed, but it is probable that the anti-incrustation action is mainly physical and due more to the organic extractives than the sodium tannate itself, except in so far as the alkali itself acts in accordance with reactions already dealt with.

Oily Deposits.

The presence of oil globules carried into the boiler by the condensed steam from the cylinders has been the cause of several boilers collapsing, owing chiefly to overheating of the crown plates of the furnace. Even with good mineral cylinder oils a process akin to steam distillation may take place, so that portions of the oil normally of higher boiling-point than the temperature of the steam are carried forward in the condensed feed-water. These oily globules attach themselves to any precipitated carbonates or sulphates, rendering the material lighter, so that it is carried freely by the convection currents until meeting highly heated metal surfaces it becomes deposited. It is characteristic of such deposits that they occur as frequently on the underside of tubes as on the upper side (where non-oily incrustations are usually much thicker), this being due to this circulating action. Frequently all oil may disappear from the incrustation, owing to excessive heating of the metal in contact with it.

Another action not generally recognised is that some oils derived solely from petroleum (mineral oils) are liable to oxidation with the formation of acids akin to, if not identical with, fatty acids, and these form insoluble soaps with lime and magnesia. With the latter in particular the soap is of an adhesive character, it collects other floating solids, and deposits a mass on plates and tubes. The free acids also attack copper, lead and zinc of brass fittings, and the salts of these metals are frequently found in the incrustation Paul has published analyses of several such deposits, a typical one from a wholly mineral oil being :—

Uncombined oil . . .	49·99	p.c.
Combined oily acids . .	6·72	„
Zinc oxychloride . .	22 79	„
Lead oxide	0 47	„
Copper oxide . . .	0·10	„
Ferric oxide . . .	7 02	„
Magnesium oxide . .	11·90	„
Silica	1·10	„

When mixtures of saponifiable and non-saponifiable oils were employed for cylinder lubrication the formation of fatty acids which passed to the boiler feed water was much more serious, and led to the abandonment of saponifiable oils. With boilers working at the high pressures now common, especially in conjunction with high super-heat of the steam, it has become a most important matter to select only cylinder oils of the highest quality, free from tendency to form acids. In every case where condensed water is used it is most essential to instal efficient means of removing oil, either in exhaust steam separators or feed-water filters. Aluminium sulphate or alum have been employed with success to aid the separation of the emulsified oil, the aluminium hydroxide formed by precipitation with any alkali present collecting the oil globules, and their removal by filtration is facilitated. J. S. S. B.

BOIS-PIQUANT BARK. The bark of *Zanthoxylum caribæum* (Lam.), and *Z. Perrottetii* (D.C.). Used in France as a febrifuge (Heckel a. Schlagdenhaffen, Compt. rend. 98, 996).

BOLDO. A shrub, *Peumus boldus* (Molina), belonging to the *Monimiaceæ*, growing in the Chilian Andes. The bark is used in tanning, the wood makes a good charcoal, and the bark and leaves contain a glucoside $C_{30}H_{52}O_8$, useful as a hypnotic and cholagogue (Chapoteau, Compt. rend. 98, 1052).

BOLE. (*Bol*, Ger.) A ferruginous clay-like substance, of red, brown, or yellowish colour. It is not plastic, and when thrown into water falls to pieces with emission of streams of minute air-bubbles. It has an unctuous feel, and some varieties adhere to the tongue. When cut it presents a shining streak. Before the blowpipe it fuses to a yellowish or white enamel. Its composition is very variable, but its usual limits are from 41 to 47 p.c. SiO_2, 18 to 25 p.c. Al_2O, and 24 to 25 p.c. H_2O, with a proportion of Fe_2O_3, which may reach 12 p.c. It will be noticed that the percentage of water is higher than in clays. The *Fettbol* of Freiberg in Saxony occurs in mineral veins, and contains only about 3 p.c. of Al_2O_3. The bole of Stolpen in Saxony is a yellowish substance containing only a trace of Fe_2O_3. Rammelsberg's analysis yielded SiO_2, 45·92 ; Al_2O_3, 22·14 ; CaO, 3·9 ; H_2O, 25·86. In the 'bole of Sinope' (sinopite) from Asia Minor the SiO_2 falls as low as 32 p.c. The ancients obtained this material from Cappadocia, and used it as a red pigment. It was also employed in medicine as an astringent (*v.* LEMNIAN EARTH).

The following is an analysis of bole, occurring in granite, at Steinkirchen, Bohemia :—Dried at 100° it yielded SiO_2, 46·73 ; Al_2O_3, 26·17 ; Fe_2O_3, 12·34 ; CaO, 1·64 ; MgO, 1·31 ; K_2O, 0·98 ; MnO, 0·28 ; loss on ignition, 10·53 (G. Starkl, Verh. k. k. Geolog. Reichs. Vienna, 1880, 279).

Bole is frequently found as a product of the decomposition of basaltic rocks. Thus the sheets of basalt in N.E. Ireland, representing Tertiary lava-flows, are separated by partings of bole, associated with lithomarge, bauxite, pisolitic iron-ore, and seams of lignite. The Antrim bole is described as a poor variety of aluminous iron-ore (G. A. J. Cole, The inter-basaltic rocks (iron ores and bauxites) of north-east Ireland, Mem. Geol. Survey, Ireland, 1912).

L. J. S.

BOLOGNIAN STONE. A native variety of barium sulphate found as nodular masses embedded in clay near Bologna ; when partially reduced to sulphide by calcination with charcoal it exhibits phosphorescence. Vanino and Zumbusch (J. prakt. Chem. 1911, 84, 305) have attempted to ascertain the factors which determine the phosphorescent quality of Bologna stones. Good samples may vary in sulphur content between 12 and 33 p.c. Marked phosphorescing power seems to depend upon the presence of polysulphides ; products containing only monosulphide are deficient in this respect. The presence of calcium oxide appears to increase the phosphorescing power (*v.* BARIUM and BARYTES).

BOLORETIN *v.* RESINS.

BOMBICESTOROL *v.* STEROLS.

BONE. Bony tissue may be either compact as in the shafts of the long bones, or spongy or cancellated as in the flat bones of the skull and in the extremities of the long bones ; here an external compact layer encloses a mass of spongy bone or diploë. From the embryological point of view, bones may be divided into cartilage bones and membrane bones. The cartilage bones are those which in embryonic life are preceded by cartilaginous prefigurements ; these comprise the majority of the bones in the body, and include all the long bones except the clavicle. In the case of membrane bones (for instance, the flat bones of the cranium), there is no such preliminary cartilaginous prefigurement. It must not, however, be supposed that in the cartilage bones the cartilage is converted into bone ; for here, as in the cases where there is no cartilage present, the true bony tissue is laid down by the agency of certain cells termed osteoblasts in the connective tissue sheath (periosteum) of the bone, and the cartilage when present, after undergoing a certain amount of calcification, is then entirely eaten away by certain large cells called osteoclasts. In the cartilaginous, as distinguished from the bony or teleostean, fishes, the replacement of the cartilage by true bone does not occur.

Bone is deposited in concentric laminæ, the majority of the layers encircling the channels called Haversian canals, in which the blood-vessels lie. The living elements in bone, the bone cells, lie in spaces between the laminæ, and these spaces (lacunæ) intercommunicate by minute canals, in which lymph flows and maintains their nutrition.

The chemical materials present are organic and inorganic. The organic materials are proteins and nucleïn derived from the bone cells, a small quantity of an elastin-like substance which forms a lining to the Haversian canals, and a mucoid or glucoprotein ; but the principal organic material, sometimes misnamed bone cartilage, is better termed osseïn. Osseïn is identical with the collagen of connective tissues, and like it yields gelatin on boiling with water. If the inorganic salts are dissolved out by mineral acids, the osseïn remains as an elastic mass which preserves the original shape of the bone.

The inorganic constituents remain as the so-called bone earth after the bone is completely calcined ; it consists chiefly of calcium phosphate, but also contains calcium carbonate, and small amounts of magnesium, chlorine, and fluorine. Gabriel (Zeitsch. physiol. Chem. 18) states that potassium and sodium also occur. Traces of iron come from the blood in the bone, and of sulphate from chondroitin-sulphuric acid (Mörner, *ibid.* 23).

Investigators differ as to the manner in which the inorganic substances are combined. Chlorine and fluorine are present in the same form as in apatite ($CaFl_2 \cdot 3Ca_3P_2O_8$), and according to Gabriel, the remaining mineral constituents form the combination $3(Ca_3P_2O_8)CaCO_3$. He gives as the simplest expression for the composition of the ash of bones and teeth the formula $Ca_3(PO_4)_2 + Ca_3HP_3O_{12} + H_2O$, in which 2–3 p.c. of the lime is replaced by magnesia, potash, and soda, and 4–6 p.c. of the phosphoric acid by carbon dioxide, chlorine, and fluorine.

Zalesky's analyses (Hoppe-Seyler's Med. Chem. Untersuch. 19) show how closely bone earth agrees in composition in different animals. The figures represent parts per 100. (See Table.) The various bones of the skeleton differ a good deal in the proportion of water, organic solids, and inorganic solids which they contain. This depends to some extent on the admixture of marrow, blood-vessels, and other formations from which it is difficult to free entirely the osseous tissue proper. The quantity of water in fresh bones thus varies from 14 to 44 p.c., and of fat between 1 and 27 p.c. The quantity of total organic substance varies from 30 to 52 p.c., the remainder being inorganic.

—	Man	Ox	Tortoise	Guinea-pig
Calcium phosphate $Ca_3(PO_4)_2$	838·9	860·9	859·8	873·8
Magnesium phosphate $Mg_3(PO_4)_2$	10·4	10·2	13·6	10·5
Ca combined with CO_2, Fl, and Cl	76·5	73·6	63·2	70·3
CO_2 (partly lost on calcining)	57·3	62·0	52·7	—
Chlorine	1·8	2·0	—	1·3
Fluorine	2·3	3·0	2·0	—

The marrow is from the chemical point of view mainly fat; its cells yield protein and nucleoprotein.

On a rough average it may be said that two-thirds of the solids consist of inorganic and one-third of organic compounds.

With regard to the minute composition of bones at different ages, we have no very accurate information. Voit found in dogs and Brubacher in children, that the water in the skeleton decreases and the ash increases with advance of years. Graffenberger's observations on rabbits confirmed this view.

A great many experiments have been made to determine the influence of food—for instance, rich or poor in lime salts—on the composition of bone, but the results have been doubtful or contradictory. The attempts to substitute other alkaline earths for lime have also given uncertain results (*see* H. Weiske, Zeit. f. Biol. 31; also Hammarsten's Physiol. Chem. translated by Mandel).

A large number of data have also been published regarding the variations in chemical composition in different diseases of bone. Thus in exostoses the inorganic material is usually increased; in rickets and osteomalacia, the proportion of water and ossein to bone earth is raised. The view that lactic acid is responsible for the washing out of lime salts from bones in rickets is, however, discredited.

The somewhat rare condition of a curious protein (called Bence-Jones protein, after its discoverer) in the urine is almost invariably associated with bone disease (osteomalacia, or malignant new growths). This protein in many of its characters resembles a proteose, but is probably derived from the mucoid of osseous tissue (Rosenbloom, J. Biol. Chem. 1910, 7, 14; Williams, Bio. Chem. J. 1910, 5, 225).

On heating out of contact with air, bone evolves a large quantity of volatile matter (*v.* Bone oil) which contains ammonia, pyridine bases, pyrrol, nitriles, &c. A black residue is left, consisting of the bone ash in association with carbon, which is called animal charcoal (*q.v.*).

The industrial uses of bone are very numerous and involve a large import trade; not only is the bone itself made into many utensils, but the materials made from the bone (charcoal, bone ash, gelatin, &c.) are put to many uses.

Thus animal charcoal or bone black is employed in many chemical operations, in sugar refining, as a polish for silver work, &c.

Bone meal and bone ash are extensively employed as manure, and in the preparation of the superphosphates of commerce.

The gelatin in an impure form is used in the preparation of paper, silk, furs, &c., and the purer varieties are also put to numerous uses, for instance, as a clarifying agent in the preparation of wines, beers, liqueurs, for food in the preparation of soups, jellies, and puddings, in the making of photographic films, and in Bacteriology for the preparation of culture media. (*See* Merck's Waren-Lexikon, arts. 'Knochen,' 'Knochenasche,' 'Knochenkohle,' 'Knochenöl'; H. Ost, Lehrbuch der Chem. Technologie, 6th ed. 1907, 'Knochenmehl,' 187, 'Knochenleim,' 621; Dammer, Handbuch d. chem. Technologie, 1898, 5, art. 'Knochenverarbeitung,' 254.)

The mention of gelatin as food suggests a word on its nutritive value. It is easily digestible and assimilable, and so is much employed in invalid cookery; nevertheless, it has long been recognised that it is of inferior nutritive value. If animals receive gelatin as their sole nitrogenous food, they waste and die more rapidly than if nitrogenous food is entirely withheld from them; still, when mixed with other proteins, less of the latter is sufficient to maintain life. Recent investigations on the chemistry of proteins have shown that gelatin is destitute of the tyrosine and tryptophane groups, and these groups appear to be of special value or even indispensable for tissue repair; the previously puzzling behaviour of gelatin in nutrition is thus explicable. W. D. H.

BONE ASH *v.* Bone and Fertilisers.

BONE BLACK *v.* Animal charcoal.

BONE EARTH. The calcined residue of bones, consisting chiefly of calcium phosphate (*v.* Bone).

BONE FAT is the fatty matter contained in the bones of animals, and is practically a by-product in the process of working up bones, whether it be for the manufacture of bone char or for the production of glue and gelatin. In either of these manufactures, the 'degreasing' of the bones precedes all further manipulations. Bones from head, ribs, shoulder blades, &c., contain from 12 to 13 p.c. of fat, whilst the 'marrow' bones, *i.e.* the large thigh bones, contain as much as 18–20 p.c. Formerly bone fat was produced by boiling the broken bones with water in open vessels, and allowing the hot liquor to stand, so that the fat could separate on the top and be skimmed off. In the case of fresh bones, the recovered bone fat had a white to yellowish colour, a faint odour and taste, and the consistence of butter. When putrid bones were employed, the bone fat passed, according to age and state of decomposition of the organic matter in the bones, through all gradations from a white fat to a dark rancid fat of a very disagreeable smell. The boiling-out process allows only about one-half of the fat to be recovered. The small yield, and the nuisance connected with the preparation of the bone fat forced the manufacturers to treat the bones with steam under pressure. The broken bones were placed in a cage fixed inside an autoclave, and were heated therein with open steam, under a pressure of 2 to 3 atmospheres. The bone fat so obtained was of the same quality as that prepared by the former process. The best bone fat obtainable in the market is at present prepared by this process, especially in the large packing houses of the United States and South America, where the bones are worked up in the fresh state. They are first washed in 'bone-washing machines.' These are cylinders usually 10 feet long and 3 feet to 4 feet in diameter, built up from iron bars, 1 inch apart, fixed into two cast-iron heads. They are driven by chain and sprocket, and rotate slowly, making about ten revolutions per minute. Through the entire length of the drum there is a hinged door made of bars, which allows the filling and emptying of the cylinder. The machines are usually set at an angle to facilitate the washing and emptying operations. Some manufacturers even resort to steeping the bones in a solution of sulphurous acid in order to obtain a whiter fat (as also a better glue) than unbleached bones afford (*see*, however, Head and Lloyd, J. Soc. Chem. Ind. 1912, 31, 317). The yield of bone fat in the steaming-out process under pressure is considerably higher (by about 50 p c.) than in the boiling-out process in open vessels, so that from bones containing 12 p.c. of fat, 8 to 9 p.c. can be recovered.

Bone fats of this quality can be bleached, but only the best kinds are likely to yield a good product. The higher the percentage of free fatty acids, the greater is the difficulty in bleaching. In fact, products containing more than 50 p.c. of free fatty acids could hitherto not be bleached successfully.

The highest yield of bone fat is obtained by treating the bones with an organic solvent, whereby the animal tissue remains unimpaired, so that the whole of the glue-yielding organic substances can be converted into glue after the fat has been removed. The solvent used in bone-extracting works is almost exclusively petroleum spirit or Scotch shale oil, boiling between 100° and 130°. Proposals have been made to use carbon tetrachloride or chloro- compounds of ethylene and ethane. Experiments with carbon tetrachloride have, however, been abandoned as unremunerative. Extraction with 'benzine' or shale oil takes place in iron digesters under pressure or in open apparatus. The fat obtained by the extracting process is dark-brown, and has a very penetrating, unpleasant smell. In addition to a considerable amount of free fatty acids, it contains lime-soap, calcium lactate, calcium butyrate, and hydrocarbons from the 'benzine' which cannot be fully removed even by prolonged steaming. Hitherto, this kind of fat has not been treated successfully, and even when some immediate improvement was obtained, the colour and also the unpleasant smell 'reverted' after a short time. A patent by Volland (D. R. P. 222669) claims, however, to bleach extracted bone fat by means of barium peroxide.

In von Girsewald's process (Fr. Pat. 430015, 1911) the vapour of the petroleum spirit or other solvent finally remaining in the pores of the material is condensed by the introduction of vapour of the same solvent at a pressure sufficient to produce condensation within the extractor. More complete extraction of the bones is thus effected and the re-admission of air is prevented.

The process patented by Schmidt (Eng. Pat. 5368, 1913) has for its object the rapid separation of water from the solvent. This is effected by condensing the vapours from the extractor in a series of compartments at temperatures just below the boiling-point of the solvent or of the respective fractions, and conducting the condensed liquids to a common separator, where the water is removed prior to the return of the solvent to the extractor.

A method of removing the fat from bones without the use of a solvent is claimed in Powling's process (Eng. Pat. 8397, 1912), the material being agitated in a steam jacketed cylinder until the fat has separated and the water has evaporated.

The bone fat obtained by the boiling-out or steaming-out process can be used for soap making; the fat obtained by the extracting process is utterly unsuitable for that purpose in this country, on account of its rank smell. On the continent, however, such benzine-extracted fat is used up for soap in small quantities, especially when the price of fatty materials is high. The bulk of bone fat is, however, used in candle works, where it is hydrolysed in an autoclave and subsequently subjected to the usual acidifying and distilling processes.

Bone fat is an important article of commerce. The chemical composition of bone fat lies midway between that of marrow fat and tallow. On account of the large amount of fatty acid contained in bone fat, this fat must be examined by special methods, for which the reader is referred to Lewkowitsch, Chemical Technology and Analysis of Oils.

Bone oil, fatty bone oil (not to be confounded with Dippel's oil), is the liquid portion of bone fat which is sometimes prepared in the same manner as tallow oil is obtained from tallow. Bone oil is used as a lubricant, and in the leather industries replaces neat's-foot oil in the preparation of 'fat liquor' and other emulsions. If such bone oil is free from fatty acids, it represents one of the best lubricating oils on account of its very low 'cold test.'

J. L.

BONE MEAL *v.* FERTILISERS.

BONE OIL. *Animal oil*; *Dippel's oil*; *Oil of hartshorn*; *Oleum animale empyreumaticum*; *Oleum cornu cervi*; *Oleum Dippelii.* (*Knochenol*, *Thierol*, Ger.) The product obtained by distilling bones in the preparation of bone black or animal charcoal. The first mention of an animal oil appears to be in the writings of C. Gesner, 1552, and of A. Libavius (Alchemia Lib. II, Tract II.), 1595, whilst J. R. Glauber (1604–1668) also describes the unpleasant-smelling oil derived from the distillation of animal parts. Apparently the first consistent steps in an examination of the oil were made by Johann Dippel in 1711, and afterwards by O. Unverdorben (1826), who isolated from it four bases which he described as *odorin*, *animin*, *olanin* and *ammolin*. The investigations of Anderson (Trans. Roy. Soc. Edin. 1[illegible], 123; 463; 20, 247; 21, 219) were the first in which the pure pyridine bases present in the oil, were obtained.

The bones are first boiled in a large quantity of water, which removes the greater part of the fatty matters; they are then roughly dried and are subjected to dry distillation in iron retorts, similar to those used in the manufacture of coal gas. Bone black or animal charcoal remains behind and bone oil distils. The products of distillation are conducted through long iron tubes, which act as condensers and lead into receivers, where the crude bone oil collects, together with water. The gases are then passed into a separator containing sulphuric acid to retain ammonia, and can afterwards be used for heating purposes, or, if passed through purifiers, for illumination. The crude oil is separated from the aqueous distillate and is subjected to redistillation. The aqueous liquid consists of a solution of ammonium sulphide, ammonium thiocyanate and cyanide, ammonium carbonate, and small quantities of very volatile organic bases. This is treated with sulphuric acid and afterwards distilled with slaked lime The distillate, on treating with solid potash, yields large quantities of ammonia, whilst some oily bases separate out, and are afterwards worked up with the bases contained in the crude oil. This latter is a dark-brown, nearly black liquid, having a fœtid, most offensive smell, and a sp gr. 0·970.

On subjecting it to redistillation it begins to boil at 80°, when quantities of ammonia come over together with an oil. The temperature rises very gradually to about 250°. From 180° upwards large quantities of ammonium cyanide and ammonium carbonate sublime over, and care has to be taken to prevent the condenser being stopped up. A black resinous tar remains, which is employed in making Brunswick black

The following substances have been isolated from bone oil by fractional distillation combined with treatment with acids to separate basic from non basic constituents :—

Chief constituents	*Subsidiary constituents*
Butyro nitrile	Methylamine
Valero-nitrile	Ethylamine
Hexo nitrile	Aniline
Isohexo-nitrile	Pyridine
Deco-nitrile	Methyl-pyridine
Palmito nitrile	Dimethyl-pyridine
Stearo-nitrile	Quinoline
Pyrrole	Phenol
Methyl pyrrole	Propionitrile
Dimethyl-pyrrole	Valeramide
Hydrocarbons C_9H_{14}	Toluene
$C_{10}H_{16}$	Ethyl-benzene
$C_{11}H_{16}$	Naphthalene

(Weidel and Ciamician, Ber. 13, 65)

As to the formation of the various compounds in bone oil, the nitriles are formed by the action of ammonia on the fatty acids, pyrrole and the pyrroles are the products of decomposition of the gelatinous substances, and pyridine and its derivatives are condensation products of acrolein, from the dry distillation of the fats, with ammonia, methylamine, &c.

Pyrrole. That portion of the non-basic part of bone oil boiling at 98°–150° contains pyrrole and its homologues. Ciamician and Dennstedt (Ber. 1886, 19, 173) purify the crude pyrrole by heating for many hours under reflux with solid caustic alkali, until the solid mass becomes fused. After cooling, the unaltered oil is separated from the solid residue, and the residue powdered and washed with absolute ether. Water is added and the mass distilled in a current of steam when the pyrrole distils over. The fraction 140°–150° consists of a mixture of homopyrroles—*i.e.* methylpyrroles. That above 150° contains dimethylpyrrole. To separate the α- and β- derivatives, the mixture is converted into the potassium compound by fusion with potash, and heated in a current of carbon dioxide to 200°. Two isomeric homopyrrole carboxylic acids are formed, which differ in the solubility of their lead salts. α-Homopyrrole carboxylic acid melts at 169·5°, and its lead salt is very soluble in water, differing from the β-acid, which melts at 142·1°, and forms a slightly soluble lead salt. The acids obtained respectively yield on distillation with lime the corresponding methypyrroles. α-Homopyrrole boils at 148° under 750 mm. pressure, and β-homopyrrole at 143° at 743 mm.

The constitution of pyrrole is represented as follows :—

$$\left.\begin{array}{l} CH=CH \\ CH=CH \end{array}\right> NH$$

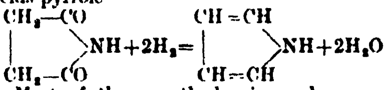
the positions 2 and 5 and 3 and 4 being known as the α- and β- positions respectively. It boils at 130°–131°, and its sp gr is 0·9752 at 12°. Refractive index $\mu_D = 1·5074$ (Gladstone, Chem. Soc. Trans 1884, 246) It is slightly soluble in water, readily soluble in alcohol and ether. It is a weak base, and is only slowly dissolved by dilute acids in the cold, it also possesses faintly acidic properties.

By the action of iodine on potassium pyrrole, tetriodopyrrole is formed, which crystallises in yellowish-brown prisms and decomposes at about 140°. It acts like iodoform as an antiseptic, and is known as iodol. It has the advantage over iodoform of being free from smell.

Pyrrole has been synthesised by passing acetylene and ammonia through red-hot tubes :

$$2C_2H_2 + NH_3 = C_4H_4NH + H_2 ;$$

also by distilling the ammonium salts of mucic and saccharic acids Succinimide, on heating with zinc-dust containing zinc hydrate, also yields pyrrole



$$\left.\begin{array}{l} CH_2—CO \\ | \\ CH_2—CO \end{array}\right> NH + 2H_2 = \left|\begin{array}{l} CH=CH \\ \\ CH=CH \end{array}\right> NH + 2H_2O$$

Most of these methods give only a small yield of pyrrole, but Khotinsky (1909) obtained a 42 p.c. yield by heating ammonium mucate with an excess of glycerol, saturating the mixture with ammonia at 270° and then distilling at 320°–30°.

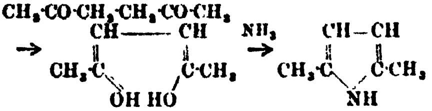
Potassium dissolves in pyrrole with the formation of potassium pyrrole C_4H_4NK, a substance insoluble in ether and decomposed by water into pyrrole and potassium hydroxide. This substance reacts with alkali iodides to form substituted pyrroles ; *e.g.* :

N-Methylpyrrole, $C_4H_4N·CH_3$: boils at 113° ; sp.gr. 0·9203.

N.Ethylpyrrole $C_4H_4N·C_2H_5$: boils at 131° ; sp.gr. 0·9042.

N-Phenylpyrrole $C_4H_4N·C_6H_5$, obtained by distilling the anilides of mucic and saccharic acids, melts at 62°. The homologues of pyrrole contained in bone oil are, however, all substituted in the group C_4H_4.

Pyrrole homologues may be prepared by Paal's method, which consists in the condensation of γ-diketones (*e.g.* acetonyl-acetone) with ammonia :



By the action of benzalchloride on pyrrole in presence of sodium a phenylpyridine is obtained in which the phenyl is in the meta- position to the nitrogen (Ciamician and Silber, Ber. 20, 191).

By reducing pyrrole with zinc and acetic acid Δ^3 pyrroline is produced (Ber. 1901, 3052). Electrolytic reduction to the same substance may be effected by suspending pyrrole in dilute sulphuric acid in the cathode cell of an electrolytic apparatus, the cathode being lead, and passing a current of density 1 amp. per sq. cm. Homologues may be similarly reduced (D. R. P. 127086, 1902). The stronger reduction of pyrrole, by means of hydriodic acid and phosphorus, or by passing pyrrole vapour mixed with hydrogen, over reduced nickel at 180°, converts it into pyrrolidine (tetrahydro pyrrole) C_4H_9N.

Nascent hydrogen converts pyrrole into pyrroline C_4H_6NH, a liquid boiling at 91° which dissolves easily in water. It yields, with nitrous acid, a nitrosoamine $C_4H_6N{\cdot}NO$, m.p. 37°, and on heating with methyl iodide gives methyl pyrroline (Ber. 16, 1536).

Pyrrole is readily oxidised to *maleimide* $C_4H_3O_2N$, which forms faintly yellow crystals, melting at 93°, and readily yields a *dibromide*, melting at 226° under the influence of light and bromine water (Atti. R. 1904, (v.) i. 489).

The action of *formaldehyde* and *methylene chloride* on pyrrole is described by Pictet and Rilliet (Ber. 1907, 1166).

By the action of *chloroform* in absolute ether on the potassium derivative of pyrrole, β-chloropyridine is obtained.

Pyrrole derivatives condense with aldehydes under the following conditions: (1) When the derivatives contain at least one hydrogen atom combined with a carbon atom of the nucleus, either in the α- or β- position; (2) when both α- and β- positions are occupied by substituents, no combination occurs even if the imine hydrogen is present; (3) pyrrole derivatives containing more than one CH group in the ring may combine with aldehydes in molecular proportions (Ber. 1902, 1647). On the constitution of the tripyrrole, obtained by passing dry hydrogen chloride into a benzene solution of pyrrole, *see* Tschelincev, J. Russ. Phys. Chem. Soc. 1915, 47, 1224.

Indole $C_6H_4{<}^{CH}_{NH}{>}CH$ is obtained by dissolving pyrrole in 10 p.c. sulphuric acid, allowing the mixture to stand 1–2 hours, and then distilling in steam after adding excess of sodium hydroxide. Diethyl indole prepared by this process is a viscid ill-smelling oil, boiling at 270°–310° (D. R. P. 125489).

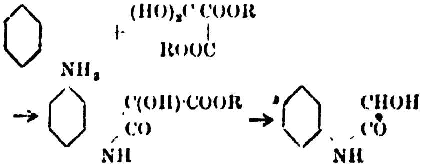
Pyrrole may also be converted into indole by dissolving in dilute hydrochloric acid, adding slight excess of ammonia, filtering, extracting the filtrate twice with ether, and heating the tripyrroline obtained in the extract to above 300°, when indole and pyrrole result (Ber. 1894, 476).

Indole may also be obtained by the reduction of *o*-nitrophenyl acetaldehyde, by fusion of *o*-nitrocinnamic acid with iron and caustic potash

$$NO_2{\cdot}C_6H_4{\cdot}CH:CH{\cdot}CO_2H+2KHO+4H$$
$$=K_2CO_3+3H_2O+C_8H_7N$$

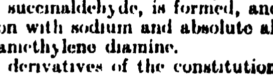
or from *o*-aminophenylacetamide by internal condensation to the amino-indole and subsequent reduction with sodium amalgam (Pschorr).

It crystallises in colourless laminæ, melts at 52°, and is soluble in hot water. It behaves as a feeble base. On treatment with sodium ethoxide and chloroform it is converted into quinoline. The indole molecule is rather difficult to oxidise, without more or less complete decomposition, but if it be first converted into 1-benzoyl indole then on oxidation in acetone solution by potassium permanganate it yields benzoyl anthranilic acid readily, from which anthranilic acid is easily obtained by hydrolysis. In a similar manner halogen substituted indoles can be obtained by the direct action of halogen on the benzoyl indole in carbon bisulphide solution, followed by hydrolysis of the benzoyl group with aqueous ammonia (Weissgerber, Ber. 1913, 46, 651). When large quantities of indole are distilled, a small quantity of high boiling residue is left behind, this is a trimeric form of indole (Keller, Ber. 1913, 46, 726). Substituted indoles may be prepared by the action of heat and a catalyst (zinc chloride or cuprous chloride) on the hydrazones of aldehydes and ketones *e.g.* methyl ethyl ketone phenylhydrazone at 180°-230° with a trace of cuprous chloride yields 2 3 dimethyl indole (Arbuzov, J. Russ. Phys. Chem. Soc. 1913, 45, 70). Primary and secondary amines on condensation with mesoxalic esters also yield substituted indole derivatives; thus from aniline, dioxindole-3-carboxylic acid is obtained, from which dioxindole results on hydrolysis of the carboxylic acid ester in the absence of air (Guyot and Martinet, Compt. rend. 1913, 156, 1625)



Pyrrole may be converted into *tetramethylene diamine* as follows. On treatment with hydroxylamine, a solid compound, probably the dioxime of succinaldehyde, is formed, and this, by reduction with sodium and absolute alcohol, yields tetramethylene diamine.

Pyrrole derivatives of the constitution



have been synthesised from the three nitroanilines by the action of ethylphenacyl acetate (Ber. 1907, 1343).

In addition, a large number of pyrrole derivatives has been synthesised by Paal and Braikoff (Ber. 1890, 1086, and also Ber. 1886, 558, 3156).

The physiological action of pyrrole and its derivatives is characterised by their paralysing action on the peripheral nerves connected with the mechanism of the heart. By the introduction of a side group, such as, for instance, the inactive pyridine ring, the physiological effect is greatly intensified. The action of 1-methyl pyrrolidine resembles that of nicotine, atropine, or cocaine, as might be anticipated from their similarity of constitution (Chem. Zentr. 1902, ii. 390).

Chloro- and Bromo- Pyrroles. Sulphuryl chloride in excess acting on an ethereal solution of pyrrole at 0° produces *pentachloropyrrole* in nearly theoretical yield; b.p. 209° or 142°/15 mm. If two molecules only of sulphuryl chloride are used, followed by bromine (2 mols.), *chlorotribromopyrrole* C_4NHBr_3Cl is obtained, which separates from light petroleum in large prismatic masses of a pink colour.

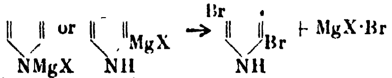
Sulphuryl chloride (3 mols.) followed by bromine (1 mol.) gives *dichlorodibromopyrrole* $C_4HNCl_2Br_2$, which crystallises in large shining scales decomposing just above 100° (Gazz. chim. ital. 1902, 313).

Trichloromonobromopyrrole

$$\begin{array}{ll} CCl:CCl & \\ | & >NH \\ CBr:CCl & \end{array}$$

may be obtained by the action of sulphuryl chloride and bromine on ethereal solution of pyrrole at 0°. It crystallises in monoclinic prisms with yellowish-red reflex, turning brown at 105°, and melting and decomposing at 115° (Gazz. chim. ital. 1902, 313; 1904, ii. 178).

Monohalogen derivatives of pyrrole may be prepared by the action of magnesium methyl iodide on a secondary pyrrole, followed by halogen at low temperature (Hess and Wissing, Ber. 1914, 47, 1416)



These compounds are very unstable, and decompose even on keeping; thus, bromopyrrole explodes violently even when kept in a sealed tube, decomposing into carbon and ammonium bromide.

The **dimethylpyrrole** contained in the fraction of bone oil boiling above 150° has been obtained synthetically as follows: By the action of ammonia on diacetosuccinic ether, the ether of dimethylpyrrole dicarboxylic acid is obtained This, on saponification, yields the acid, and, on heating, carbon dioxide is split off, leaving dimethylpyrrole. It has the composition

$$\begin{array}{ll} CH-C\,CH_3 & \\ | & \diagdown NH \\ CH=C{\cdot}CH_3 & \end{array}$$

and is an almost colourless oil boiling at 165°. It is very volatile with steam, colours a pine splint an intense red, and yields on boiling with acids a pyrrole-red similar to other pyrrole homologues.

Pyrrolecarboxylic acids $C_4(NH)H_3CO_2H$. The α-acid is obtained from α-homopyrrole by fusion with potash or by the action of tetrachloride of carbon and alcoholic potash on pyrrole. It melts at 191°, and differs from the β- acid in forming a soluble lead salt. On heating with acetic anhydride, the substance pyrocoll

$$\begin{array}{l} C_4H_3=N-CO \\ |\qquad\qquad\quad | \\ CO-N=C_4H_3 \end{array}$$

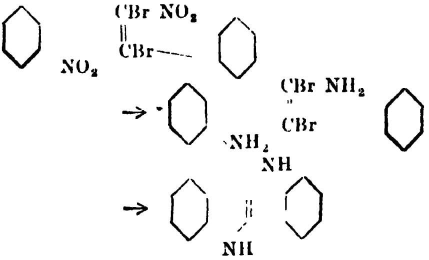
is formed, which is a product obtained by distilling gelatine (Ber. 17, 103).

β-Pyrrolecarboxylic acid is formed by fusing β-methylpyrrole with potash. It crystallises in fine needles, melting at 162°, and forms an insoluble lead salt.

N-Acetylpyrrole $C_4H_4N{\cdot}C_2H_3O$, obtained by the action of acetyl chloride on potassium pyrrole, is an oil boiling at 178°. It is decomposed by alkalis into pyrrole and acetic acid (Ber. 16, 2352).

C-Acetylpyrrole $C_4H_3(C_2H_3O)(NH)$ is formed, together with the foregoing, by acting on pyrrole with acetic anhydride. It melts at 90° and boils at 220°, but is not decomposed by alkalis.

A di-indole has been obtained from di-(ortho-nitrophenyl-bromo) ethylene by reduction with stannous chloride to the corresponding di-amino compound, followed by elimination of hydrobromic acid, first by boiling for a short time with alcoholic picric acid and subsequently with alcoholic potash (Ruggli, Ber. 1917, 50, 883).



Pyridine C_5H_5N is contained in that fraction of the basic oils of bone oil which boils below 120°, but is also found in smaller quantities in the higher fractions. It can be separated in these by means of its picrate

$$C_5H_5N,C_6H_2(NO_2)_3OH$$

which melts at 162°. It is not easily acted on by oxidising agents, and can be separated by this means from the other components of the fraction.

It is formed from all pyridinecarboxylic acids by distilling with lime.

The following are some of the synthetic methods for preparing pyridine and its homologues:—

1 Hydrocyanic acid and acetylene when passed through a red-hot tube yield pyridine

$$2C_2H_2+HCN=C_5H_5N$$

(Ramsay, Ber. 10, 736).

2. Isoamyl nitrate when heated with phosphoric anhydride yields pyridine

$$C_5H_{11}ONO_2+3P_2O_5=C_5H_5N+6HPO_3$$

(Chapman and Smith, Ann. Suppl. 6, 329).

3. Acrolein ammonia, on heating, gives off water yielding methylpyridine

$$C_6H_9NO=C_5H_4(CH_3)N+H_2O$$

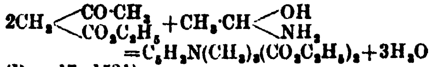
4. The same compound is formed by heating allyl tribromide with alcoholic ammonia at 250°

$$2C_3H_5Br_3+NH_3=C_5H_4(CH_3)N+6HBr$$

5. Glycerol and acetamide, on heating with phosphorus pentoxide, yield methylpyridine (Ber. 15, 528).

6. Potassium pyrrole, on heating with chloroform, yields chloropyridine.

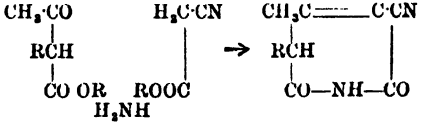
7. Ethyl acetoacetate, heated with aldehyde ammonia, gives dihydrocollidine dicarboxylic ester



$$2\mathrm{CH_2}\!\left\langle\begin{matrix}\mathrm{CO\cdot CH_3}\\ \mathrm{CO_2C_2H_5}\end{matrix}\right. + \mathrm{CH_3\cdot CH}\!\left\langle\begin{matrix}\mathrm{OH}\\ \mathrm{NH_2}\end{matrix}\right. = \mathrm{C_5H_2N(CH_3)_3(CO_2C_2H_5)_2} + 3\mathrm{H_2O}$$

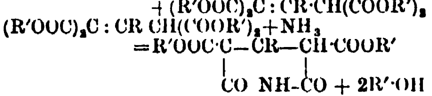
(Ber. 17, 1521).

8. Guareschi has obtained compounds of the pyridone type by condensing alkyl aceto-acetic esters with cyanacetic esters and ammonia



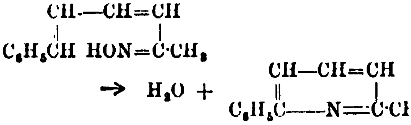
9. Ruhemann has also obtained the pyridone type by the condensation of alkyl dicarboxyglutaconic esters with ammonia

$$\mathrm{RCCl_3} + 3\mathrm{CHNa(COOR')_2} = \mathrm{CH_2(COOR')_2} + 3\mathrm{NaCl} + \mathrm{(R'OOC)_2C:CR\cdot CH(COOR')_2}$$



$$\mathrm{(R'OOC)_2C:CR\,CH(COOR')_2} + \mathrm{NH_3} = \mathrm{R'OOC\cdot C{-}CR{-}CH\cdot COOR'} \; (\mathrm{CO\;NH{-}CO}) + 2\mathrm{R'\cdot OH}$$

10. Cinnamenylidine acetoxime on distillation is converted in α-phenyl-α′-methyl pyridine



11. Pyridine bases are obtained by the condensation of ketones with acid amides (Pictet and Stehelin, Compt. rend. 1916, 162, 867); thus by heating acetone (2 mols.) with acetamide (1 mol.) at 250°, 2.4.6-trimethyl pyridine is formed, whilst triphenyl pyridine results similarly from acetophenone and benzamide.

By heating a mixture of glycerol and ammonium phosphate, a mixture of a large number of pyridine bases is formed. β-methyl, β-ethyl, probably β-propyl, pyridine, besides pyridine itself and homologues of the diazine $C_4H_4N_2$, have been recognised (Stoehr. J. pr. Chem. 1892, 20).

Pyridine is a liquid with a pungent smell, miscible with water; sp. gr. 0·9855 at 15°, and 0·9944 at 4°; and boils at 115·2°/760 mm. It forms a hydrochloride C_5H_5N,HCl, and a platinichloride $(C_5H_5NHCl)_2PtCl_4$. Sodium amalgam yields piperidine, *i.e.* hexahydropyridine, which is reconverted into pyridine on oxidation. It forms an ammonium iodide with alkyl iodides, and with chloracetic acid a pyridine-betaïne $\mathrm{C_5H_5N}\!\left\langle\begin{matrix}\mathrm{CH_2}\\ \mathrm{O}\end{matrix}\right\rangle\mathrm{CO}$. By the action of sodium on pyridine a dipyridine $C_{10}H_{10}N_2$ is obtained, an oil boiling at 280°–281°/744 mm., which on oxidation with permanganate yields *iso*nicotinic acid. Together with dipyridine, a body *p*-dipyridyl is formed $NC_5H_4\cdot C_5H_4N$, which melts at 114° and distils at 304°. It also yields *iso*nicotinic acid on oxidation, and on reduction with tin and hydrochloric acid forms *iso*nicotine, which melts at 78° (Ber. 16, 423).

Sodium reacts with pyridine at ordinary temperature (best in an atmosphere of nitrogen) to form dipyridine sodium $(C_5H_5N)_2Na$, which on heating to 130° is transformed into pyridine sodium $C_5H_5N\cdot Na$ (B. Emmert, Ber. 1914, 47,

The isomeric *m-dipyridyl* is obtained from *m*-dipyridyldicarboxylic acid (by oxidising phenanthroline). It boils at 293°, and yields on reduction with tin and hydrochloric acid *nicotidine* $C_{10}H_{14}N_2$, which boils at 228° (Ber. 16, 2521).

Piperidine between 180° and 250° is converted into pyridine in presence of nickel; pyridine when passed together with hydrogen over reduced nickel at 160°–180°, yields amylamine not piperidine, and this in poor yield. At higher temperatures ammonia, pentane and lower hydrocarbons are obtained (Sabatier and Mailhe Compt. rend. 1907, 784).

Pyridine may advantageously be employed as a halogen carrier in halogenation of aromatic compounds (Cross and Cohen, Chem. Soc. Proc. 1908, 15).

The compound of pyridine with methy iodide, when added to a solution of the necessary amount of iodine in alcohol, is converted into pyridine methylpentiodide $C_5H_5N(MeI)I_4$ melting at 47·5°. Various other periodides are described by Prescott and Trowbridge (J. Amer. Chem. Soc. 1895, 859).

Acetyl and benzoyl chlorides if quite pure do not react with pyridine in the presence of anhydrous aluminium chloride, but if a trace of thionyl chloride be introduced, then the norma ketone production takes place (Wolffenstein and Hartwich, Ber. 1915, 48, 2043).

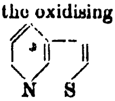
Double compounds with zinc bromide nickel bromide, copper bromide, and silver iodide, are formed, but are rather unstable (Compt. rend. 1891, 622).

The physiological action of pyridine is similar to that of piperidine, but more energetic. Both produce paralysis of the motor nerves, by their effect on the motor centres. There are also destructive changes in the blood corpuscles, and paralysis of the heart, especially in pyridine poisoning (Chem. Soc. Abstr. 1891, 603). It is excreted as methylpyridylammonium hydroxide (Chem. Soc. Abstr. 1893, ii. 544).

The double compound of pyridine with silver nitrate $AgNO_3\cdot 2C_5H_5N$ has been recommended by Witt as a ripening agent for photographic emulsions (J. Soc. Chem. Ind. 1904, 235). Luppe-Cramer, however, denies that it has any advantages over the ordinary ammonia ripening (*ibid.* 1906, 197).

Sulphurous acid esters of pyridine, which may be obtained by heating under a reflux condenser with excess of a bisulphite solution, are useful in the preparation of dyestuffs, and are also used as medicaments (D. R. P. 208638).

A pyridine-2.3-thiophen has been obtained in small quantity by the application of the Skraup reaction to 2-aminothiophen; using 2-nitrothiophen as the oxidising agent



(Steinkopf and Lutzendorff, Annalen, 1914, 403, 45).

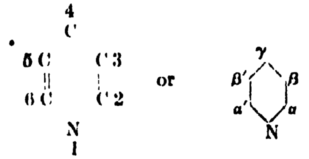
On heating pyridine with concentrated sulphuric acid to 300°, β-pyridine-sulphonic acid is obtained. The sodium salt of this acid, distilled with potassium cyanide, yields β-pyridyl cyanide, which on hydrolysis forms nicotinic

Sulphonation of the pyridine nucleus can be carried out more readily in the presence of vanadyl sulphate.

Pyridine may be directly nitrated by heating with a mixture of fuming nitric and fuming sulphuric acids. Pyridine nitrates more readily if an amino group is present, *e.g.* 2-aminopyridine nitrates nearly as readily as aniline. The nitro pyridines resemble the nitro-anilines, are yellow in colour and feebly basic.

Pyridine may be estimated in aqueous solution by heating with excess of gold chloride and dilute HCl, evaporating to dryness and heating the ppt. after repeated washing with pure dry ether. The ppt. has the composition $C_5H_5N \cdot HCl \cdot AuCl_3$ (Compt. rend. 1903, 324).

Pyridine can be represented as a benzene ring in which one CH group is replaced by nitrogen according to the following scheme:—



The positions 2, 6, and 3, 5 are known as ortho- and meta-, and 4 as the para- position. Hence three mono- derivatives of pyridine are possible. The position of the substituting groups in these isomerides has been proved by means of the phenylpyridines obtained from the naphthaquinolines (Monatsh. 4, 437; Ber. 17, 1518).

HYDROXY- DERIVATIVES OF PYRIDINE.

The three possible hydroxypyridines are known:—

α-**Hydroxypyridine,** α-**pyridone,** by distilling the silver salt of hydroxyquinoline acid; melts at 107°, and is coloured red by ferric chloride.

β-**Hydroxypyridine** is formed from the β sulphonic acid by fusing with potash. It melts at 123°, and is also coloured red by ferric chloride.

γ-**Hydroxypyridine** or γ-**pyridone** (which is probably not a hydroxyl- but a carbonyl compound) is obtained from hydroxypicolinic acid with evolution of CO_2. It melts at 148° or at 62° in the hydrated form, and is coloured yellow by ferric chloride (Ber. 17, Ref. 169).

AMINO- PYRIDINES.

Of the three possible aminopyridines, two have been definitely isolated.

1.—*Aminopyridine* is formed by the distillation of 2-aminopyridine-5-carboxylic acid. It melts at 56° and boils at 204°. It is not diazotisable, but on treatment with concentrated hydrochloric acid and nitrous acid yields 2-chloropyridine.

2.—*Aminopyridine* is formed by the action of sodium hypobromite on the amide of nicotinic acid, or by the action of sodamide on pyridine below 120°, and decomposition of the resultant product with water; the further action of sodamide yields 2·6-di-aminopyridine, which couples with diazo-compounds (Tschitschibabin, J. Russ. Phys. Chem. Soc. 1914, 46, 1216). It melts at 62° and boils at 250°–252°. It is a diazotisable base.

PYRIDINE MONOCARBOXYLIC ACIDS $C_5NH_4(CO_2H)$.

α-**Pyridinecarboxylic acid** (2- or ortho-), *picolinic acid* was first obtained by oxidising α-picoline. It is easily soluble in water, crystallises in white needles, melts at 137°, and sublimes. By the action of sodium amalgam, ammonia is given off with the formation of an acid $C_6H_8O_3$ (oxysorbinic acid).

β-**Pyridinecarboxylic acid** (3- or meta-), called *nicotinic acid* from the fact of being first obtained by oxidising nicotine, is also obtained from β-methyl- or ethyl-pyridine, from β-pyridyl cyanide, and from three dicarboxylic acids of pyridine (quinolinic acid, cinchomeronic acid, and *iso*cinchomeronic acid), which on heating give off carbon dioxide. It crystallises in needles and melts at 232°. It is readily soluble in hot water and in alcohol, but is insoluble in ether.

γ-**Pyridinecarboxylic acid** (4- or para-), *isonicotinic acid* is obtained from cinchomeronic acid and 2 : 4-pyridinedicarboxylic acid on heating, and also by the oxidation of all γ-substituted pyridines. It melts at 299 5° with sublimation or at 315° in a closed tube, and crystallises from hot water in fine needles.

HYDROXYPYRIDINE-MONOCARBOXYLIC ACIDS.

Several of these acids have been prepared either synthetically, *e.g.* by heating komanic acid $C_6H_4O_4$ with ammonia, or from the dicarboxylic acids by splitting off 1 mol. of carbon dioxide (Ber. 17, 589).

Komenaminic acid $C_5NH_2(OH)_2COOH,2H_2O$ is obtained by boiling komenic acid $C_6H_4O_5$ with ammonia. It decomposes at 270° into carbon dioxide and dihydroxypyridine.

PYRIDINE-DICARBOXYLIC ACIDS $C_5NH_3(CO_2H)_2$.

The acids of this type may be obtained as follows:—

1. By the oxidation of disubstituted pyridines, containing aliphatic side chains; or of monosubstituted monocarboxylic acids.
2. By heating the tricarboxylic acids.
3. By the oxidation of quinoline and its homologues.
4. By the oxidation of various alkaloids (cinchonine, cinchonidine, &c.).

Quinolinic acid (αβ- or 2 : 3-) is formed by oxidising quinoline. It decomposes and softens at 190°–195°, solidifies at 200°, and melts again at 231°. It decomposes on heating into carbon dioxide and nicotinic acid.

Cinchomeronic acid (βγ- or 3 : 4-) is formed by the oxidation of the quinine alkaloids with nitric acid, or from βγ-methylpyridinecarboxylic acid on oxidation with permanganate. It melts at 259°, decomposing into carbon dioxide, *iso*nicotinic acid, and some nicotinic acid.

Lutidinic acid (αγ- or 2 : 4-) is obtained, together with some *iso*cinchomeronic acid, by oxidising lutidine. It melts at 239°–240° (Voigt, Annalen, 228, 54), 235° (Ladenburg, Annalen, 247, 27), decomposing into carbon dioxide and *iso*nicotinic acid.

***Iso*cinchomeronic acid** (βα′-) melts at 236°, decomposing into carbon dioxide and nicotinic acid (Werdel and Herzig, Wiener Akad. B. 1879, 825).

Dicarboxylic acid ($\beta\beta'$-) or **Dinicotinic acid**. By heating to 150° *s*-pyridine tetracarboxylic acid obtained by oxidising the lutidinecarboxylic acid, prepared by the condensation of *iso*butaldehyde ethylacetoacetate and ammonia. The acid does not melt at 285° (Hantzsch and Weiss, Ber. 1886, 19, 284).

Dicarboxylic acid (aa'-) or **Dipicolinic acid.** Obtained by oxidising 2 : 6-dimethylpyridine. It melts at 243° (Epstein, Annalen, 231, 32), decomposing into carbon dioxide and pyridine.

Hydroxypyridine-dicarboxylic Acids
$C_5NH_2(OH)(CO_2H)_2$.

Hydroxyquinolinic acid [$OH : (CO_2H)_2 = (a' : a : \beta)$]. By fusing quinolinic acid with potash. It blackens without melting at 254° (Ber. 16, 2158). Heated with water to 195° it decomposes into carbon dioxide and hydroxypyridinecarboxylic acid. Its silver salt on heating yields a-hydroxypyridine (Ber. 17, 590).

Ammoniochelidonic acid is obtained by heating chelidonic acid with ammonia.

Pyridine-tricarboxylic Acids $C_5NH_2(CO_2H)_3$.

$a\beta\gamma$-**Tricarboxylic acid, Carbocinchomeronic acid**, is formed by completely oxidising the quinine alkaloids, also from γ-methylquinoline and from γ-quinolinecarboxylic acid. It loses $1\frac{1}{2}H_2O$ (of crystallisation) at 115°-120°, and melts, if quickly heated, at 250° (Annalen, 204, 308).

$a\beta\beta'$-**Tricarboxylic acid, Carbodinicotinic acid**, is obtained from β-quinolinecarboxylic acid.

The six tricarboxylic acids theoretically possible are known and characterised.

Pyridine tetracarboxylic Acids
$C_5NH(CO_2H)_4$.

$a\beta a'\beta'$-**Tetracarboxylic acid.** By oxidising the lutidinedicarboxylic acid formed by the condensation of *iso*butylaldehyde with ethyl acetoacetate and ammonia (Hantzsch and Weiss, Ber. 19, 284).

The acid obtained by oxidising collidinemonocarboxylic acid crystallises with 2 molecules of water. It does not possess basic properties. Energetic oxidation converts it into oxalic acid.

Pyridine-pentacarboxylic acid $C_5N(CO_2H)_5$ from trimethylpyridine-dicarboxylic acid. Crystallises from water with $3H_2O$. Decomposes without melting about 200°.

Halogen Derivatives of Pyridine.

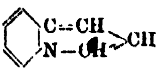
a-Chloropyridine results from the action of PCl_5 on a-hydroxypyridine; is an oil boiling at 166°/714 mm. (Ber. 1891, 3150).

β-Chloropyridine By the action of chloroform or carbon tetrachloride on potassium pyrrole (Ber. 14, 1153) is an oil; b.p. 148°/743 mm.

Dichloro- and trichloro-pyridine are known.

A *dibromopyridine* ($\beta\beta'$) has been obtained by acting on collidine-dicarboxylic acid with bromine and afterwards removing the carboxyl-groups (Pfeiffer, Ber. 20, 1349). It is identical with that obtained by acting on pyridine with bromine (Hofmann, Ber. 12, 988).

a-Picoline is transformed by acetic anhydride into *picolide* $C_{12}H_{14}O_2N$, which on heating with hydrochloric acid yields *pyrindole* C_8H_7N, an isomeride of indole.



(Scholtz and Fraude, Ber. 1913, 46, 1069).

Homologues of Pyridine.

Picoline (*a-methylpyridine*) $C_5NH_4(CH_3)$. This base is separated from that portion of bone oil which boils between 130° and 145°. On subjecting this to redistillation, the greater part of the oil comes over between 133° and 139°. It is not possible to effect a separation of the bases by means of fractional distillation, but a difference in the solubility of the platinum salts of the two bases furnishes a means of separating them. According to Ladenburg (Ber. 1885, 47), commercial picoline consists of three bases: a-methylpyridine, a little β-methylpyridine, and probably aa'-dimethylpyridine. The same observer (Ber. 1885, 51) has also noticed the presence of pyridine in this fraction. It can be separated by means of its picrate, which melts at 162°.

Picoline boils at 128.8°/760 mm.; is an optically inactive oil, and on oxidation yields picolinic acid (*v. supra*).

β-Methylpyridine may be synthetically prepared by heating acetamide with glycerol and phosphoric anhydride. It boils at 143·5°, and on oxidation yields nicotinic acid. It also differs from the a-derivative in being slightly lævorotatory. Landolt shows this effect to be due to errors in manipulation (Ber. 1886, 157).

γ-Methylpyridine does not appear to be contained in bone oil. It has been obtained synthetically by the action of heat on acroleïn-ammonia, and also from allyl tribromide; b.p. 143·1°/760 mm.

Picoline monocarboxylic Acids
$C_5NH_3(CH_3)CO_2H$.

Picolinecarboxylic acid (*pyridine-a-methyl-γ-carboxylic acid*) is formed from uvitonic acid, the product of condensation of pyruvic acid and ammonia. It sublimes without melting, and yields on oxidation $a : \gamma$-pyridinedicarboxylic acid.

$\beta\gamma$-**Methylpyridine carboxylic acid** ($CH_3 \cdot CO_2H - \gamma : \beta$) is obtained by heating methylquinolinic acid to 180°-185°. It melts at 212° (Ann. Chim. Phys. [5] 27, 493), and yields on oxidation cinchomeronic acid.

Six of the ten possible picoline monocarboxylic acids are known and characterised.

Picoline-dicarboxylic Acids
$C_5NH_2(CH_3)(CO_2H)_2$.

Methylquinolinic acid ($(CO_2H)_2 : CH_3 = a\beta\gamma$). By oxidising γ-methylquinoline with permanganate. It melts at 186°, giving carbon dioxide and γ-methyl-β-pyridine-carboxylic acid.

Uvitonic acid [$(CO_2H)_2 : CH_3 = a\gamma a'$] is the condensation product obtained from pyruvic acid and alcoholic ammonia. It melts at 274°, splitting up into carbon dioxide and picolinecarboxylic acid.

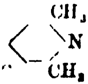
Picoline-dicarboxylic acid, from aldehydine, the condensation product of ethylidine chloride and aldehyde ammonia. It sublimes easily without melting.

Three other isomerides are known.

A picoline-tetracarboxylic acid is also obtainable from the dicarboxylic acid of collidine by oxidation of the methyl- groups with permanganate. Lutidine-tricarboxylic acid is formed as an intermediate product

Lutidine (*dimethylpyridine*). The bases having this constitution are mainly contained in that portion of the basic oil boiling between 150°–170°. After redistilling, it is separated into the two fractions 150°–160° and 160°–170°. The position of the methyl groups in these two fractions is determined by means of the oxidation products formed. The first fraction yields on oxidation *iso*cinchomeronic acid, which melts at 236°. On heating, carbon dioxide is split off and nicotinic acid is formed. From this is inferred that the position of the two methyl groups is $\alpha'\beta$. The higher fraction yields lutidinic acid on oxidation, and this, on heating, gives *iso*nicotinic acid, from which it follows that the methyl- groups have the positions $\alpha\gamma$. All the acids give pyridine on distillation with lime. According to the researches of Ladenburg and Roth (Ber. 18, 49), the fraction 139°–142° also contains a lutidine, which was separated by means of the mercuric chloride salt, melting at 186°. This was decomposed with potash, and distilled, when, after drying, an oil was obtained which boiled at 142°–143°, and yielded on oxidation with permanganate a dibasic acid which is identical with that obtained from synthetical lutidine prepared by condensing cinnamic aldehyde, ethyl acetoacetate, and ammonia (Epstein, Annalen, 231, 1). Its sp gr. is 0 9545, and b.p. 143°.

The constitution of the β lutidine is



(Ladenburg and Roth).

By distilling dimethyl pyridine dicarboxylic acid with lime a 91 p.c. yield of 2 · 6-lutidine can be obtained This method appears to be the most convenient way of preparing pure lutidine (Mumm and Hüneke, Ber. 1917, 50, 1568; 1918, 51, 150).

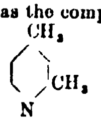
The isomeric α, β and γ-ethyl pyridines are also known, the β and γ-forms being produced when cinchonine or brucine are distilled with caustic alkali, and the α-form on heating pyridinium ethyl iodide to 290°.

Lutidine-monocarboxylic acid (*$\alpha\alpha'$-dimethylnicotinic acid*). Obtained by distilling lutidine-dicarboxylic acid (Weiss, Ber. 19, 1308). It crystallises in fine needles melting at 160°.

Lutidine-dicarboxylic acid (*$\alpha\alpha'$-dimethyl-$\beta\beta'$-dicarboxylic acid*). Obtained by the condensation of *iso*butylaldehyde, ethyl- aceto-acetate, and ammonia (Engelmann, Annalen, 231, 51; Hantzsch and Weiss, Ber. 19, 284).

Lutidine-tricarboxylic acid (*$\alpha\gamma$-dimethyl-$\beta\alpha'\beta'$-tricarboxylic acid*) is formed by the oxidation of collidine-dicarboxylic acid with permanganate.

α-Lutidine (2 : 4-*dimethylpyridine*). Separated by adding mercuric chloride to a solution in hydrochloric acid of the bases boiling at 158°–160°. The salt has the composition $C_7H_9N,HCl,2HgCl_2$, and melts at 127°. On distilling with potash, the salt is decomposed, and the base, after drying, boils at 157°. Its sp.gr. is 0 9493 at 0°/4°. It yields a pyridine-dicarboxylic acid on oxidation with permanganate, and the acid melts at 235°. This is known as α-lutidinic acid or $\alpha\gamma$-pyridine-dicarboxylic acid, since on heating carbon dioxide is given off and *iso*nicotinic acid is formed. Hence α-lutidine has the composition

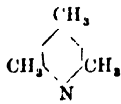


(Ladenburg and Roth, Ber. 18, 913).

Collidines (*γ-collidine, trimethylpyridine*)

$C_5NH_2(CH_3)_3$

may be prepared by distilling collidine dicarboxylic ester (obtained by oxidising the condensation product of aldehyde ammonia and ethyl acetoacetate) with lime. It boils at 171°–172°, and has the constitution



A base, $C_8H_{11}N$, has been isolated from the fraction of bone oil boiling between 170° and 180°, but this has been shown by Weidel and Pick to be a 2-methyl-4-ethylpyridine from the fact of its giving on oxidation lutidinic acid melting at 219°. The base is more soluble in cold than in hot water. Its sp gr. is 0 9286 at 16 8°; it boils at 177 8°/758 mm. (Weidel and Pick, Monatsh. 5, 656). These authors are of opinion that Anderson's collidine (Phil. Mag. 4, 9, 145, 214) was impure. The base does not form any crystallised salts, and is not identical with any synthetical collidine.

Aldehydine (2 *methyl-5-ethylpyridine*). Formed by the condensation of ethylidene chloride with ammonia (Durkopf, Ber. 18, 921), by heating an alcoholic solution of aldehyde-ammonia to 120° (Baeyer and Ader, Annalen, 155, 294), and as a decomposition product of cinchonine or brucine when these alkaloids are distilled with caustic alkali It boils at 176°, and has sp.gr 0 9389 at 0°/4°.

Of the isomerides of collidine, α-normal propyl pyridine (conyrine) is of considerable theoretical importance, owing to its relationship with the alkaloid conine (*q v.*).

Collidine dicarboxylic acid is obtained by oxidising hydrocollidine-dicarboxylic acid with nitrous acid. The ester of the latter acid is the product of condensation of ethyl acetoacetate with aldehyde ammonia. It yields on heating with lime $\alpha\alpha'\gamma$-trimethylpyridine. The acid yields by successive oxidation of the methyl-groups by permanganate the following carboxylic acids:

Lutidine-tricarboxylic acid

$C_5N(CH_3)_2(CO_2H)_3$,

Picoline-tetracarboxylic acid

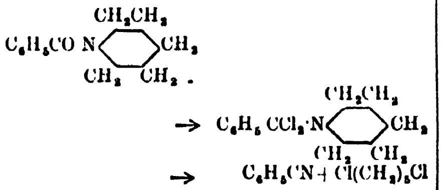
$C_5N(CH_3)(CO_2H)_4$.

Pyridine-pentacarboxylic acid $C_5N(CO_2H)_5$.

If one carboxyl- group be removed from the original acid and then it be oxidised, the following acids are successively obtained:—

From collidine-monocarboxylic acid $C_5NH(CH_3)_3CO_2H$ the acids lutidine-dicarboxylic acid $C_5NH(CH_3)_2(CO_2H)_2$, picoline-tricarboxylic acid $C_5NH(CH_3)(CO_2H)_3$, pyridine-tetracarboxylic acid $C_5NH(CO_2H)_4$.

Piperidine, hexahydro-pyridine, is obtained in small quantity by the reduction of pyridine with tin and hydrochloric acid (Konigs, Ber. 1881, 14, 1856). A better yield is obtained by operating in absolute alcoholic solution with sodium. It may be prepared from pyridine in 95 p.c. yield by electrolytic reduction (E. Merck, D. R. P. 90308; Pip, Eng. Pat. 21471). It may also be prepared by heating piperine, obtained from pepper, with soda lime, or by the reduction of trimethylene cyanide in alcoholic solution with sodium. It is a liquid smelling like pepper and ammonia, boiling at 105·7°, sp.gr. 0·8810 at 0°. Miscible in all proportions with water. It combines with quinones to form dyes. J. v. Braun (1904) has shown that by benzoylation of piperidine and subsequent heating with phosphorus pentachloride to 250° the cyclic system is destroyed and a good yield of pentamethylene dichloride is obtained, such 1·5-dichloro-compounds being very difficult to obtain by ordinary synthetic methods.



Its combination with hydroquinone, pyrocatechin, and several other phenols, has been patented by Joseph Turner & Co., Ltd. (D. R. P. 98465).

An account of the physiological action of piperidine and allied compounds is given by Wolffenstein (Ber. 34, 2410).

Piperidine guaiacolate prepared by the action of piperidine on guaiacol dissolved in benzene or petroleum melts at 79·8°. It is used in the treatment of phthisis (Pharm. J. 1897, 81), and is important as combining the properties of a strong vascular and nervine tonic—piperidine—with an antiseptic guaiacol (Tunnicliffe, Chem. Soc. Trans. 1898, 145).

Various derivatives of piperidine have been synthesised by Ahrens (Ber. 1898, 2278).

Quinoline. *See* QUINOLINE.

COLOURING MATTERS DERIVED FROM BONE-OIL BASES.

1. **From Pyrrole.** A red dye may be obtained from pyrrole by treating cotton cloth, after dipping in a weak alcoholic solution of bitter almond oil (benzaldehyde), with alcoholic pyrrole solution, hydrochloric acid, ferric chloride, and gently warming. A black colour is obtained by substituting cinnamon oil (cinnamic aldehyde) (Chem. Zeit. 1890, 348).

Pine wood may be dyed red by moistening with hydrochloric acid, and treating with the vapour of pyrrole.

Pyrrole blue may be obtained in two varieties: (*a*) by mixing pyrrole and isatin (1 mol. of each) in sulphuric acid, yielding the 'A' variety; and (*b*) by operating in acetic acid under specified conditions, when pyrrole blue 'B' is obtained with a certain amount of A. Pyrrole blue B has a metallic lustre, and is much less soluble than pyrrole blue A. Pyrrole blue A cannot be acetylated, but on treating pyridine solution with acetic anhydride a small amount of the pyrrole blue B derivative is obtained. This acetyl derivative dissolves in sulphuric acid to a magenta solution, which rapidly changes to a cornflower blue, owing to the formation of a disulphonic acid. This acid is very soluble in water and dyes silk blue (Liebermann and Hase, Ber. 1905, 2847; *see* also Ber. 17, 1034).

2. **From Pyridine.** Pyridine dyestuffs may be obtained by diazotising aminobenzyl pyridine, and combining with the usual components. Aminobenzylpyridine is obtained by reducing the nitro- compound produced by the condensation of nitrobenzyl chloride and pyridine bases. These products dye tannin-mordanted cotton, or wool and cotton from an acid-bath (Farb. vorm. Meister, Lucius and Bruning, Eng. Pat. 4545).

When mixtures of pyridine (1 mol.) and aromatic amines (2 mols.) are acted upon by cyanogen chloride or bromide dyestuffs are formed practically quantitatively and very pure, with the elimination 1 mol. of cyanamide. They crystallise well, and vary from yellow, through orange and red, to violet, and dye silk in shades showing fine fluorescence; and some show marked affinity for unmordanted cotton. They are soluble in water with difficulty, more readily in acetic acid and alcohol, and in pyridine (W. König, J. pr. Chem. 1904, 105).

3. **From Piperidine.** The quinones (benzo-, tolu-, naphtha-, phenanthra-quinones) interact with piperidine, yielding colouring matters which are readily changed by acids and alkalis. The compound with benzoquinone $C_6H_2O_2(NC_5H_{10})_2$ forms thick, reddish-violet prisms with blue reflex, melting at 178°. Neutral or alkaline solutions are blood-red, acid solutions carmine (Lachowicz, Monatsh. 1888, 505).

Isatin blue is derived from piperidine as follows: Dipiperidyl isatin is prepared by heating an alcoholic solution of isatin (1 mol.) with (2 mols.) piperidine on the water-bath for an hour, and crystallising from alcohol. Isatin blue results from heating this compound to 125°–160° in a current of air, or by agitating with acetic anhydride at 60° for some time and pouring into water. It forms indigo-blue solutions in alcohol, ether, or acetic acid, and is insoluble in benzene or chloroform. It may be heated without change to 160°, but is completely decomposed at 230° (Schotten, Ber. 1891, 1366).

p-Aminophenyl piperidine, which may be compared with *p*-aminodimethyl aniline, reacts in many cases in a similar way to this compound. When oxidised with a primary, secondary, or tertiary amine, *indamines*, varying from blue to green, are produced. Oxidised in the presence of meta-diamines, compounds may be precipitated by means of zinc chloride which dye cotton blue.

With phenol, when oxidised with the theoretical quantity of potassium ferricyanide, a blue indophenol is obtained. With naphthols violet colours result. Other colours are also described by Lellmann and Geller (Ber. 1888, 2287).

Literature.—Anderson, Trans. Roy. Soc. Edin. 16, 463; 20, 247; 21, 219; 21, 571; Annalen, 70, 32; 84, 44; 94, 358; 105, 335; Weidel, Sitz. Ber. 79, 837; 80, 443; 80, 821; 81, 512; 90, 972; Ciamician, Ber. 1904, 4200–4255; Bamberger, Ber. 1891, 1758; and in general the papers of the following: Ciamician, Dennstedt, Hoogewerff and van Dorp, Liebermann, Oechsner de Coninck, and Weidel.

BONE PHOSPHATES *v.* FERTILISERS.

BOOKUM or **SAPPAN WOOD.** An Indian wood, the product of *Cæsalpinia Sappan* (Linn.). Used in dyeing reds.

BOOMAH NUTS. The fruit of *Pycnocoma macrophylla* (Benth.), belonging to the Euphorbiaceæ. Used in tanning (Holmes, Pharm. J. [3] 8, 363).

BORACIC or **BORIC ACID** *v.* BORON.

BORACITE. Borate and chloride of magnesium, $6MgO\cdot MgCl_2,8B_2O_3$, forming small, bright, sharply-developed cubic crystals of tetrahedral symmetry, in which the cube faces usually predominate. The crystals are interesting on account of their strong pyro-electrical characters, and the optical anomalies which they exhibit. Each cubic crystal is built up of twelve rhombic pyramids, the bases of which coincide with the twelve faces of the rhombic-dodecahedron and the apices meeting in the centre of the group. At a temperature of 265° the birefringence and twin-lamellæ disappear and the crystal is then truly cubic. This affords a good example of an enantiotropic change in state, the cubic modification being stable only above this temperature. The crystals usually occur embedded in gypsum, and are bounded on all sides by bright facets. Sp.gr. 2·9–3·0, H 7 (as high as that of quartz). They are found in considerable numbers at Luneburg, in Hanover, and at Stassfurt, and elsewhere in the Prussian salt-deposits. A massive earthy variety, known as 'stassfurthite,' occurs as nodules at Stassfurt in quantities sufficiently large for collecting for commercial purposes. J. L. S.

BORAL *v.* SYNTHETIC DRUGS.

BORATES *v.* BORON.

BORAX. As a mineral, borax ($Na_2B_4O_7,10H_2O$) is found as an efflorescence and as monoclinic crystals, sometimes of considerable size, on the shores of the salt lakes of Tibet and California. In San Bernardino and Lake counties in California there are several places known as 'Borax Lake'; but most of the borates commercially mined in this region belong to other species (ulexite, colemanite, &c.). The Tibetan deposits extend from the lake-plain of Pugha in the west to the lakes of Tongri Nur in the east, and formerly, since very early times, much crude material was exported under the name of tincal (*v.* Boron.) L. J. S.

BORDEAUX *v.* AZO- COLOURING MATTERS. Lambert (Zeitsch. anal. Chem. 22, 46) detects this dye in wines by precipitating with basic lead acetate, and extracting the precipitate with alcohol; the red solution thus obtained is turned yellow by alkalis. Wool heated with the wine withdraws its colouring matters.

Bellier (J. Pharm. Chim. [5] 14, 7) describes a method of determining quantitatively the amount of this dye in wines.

BORDEAUX MIXTURE *v.* PLANT SPRAYS.

BORNEO CAMPHOR *v.* CAMPHORS.

BORNEOL *v.* CAMPHORS; TERPENES.

BORNEO TALLOW is a generic term for a large variety of fats obtained from the kernels of a number of plants belonging to the *Dipterocarpus* family, such as *Shorea stenoptera* (Burck.), *Shorea aptera* (Burck.), *Hopea aspera* (de Verise), *Pentacme siamensis* (Kurz), all of which are indigenous to the Sunda Islands, Indo-China, and the Malay States. All the fats derived from these trees are also in commerce known under the native name of Minjak Tangkawang (Tangkawang Fat). Minjak Tangkawang represents a mixture of at least six fats, obtained from six varieties of trees known to the natives as Tangkawang toengkoel, T. rambei, T. lagar (these trees have a diameter of more than 3 ft.), T. goentjang (growing in swampy regions, and reaching a height of 22 ft., whilst the diameter of the trunk rarely exceeds 6 inches), T. madjan, T. terindak. The trees fruit only at irregular intervals, the nuts yielding, according to the species, from about 43 to 61 p.c. of fat.

The fat is prepared by the natives in a very crude manner. In the 'wet process' the fruits are placed in baskets, immersed in water, and left therein for from 30 to 40 days. After that time the shells are removed, the kernels are split into four parts, and these spread on boards, exposed to the sun to dry. The dried fruit is then pounded, boiled with water, and the liquid fat skimmed off and moulded in the internodes of bamboo stems; hence the commercial samples have a cylindrical shape. The 'dry process' consists in cutting the kernels into discs immediately after the fruit has been collected, drying the discs by exposure to the sun, and subsequently pressing. The fat obtained by the dry process yields the best product, which is largely used for edible purposes in the East. The kernels of the Shorea fruit (erroneously described in commerce as 'Illipé nuts,' *see* Bassia Oils), are shipped to Europe, where they are expressed, and the fat is used in the manufacture of candles and as a substitute for cacao butter. The commercial grades are described as 'large black Pontianac illipé nuts,' and 'large Pontianac or Sarawak illipé nuts without guarantee of colour.' 'Siak illipé nuts' are smaller, and yield a softer fat; they are the product of a species of *Palaquium* (N. O. *Sapotaceæ*).

In 1913, 8275 cwt. of illipé nuts, valued at £5954, were exported from Singapore, principally to Belgium, whilst small quantities were sent to the United States and to England (Bull. Imp. Inst. 1915, 23, 335).

Borneo tallow contains considerable quantities of stearic acid. Samples examined in the writer's laboratory contained as much as 66 p.c. of stearic acid. The fat melts at 29°–38°; and has iodine value 31–35·9; and saponification value, 190·4–194·5. The insoluble fatty acids have a high melting-point, viz. 53°–58°, and seem to consist of 66 p.c. of stearic acid and 34 p.c. of oleic acid. The fat separated from the kernels in Europe usually contains a high proportion of free fatty acids, the acid value of the product of Pontianac nuts being as high as 35.

The fats from *Shorea Ghysbertiana* and from *Isoperta bornensis* have been described as Enkabang fat and Teglam fat respectively (Brookes, Analyst, 1909, 206). J. L.

BORNESIT v. Glucosides.

BORNITE. A sulphide of copper and iron, of importance as an ore of copper (Cu 45–71 p.c.). On a freshly fractured surface the colour is dark bronze, but this quickly tarnishes to purple or deep reddish; hence the names purple copper-ore, variegated copper-ore (Buntkupfererz), erubescite, and the Cornish miner's name horse-flesh-ore. Further alteration produces a black sooty coating. The massive ore is always much intermingled with copper-pyrites, and even the rarely occurring cubic crystals usually contain a nucleus of copper-pyrites. The exact composition of the mineral has therefore long been doubtful; analyses by B. J. Harrington (1903) and E. T. Allen (1916) of carefully selected material gave the formula Cu_5FeS_4. This is the bornite of W. Haidinger (1845): bornite of F. S. Beudant (1832) is an obsolete synonym of tetradymite or telluric bismuth. L. J. S.

BORNYVAL. Pharmaceutical name for the *iso*valerianic ester of borneol $C_{10}H_{17}O{\cdot}C_5H_9O$, a limpid fluid smelling like valerian, insoluble in water, freely soluble in alcohol or ether; b.p. 255°–260°; sp gr. 0·951 at 20°, $[D]_{20}$ = 27° 40′.

BOROFORM. Trade name for a solution of formaldehyde in sodium glyceroborate.

BORO-GLYCERINE. An antiseptic, patented by Barff (D. R. P. 18108; Eng. Pat. 5906, 1884), prepared by heating 92 parts glycerol with 62 parts of boric acid at 200°. It is a yellowish, transparent substance, soluble in alcohol and in 40 parts of water. Used as a preservative for fruits and wines (J. Soc. Chem. Ind. 1, 244; 4, 362).

BORON. B. At. wt. 10·90 Smith and van Haagen. An element usually reckoned among the metalloids, although it presents analogies to the metals, and has been placed by Etard (Compt. rend. 91, 627) at the head of the vanadium group, intermediate between the places of phosphorus and carbon; is a triad in most of its known combinations, but is also capable of acting as a pentad (Michaelis and Becker, Ber. 13, 58). Never occurs free; usually as boric acid, and in several minerals, as *borax* or *tincal*, *boracite*, *hydroboracite*, *rhodizite*, *sassolite*, *borocalcite*, *boronatrocalcite*, and *botryolite*, and in small quantities in *schorl*, *datolite*, *tourmaline*, *apyrite*, and *axinite*. Minute quantities of boron are found in mineral waters; in sea-water; in plant ashes, and in animal tissues.

The element was first isolated by Gay-Lussac and Thénard in 1808, by heating boric oxide with potassium. According to Wöhler and Deville (Ann. Chim. Phys. [3] 52, 63), it may be obtained by mixing 60 grams of sodium in small pieces with 100 grams of powdered boric oxide in an iron crucible, covering the mixture with a layer of 30 grams ignited sodium chloride in fine powder, and heating the whole to redness. After the completion of the reaction, which is very violent, the mixture is stirred with an iron rod, until the sodium and sodium chloride are fused, and carefully poured into dilute hydrochloric acid, and the residue washed with water containing ammonium chloride (which salt is subsequently removed by alcohol) and dried. Boron can also be obtained by heating potassium borofluoride with potassium (Berzelius), or magnesium (Wöhler and Deville); by the electrolysis of fused boric oxide (Davy); by reducing boron trichloride by hydrogen (Dumas), or preferably with hydrogen in the high tension electric arc; by fusing borax with amorphous phosphorus (Dragendorff); by heating boric oxide with magnesium or calcium, and treating the residue with dilute hydrochloric acid. Boron may also be obtained by the dissociation of the nitride, or of magnesium boride at high temperatures.

Wöhler and Deville's method gives a product containing, in addition to boron, compounds of boron with sodium, iron, and hydrogen, and boron nitride. The best method is that of Moissan, as modified by Weintraub (J. Ind. Eng. Chem. 1911, 3, 299; 1913, 5, 106). Pure and dry boric oxide is intimately mixed with as much magnesium filings as will suffice to reduce one-third of it. The mixture is placed in an earthenware crucible in a furnace at a bright-red heat, when the reaction proceeds at once rather violently. Heating is continued for ten minutes and the mass allowed to cool. The middle portion of the mass, which is of a reddish colour, is mechanically separated from the surrounding black portion as completely as possible, and boiled with a large excess of dilute hydrochloric acid which removes the boric acid and borides of magnesium. The magnesium borate is removed by repeated boiling with strong hydrochloric acid; and the silica (resulting from the disintegration of the crucible) by heating the residue in a platinum vessel with hydrofluoric acid. The residue is washed by decantation with water and dried. It is then approximately pure, but still contains a small quantity of a magnesium boride which cannot be got rid of except by fusing the product with about fifty times its weight of boric oxide, and repeating the above operations.

The product when heated *in vacuo*, at a sufficiently high temperature, or when heated to bright redness in hydrogen with excess of magnesium or sodium, and extracted successively with water, hydrochloric acid and hot dilute nitric acid yields pure boron (Ray. Chem. Soc. Trans 1914, 105, 2162).

Boron has been produced by Weston and Ellis (Trans. Faraday Soc. 1907, 170) by the action of aluminium powder on boric oxide. If 2 mols. of boric oxide to 2 atoms of aluminium are used, the chief product is boron, but with a smaller proportion of boric oxide aluminium boride is produced to a large extent.

Boron may be prepared electrolytically as follows: A fused metallic borate is electrolysed between carbon poles separated so as to prevent the boron floating to the cathode. By the use of a high-current density at the anode sufficient heat is generated to effect the reduction of the boric oxide which collects there (U.S. Pat. 785962).

Commercial boron is purified by grinding the product obtained by heating boric oxide and magnesium with hydrochloric acid, and quickly pouring off the upper liquid. This contains matter in suspension which holds a higher proportion of impurities than does the residue at the bottom. This process of 'fractional decantation' is repeated several times. The residual boron, which may still contain boron hydride, magnesium boride, boric oxide, and a borate, is compressed into a thick stick or cake, and heated to 1200° in a vacuum electric furnace, which either volatilises or dissociates all these impurities. The pure boron is then melted down in the arc in a current of inert gas, preferably hydrogen. The resulting boron is a dense solid substance which conducts electricity and is completely fusible without apparent volatilisation (British Thomson-Houston Co., Eng. Pat. 1197, 1907). Colloidal solutions of boron have been prepared by Gutbier (Kolloid. Zeitsch. 1913, 13, 137).

The amorphous boron described by Moissan and others as a chestnut-coloured powder of sp.gr. 2·45 always contains oxygen, and appears to be a solution of a lower oxide of boron and of magnesium oxide in boron in the superfused liquid state; it is tasteless, odourless, staining the fingers strongly; becomes denser on being heated in a vacuum or in gases which have no action upon it; not oxidised at ordinary temperatures in either air or oxygen; heated in air, it burns with a reddish light, forming B_2O_3 and BN; burns with dazzling brightness in oxygen, forming B_2O_3. Boiling water has no action on it, but it is readily oxidised by strong nitric acid in the cold, and by sulphuric acid when heated. When heated to redness with the alkaline salts of oxyacids, yields an alkaline borate, the formation being frequently attended with incandescence, and in the case of nitre with explosion. Heated with potash it forms potassium borate with liberation of hydrogen, and reduces the chlorides of lead, gold, mercury, and silver, and sulphides of lead, chloride or sulphide of boron being formed (Wohler and Deville, *l.c.*; and Annalen, 105, 72). Heated in nitrogen, it forms white boron nitride. It decomposes nitric oxide at a red heat, burning brilliantly and forming boric oxide and nitride, but apparently has no action on nitrous oxide. (*Cf.* Kroll, Zeitsch. anorg. Chem. 1918, 102, 1.)

Crystalline boron—the only pure form of boron—is a black solid of sp.gr. 2·34, almost as hard as diamond, and only inferior to it in toughness and strength. Melts at about 2200°, and has a sensible vapour tension at 1600°. Rapidly increases in electrical conductivity when heated. It may be obtained by placing 3 parts of aluminium with 10 parts of fused boric acid in a gas-carbon crucible filled up with ignited charcoal and placed inside another crucible of graphite which is heated to 1500°, for five hours. The aluminium is removed from the resulting mass by means of fairly strong soda, and the residue is then boiled out with hydrochloric and hydrofluoric acids. The residue contains some alumina which is separated mechanically as far as possible, and completely by glacial phosphoric acid. Crystals may also be obtained by heating 2 parts of fused and powdered borax with 1 part of magnesium. A commercial process has been patented by Kühn (Chem. Zentr. 1904, i. 64). Boron compounds are mixed with sulphur and aluminium, and the mixture, which burns, ignited. Crystals of boron are found in the resulting mass, and are separated from it by extraction with water, which decomposes the aluminium sulphide, forming aluminium hydroxide and H_2S, and leaving the crystals of boron.

It is only oxidised with very great difficulty in oxygen, and in air no change takes place even at 2000°. Molten potash or lead chromate oxidises it with incandescence, but fused potassium nitrate does not affect it. 'Boron diamonds' of the composition $B_{48}C_2Al_3$ (Hampe) ($C_2Al_3B_{44}$, Biltz) may be obtained by strongly heating a mixture of boron trioxide, sulphur, aluminium and soot. The fused mass gives a mixture of yellow transparent quadratic crystals mixed with black opaque crystals of AlB_{12}, which can be separated by fractional flotation in a mixture of methylene iodide and benzene, the yellow quadratic crystals being slightly heavier than the others. They are not attacked by hot strong hydrochloric or sulphuric acids, or by a solution of chromic anhydride in strong sulphuric acid (Biltz., Ber. 1910, 43, 297).

Boron may be introduced into steel, and the properties of the boron steel so obtained have been studied by Osmond (Compt. rend. 110, 242, and 346), by Moissan and Charpy (*ibid.* 120, 130), by L. Guillet (*ibid.* 144, 1049), and by Hannessen (Zeitsch. anorg. Chem. 1914, 89, 257). Boron steels are obtained either by heating amorphous boron with reduced iron in a current of hydrogen, or by adding crystalline boron to the molten metal. On hardening by heating to a known temperature and quenching, boron steel behaves like a high-grade hard carbon steel as regards increase in tensile strength, whilst the diminution in extension is not so great. The hardness of boron steel is not much affected by heating and quenching. The special effect of boron appears to be to communicate to the steel a high tensile strength rather than actual hardness when the metal is heated and quenched.

Boron rapidly reduces manganese oxides in the electric furnace. With excess of oxide products containing up to 97 p.c. manganese may be obtained which are soft enough to be filed. With excess of boron, harder, granular substances result, containing up to 20 p.c. boron. From these a definite boride MnB may be isolated. It is a crystalline metallic powder attacked by halogens and oxygen at high temperatures, and by alkali hydroxides and carbonates at a red heat. Water or steam slowly decomposes it with evolution of hydrogen (Binet du Jassonneix, Compt. rend. 139, 1209). The same author has obtained very similar results with molybdenum dioxide and boron (Compt. rend. 143, 169); and has also prepared two definite borides of chromium Cr_3B_2 and CrB, by fusing together chromium and boron. They are very stable towards reagents, especially the former, but are decomposed by fused alkalis, and by chlorine at a red heat. They are soluble in hydrofluoric, hydrochloric, and concentrated sulphuric acids (Compt. rend. 143, 1149). The same author has also prepared Ni_2B, NiB_2, Co_2B, and CoB_2 (Compt. rend. 145, 240); and borides of zirconium, chromium, tungsten, and molybdenum have been prepared by Tucker and Moody (Chem. Soc. Proc. 1901, 129); and borides of vanadium, uranium and titanium by Wedekind, Horst and Jochem (Ber. 1913, 46, 1198).

COMPOUNDS OF BORON WITH NON METALLIC ELEMENTS.

Boron hydrides are formed by dissolving magnesium boride in hydrochloric acid, or more easily by dissolving commercial ferroboron in dilute sulphuric acid. Spontaneously inflammable. Boron hydrides admixed with hydrogen are evolved, and an insoluble residue formed. The gases have a characteristic smell, and decompose a moderately concentrated silver nitrate solution, forming a blackish-brown precipitate with metallic lustre. They burn with a green flame and form a mirror when passed through a red-hot glass tube (Hoffmann, Chem. Zeit. 1911, 35, 265).

Four unstable hydrides have been isolated, B_2H_6, B_4H_{10}, B_6H_{12}, and a solid hydride $B_{10}H_{14}$. Boron hydride, B_4H_{10}, is a colourless liquid, b.p. 16°–17°/760 mm.; m.p. *ca.* −112°, of a peculiar and most disagreeable odour. A few bubbles of the gas affect respiration and cause headache. It is a very unstable substance, decomposing at the ordinary temperature after a few hours, especially under the influence of ultra-violet light, and quicker at higher temperatures, giving rise to B_2H_6. It is similarly decomposed by electric sparks. It takes fire spontaneously in the air or in oxygen, burning with a green flame. Water and dilute hydrochloric acid decompose it, and it is oxidised by concentrated nitric acid with explosive violence. It is rapidly absorbed by aqueous sodium hydroxide, the solution slowly evolving hydrogen. Ammonia gives a solid light brown substance, insoluble in water, whilst alcohol decomposes the hydride with evolution of hydrogen. The solution in benzene is very stable towards oxygen.

The hydride B_6H_{12} is a colourless liquid, b.p. 10°/15 mm. *ca.* 100°/760 mm., possessing a highly disagreeable odour and taking fire spontaneously in the air. It is more sensitive towards water and moisture than the hydride B_4H_{10}. With aqueous alkalis, hydrogen is immediately evolved (Stock and Massenez, Ber. 1912, 45, 3568).

B_2H_6 is a colourless gas possessing a characteristic, repulsive odour, resembling that of the hydride B_4H_{10}. B.p. −87° to −88°/760 mm., m.p. −169°. It is more stable than B_4H_{10}, but decomposes slowly at ordinary temperatures. It only takes fire in the air when mixed with other boron hydrides. With alkalis, it reacts similarly to B_4H_{10}; with sodium hydroxide it gives solutions containing hypoborates.

The formula B_2H_6 shows that boron must be at least quadrivalent and not tervalent as a maximum, as it should be according to its position in the periodic system (Stock and Friederici, Ber. 1913, 46, 1959).

The solid hydride $B_{10}H_{14}$ obtained by heating the other hydrides is a colourless substance with a penetrating peculiar odour, dissimilar to that of the gaseous hydrides. It sublimes in a vacuum giving long needles, m.p. 99·5; D 0·94. Not attacked by water, even when boiling, soluble in alkaline hydroxide, giving intense yellow solutions (Stock, Friederici and Priess, Ber. 1913, 46, 3353).

All the hydrides when treated with caustic alkalis evolve hydrogen and form alkaline hypoborates: thus with potassium hydroxide, $B_4H_{10}+4KOH=4KOBH_3+H_2$. The solutions of the hypoborates thus formed are stable for hours at 0°, but on boiling they decompose rapidly. *Potassium hypoborate* $KOBH_3$ forms glistening, octahedral, colourless crystals which are stable in dry air. It is deliquescent, and its solutions gradually decompose at ordinary temperatures, evolving hydrogen and forming potassium borate. The aqueous solution is a strong reducing agent, giving with copper salts a precipitate of copper hydride, and with nickel salts black insoluble nickel boride, Ni_2B (Stock and Kuss, Ber. 1914, 47, 810. For action of halogens on the hydrides, *see* Stock, Kuss and Priess, Ber. 1914, 47, 3115).

Boramide $B(NH_2)_3$ is formed together with ammonium chloride by the action of ammonia on boron trichloride at a low temperature (Joannis, Compt. rend. 135, 1106).

Borimide $B_2(NH)_3$ is a spongy white mass insoluble in most solvents. On heating it begins to give off ammonia at 125°–130°, and is completely transformed into boron nitride at slightly higher temperatures. It is prepared by heating the compound of boron trisulphide and ammonia $B_2S_3,6NH_3$ for some time at 115°–120° in a current of hydrogen or dry ammonia (Stock and Blix, Ber 1901, 3039; and Joannis, Compt. rend 135, 1106).

Boron carbide B_6C forms exceedingly hard shining black crystals, which are capable of polishing diamonds. It may be obtained massive by fusing together boric oxide and carbon in an electric resistance furnace and cooling fairly rapidly (E. A. Sperry, U.S. Pat. 869114).

Shaped blocks of boron carbide are obtained by preparing the body of the block in pure carbon, embedding this in powdered carbide, and firing in an electric furnace (Bolling, Eng. Pat. 6693, 1905). Modifications of this process have also been patented (Additions (2) Sept. 30, 1904, to Fr. Pat. 353017).

Boron nitride BN is a white, amorphous, bulky powder discovered by Balmain in 1842. It is infusible, insoluble in water, and generally somewhat inert to reagents, but Stock and Blix (Ber. 1901, 3039) have described another modification which is chemically much more active. It may be obtained mixed with B_2O_3 by burning boron in air; or by the action of nitrogen on a mixture of boric anhydride and carbon heated to redness (Wöhler and Deville, Ann. Chem. Phys. [3] 52, 84). It may be prepared by the action of ammonium chloride vapour on a porous mass of calcium phosphate and borax or boric oxide heated to bright redness, afterwards extracting the cold mass with hydrochloric acid and water, and drying the residue of BN in a vacuum desiccator (Moeser and Eidmann, Ber. 1902, 535); or by allowing boron bromide to drop into liquid ammonia, and heating the precipitated mixture of boramide and borimide to 750° in a current of ammonia gas (Stock and Holle, Ber. 1908, 2095); or by heating boric acid and calcium cyanamide. A mixture of borocalcite CaB_4O_7 and carbon heated to 1850° and then to 1400°, affords a theoretical yield of boron nitride (Stähler and Elbert, Ber. 1913, 46, 2060). B_3N has been prepared by heating boric acid with magnesium nitride.

Boron sulphide B_2S_3 forms fine white needles of density about 1·55, which melt at 310°. It is volatile in hydrogen without decomposition (Moissan, Compt. rend. 115, 203). It may be prepared by heating together sulphur and amorphous boron (Wöhler and Deville); or, better, by heating ferroboron in a stream of dry hydrogen sulphide at 400°, and purifying the resulting product by dissolving out the sulphur with carbon disulphide (Hofmann, Zeit. angew. Chem. 1906, 1302). Combines with hydrogen sulphide to form *thiometaboric* acid $H_2B_2S_4$. Is decomposed by carbon dioxide.

Boron trifluoride BF_3. Amorphous boron unites with fluorine at the ordinary temperature. It is a gas at ordinary temperatures, and may be prepared by heating a mixture of boron trioxide and calcium fluoride with sulphuric acid, or a mixture of potassium borofluoride and boron sesquioxide with sulphuric acid. It may be liquefied and solidified by cold and pressure: melts at −127° and boils at −101°. It is rapidly decomposed by water, forming hydrofluoboric and boric acids.

Boron trichloride BCl_3 is a colourless, very mobile, refractive liquid which fumes in the air. Sp.gr. 1·4338 at 0°; m.p. −107°, b.p. 12·5°. It is decomposed by water with formation of hydrochloric and boric acids. It is prepared by passing dry chlorine over amorphous boron, and collecting the vapours in a U-tube immersed in a freezing mixture. The product is purified by shaking with mercury to remove chlorine, and by fractionation. It may also be prepared by heating boron sesquioxide with phosphorus pentachloride.

Boron tribromide BBr_3 resembles the chloride in physical properties. It is prepared in the same way, substituting bromine for chlorine, or by treating a red-hot mixture of carbon and boric oxide with bromine vapour. M.p. −46°; b.p. 90·5°; sp.gr. 2·65 at 0°.

Boron tri-iodide BI_3 may be obtained by acting on heated amorphous boron with iodine or hydriodic acid, or by treating the vapour of the trichloride with hydrogen iodide. It crystallises in colourless nacreous plates and is readily acted upon by light. M.p. 43°; b.p. 210°. Soluble in carbon disulphide, benzene, and other organic solvents. Burns when heated in oxygen, and is decomposed when warmed with sulphur or phosphorus.

Boric oxide B_2O_3 may be obtained by burning boron in oxygen, or, more easily, by strongly heating boric acid, when it melts at 577° to a viscid mass, cooling to a colourless brittle glass of sp.gr. 1·88. May be vaporised *in vacuo*, and is capable of expelling carbonic, nitric, and sulphuric acids from their salts at a red heat. Soluble in water, forming boric acid. For velocity of hydration of boric oxide to metaboric acid and orthoboric acid, see Myers, Chem. Soc. Trans. 1917, 111, 172.

A blue glass, 'boron-ultramarine,' of colour varying with the duration and intensity of heating, and with the proportions of the ingredients, is made from sodium sulphide and boric anhydride. It is stable in air and only slightly soluble in water (J. Hoffmann, Zeitsch. angew. Chem. 1906, 1089).

Tetraboron trioxide B_4O_3, *boron dioxide* B_2O_2, and *tetraboron pentoxide* B_4O_5 are also known.

Boric or **Boracic acid.** *Sal sedativum Hombergii*, *Sal narcoticum vitrioli.* Boric oxide forms three hydrates:

Orthoboric acid $B_2O_3{\cdot}3H_2O=H_3BO_3$.
Metaboric acid $B_2O_3{\cdot}H_2O=H_2B_2O_4$.
Pyroboric acid $2B_2O_3{\cdot}H_2O=H_2B_4O_7$.

Ray (Chem. Soc. Trans. 1918, 803) has described the mode of formation of a potassium borate $K_2B_4O_6$, and hence the existence of an acid $H_2B_4O_6$.

Boric acid appears to be a dibasic acid, and most of its salts may be regarded as derived from metaboric or pyroboric acid. Both these are so-called 'weak' acids. Their salts, when soluble, have usually an alkaline reaction, even when containing excess of boric acid, and are decomposed even by carbonic acid.

Boric acid is found free in nature in many volcanic districts. In Central Italy it is produced on a large scale in the territories of four communes: Pomerance, Massa Marittima, Castel Nuovo di Val di Cecina, Montieri, all in the province of Tuscany, the nearest shipping point being Leghorn, to which place it is brought by railroad from Volterra. It also occurs in the extinct crater of a volcano on one of the Lipari Islands, and in the crater of Stromboli, an active volcano on another island of the same group, near Sicily. Volcanic emanations containing boric acid occur in Nevada, in California, and Nova Scotia. It exists in solution in the mineral waters of Wiesbaden, Aachen, and Krankenlied, in Germany; in the mud volcanoes of the Colorado Desert, in San Diego county, California; in the water of several mineral springs in Tehama county, California. In smaller quantities it exists in sea water and in the ash of many plants.

Sassolite, or Tuscan boric acid, is never produced in the pure state, but is always associated with impurities, both soluble and insoluble. It differs considerably in quality, some parcels containing 89 p.c. of crystallised acid, while others yield only 75 p.c. The following analyses show its general composition:—

Analyses of crude Tuscan boric acid.

Boric acid B_2O_3 . . .	47·95	44·04
Water { combined . . .	37·00	33·98
Water { hygroscopic . .	0·73	2·80
Ammonium sulphate $(NH_4)_2SO_4$	5·67	10·62
Sulphate of alumina and iron	0·13	0·20
Calcium sulphate . . .	trace	1·20
Magnesium sulphate . .	6·91	4·03
Sodium sulphate . . .	0·07	1·10
Sodium chloride . . .	0·23	0·32
Sand	0·42	0·80
Sulphur	—	trace
Organic matter . . .	0·89	0·91
	100·00	100·00

An analysis of an average sample taken from 5000 tons shows it to be composed as follows :—

Crystallised boric acid $B_2O_3,2H_2O$	83·5
Hygroscopic water	1·4
Ammonium sulphate	5·3
Magnesium sulphate	7·5
Iron and alumina	0·3
Sand, organic matter, &c.	2·0
	100·0

Boric acid occurs on the West Coast of South America, principally in the form of boronatrocalcite (*ulexite*, or *hayesine*), and is found throughout the province of Atacama and in portions of Chile. Ascotan and Maricunga, to the north of Copiapo, are the places which have proved most successful commercially. The crude material, known as *tiza*, occurs in both places in lagoons or troughs; these, instead of being entirely filled with common salt, as is usually the case in the desert, contain zones or layers of boronatrocalcite, alternating with layers of salt and salty earth. The lagoons of Maricunga are estimated to cover 3,000,000 sq. metres. The raw material contains on the average about 25 p.c. of boric acid, but by washing and calcination it may be raised to 55 or 60 p.c. The roughly purified boronatrocalcite is shipped to England and Germany.

A borate of lime (*rhodizite*) is imported from the West Coast of Africa.

Pure orthoboric acid is easily obtained by treating a solution of 3 parts borax in 12 parts hot water with 1 part sulphuric acid. On cooling, boric acid separates out; it is recrystallised from hot water, dried and fused to expel traces of sulphuric acid, and again recrystallised from water. It forms white, translucent, monoclinic laminæ (Kenngott), which have a mother-of-pearl lustre and are unctuous to the touch. Sp.gr. 1·434 at 15°.

Boric acid evaporates freely in a current of steam. The loss sustained by evaporating an aqueous solution is 0·28 p.c. of the water evaporated, equal to 2 8 lbs. for every 100 gallons. (*Cf.* Nasini and Ageno Atti. R. Accad. dei Lincei, 1912, 21, ii. 125.)

The solubility of boric acid in water has been determined by Ditto (Compt. rend. 85, 1069), but his results are probably low. Herz and Knoch find considerably higher values at 13°, 20°, 25°, and 26°. The figures of Brandes and Firnhaber (Arch. Pharm. 7, 50) also differ. The results obtained by Nasini and Ageno (Zeitsch. physikal. Chem. 1909, 69, 482) are quoted below :

Temperature	Grams of H_3BO_3 per 100-gram solution.	Temperature	Grams of H_3BO_3 per 100-gram solution
0°	2·59	60°	12·90
12·2°	3·69	69·5°	15 58
21°	4·90	80°	19·11
31°	6·44	90°	23·30
40°	8·02	99·5°	28·10
50°	10·35		

Cf. Nasini and Ageno (Gazzetta, 1911, 41, i. 141).

The solubility of orthoboric acid in water is lessened (not, as stated in various places, increased) by the presence of hydrochloric acid (Herz, Chem. Zentr. 1903, i. 312) and of sulphuric, nitric, and acetic acids; but tartaric and oxalic acids have the opposite effect (*ibid.* 755). Boric acid is soluble in alcohol, glacial acetic acid, and volatile oils. A cold saturated aqueous solution colours litmus [illegible] wine-red; a hot saturated solution gives a bright-red colour.

Crystallised boric acid, heated to 100°, is converted into $H_2B_2O_4$ (Schaffgotsch, J. 1859 71), and into $H_2B_4O_7$ at 160° (Merz, J. pr. Chem 99, 179; Ebelmen and Bouquet, Ann. Chim Phys. [3] 17, 63). At a stronger heat the acid froths up, parting with its water and forming boric anhydride as a fused viscid mass, solidifying to a fissured glass on cooling. For the action of boric acid on sodium chloride on heating, *see* Levi and Castellani (Gazz. chim. ital. 1910, 40, i 138); Levi and Garavini (*ibid.* 1911, 41, i. 756).

Boric acid and its salts are extensively used in medicine as an antiseptic; and as a food preservative they are also very widely employed. They are also employed for glazing porcelain and earthenware, in the preparation of glass and certain pigments, in the manufacture of cosmetics, soaps, in the linings of safes, in the glazing of paper, for dressing leather, as a flux, by laundresses, and for soaking the wicks of stearin candles.

The effect of boric acid in glazes is to increase their hardness and their fusibility, and to modify the coefficient of expansion. A small amount of boric acid lowers the expansion, whilst a large quantity produces an increase. This effect is explained by Grenet (Compt. rend. 123, 801) to be due to the fact that when the proportion of bases to boric acid is high, devitrification occurs, whilst when the boric acid is the more important constituent, the coefficient of expansion tends to approximate to that of boric acid itself, which is higher than that of any glass.

It has also been proposed to use boric acid in the preparation of nitric acid from Chile saltpetre, so as to obtain borax as a by-product.

Industrial extraction of boric acid. The occurrence of the *sal sedativum* of Homberg in the water of the Tuscan lagoons appears to have been first noticed in 1777 by Höfer, a Florentine apothecary, and its extraction was begun about 1815, and to-day a large part of the boric acid of commerce is derived from the lagoons near Monte Rotondo, Lago Zolforeo, Sasso, and Larderello, in the Maremma of Tuscany, inclosing both natural and artificial vents. The *soffioni* or jets of steam, which often rise in thick columns to a considerable height, contain only traces of boric acid, but when these are condensed in the water of the lagoons this becomes gradually charged with the acid which is obtained from the solution by evaporation.

To obtain the boric acid, the soffioni are surrounded by basins of rough masonry, several of which are arranged in steps, one above the other, in such manner that the contents of each basin can be led by gravitation into the basin below. Fresh water from a neighbouring spring is conducted into the uppermost basin, whilst the gases and vapours of the fumaroles rise through the water from beneath, occasionally with such violence as to eject the water to a height of several feet. After twenty-four hours the water in the first basin, which is generally muddy, is allowed to pass into the second basin, the first being recharged with fresh water. After another twenty-four hours the second basin is discharged into the third and the first into the second, the second and following basins being also built round soffioni. After having passed through four or five of these basins, the solution is passed into rectangular reservoirs in which the suspended matter is deposited on standing. From these it passes into a series of leaden evaporating pans, placed in couples one above the other in the form of a terrace. These pans are heated by the gases and vapours of soffioni which, on account of their situation, are otherwise useless—by a method first adopted by Count Lardarel in 1815. The evaporating pans are square, about 1 foot deep and 9 feet square, and are supported on wooden beams. The solution is heated in these for twenty-four hours until it has attained a density of 1·017, when it is decanted into a second series of pans, where, after another twenty-four hours, it attains a density of 1·034, and is finally decanted into the last four pans, where it is evaporated to a specific gravity of 1·07.

The temperature gradually increases, being in the first pans about 60° to 70°, in the following pans about 75°, and in the last as high as 80°.

In all these pans a precipitation of gypsum takes place, which requires to be removed from time to time. When the solution in the last pans has attained a density of 1·07, it is run through funnels into the crystallising vats, consisting of wooden tubs lined with lead. After twenty-four hours the crystallisation is complete, the mother liquor is then decanted off and added to the evaporating pans a few hours before the completion of the concentration. The crystals are drained in baskets placed under the crystallising vats for twenty-four hours, and are spread out on the bottom of a large drying oven, which is likewise heated by the vapour from the soffioni. The layer of crystals, which is two or three inches thick, is stirred at intervals to assist the drying. This is complete in twenty-four hours. An improved form of evaporating apparatus consists in decanting the solution in the reservoirs from which the suspended matter has deposited into a pan, and thence running it into a slightly inclined trough made of sheet lead with the edges turned upwards. The trough has an undulatory form, is supported on wooden sleepers, and heated by the soffioni vapours. The solution of boric acid, after passing through this heated trough, becomes so concentrated as to be ready for crystallisation.

Artificial soffioni have been bored to a depth of 200 feet in the vicinity of the Monte Rotondo. The chief works are at Monte Cerboli, Larderello, San Federigo, Castel Nuovo, Sasso, Monte Rotondo, Lustignano, Serranzano, Lago, and San Eduardo, each of which has from 8 to 35 *lagoni*, 100 to 200 feet in diameter (Payen, Ind. Chem. transl. by Paul).

The boric acid thus obtained is far from pure. Analyses of different samples by Payen, Vohl, and Wittstein show that it contains from 74 to 80 p.c. crystallised boric acid, from 4·5 to 7 p.c. of hygroscopic water, ammonium and magnesium sulphates, 8–14 p.c., together with gypsum, clay, sand, sulphur, organic matter, and free acids and ammonia.

The origin of the boric acid in the soffioni is not understood. Dumas suggested that it is formed by the decomposition by means of water of a bed of boron sulphide formed at some depth below the surface. Bolley (Annalen, 68, 122) supposed that it is produced by the action of a hot solution of ammonium chloride upon the borates contained in the earth. According to Warington (Chem. Gazette, 1854, 419), Wöhler and Deville (Annalen, 105, 69), and Popp (Annalen, Suppl. 8, 1), its formation is probably due to the action of water upon boron nitride.

Dieulafait has found boric acid in regions where there are no visible manifestations of volcanic action, and concludes that it is of aqueous origin, and derived from the waters of ancient seas (Compt. rend. 100, 1017, and 1240).

Of late years the importation of boracite from South America and colemanite from California, and also some Persian ores, has had a considerable effect on the Italian industry. Besides the obvious method of separating the boric acid from these ores by acidification and crystallisation, other processes are used for its extraction.

One process consists in grinding the borate of lime or ulexite to an impalpable powder and treating it with sulphurous acid.

A large wrought-iron tank, circular in shape and egg-ended, is lined with stout sheet lead; it is provided with a cover and still head, mechanical agitator, and steam pipes. It is first of all charged about half full with water or weak liquor from a previous operation. The liquor is then boiled, and the powdered borate fed in by means of an Archimedean screw.

Sulphur is then burnt in an adjoining furnace, and the sulphurous gas is injected by means of a peculiarly constructed lead injector into the boiling liquor. A special type of sulphur burner for this process is patented by the American Borax Co. (U.S. Pat. 809550, 1906). The gas is wholly absorbed by the calcium borate, which itself is slightly soluble in water, boric acid and calcium sulphite being formed. The steam arising from the operation, containing boric acid vapours, passes from the still head through a condenser in order to prevent any loss that would occur. When the operation is complete, the steam and gas are shut off, and the contents of the pan allowed to settle, which occupies about ten hours. The clear boric acid liquor is then run either into vats made from white sugar pine, or of ordinary wood lead-lined, where the boric acid crystallises out. The mother liquors are then drawn off, to be used over again if not too highly impregnated with foreign salts, or still further treated for the recovery of the calcium sulphite and the slight percentage of boric acid they contain.

Bigot (J. Soc. Chem. Ind. 1899, 830) obtains it by heating together borate of calcium and ammonium sulphate in a closed vessel. The ammonia driven off is condensed and collected, and the boric acid obtained by extraction of the residue.

Another method is to treat boracite with sodium bisulphate, a by-product in nitric acid manufacture. The two are dissolved in theoretical quantities in water to a density of 15° B. at 100°. The solution is filtered and concentrated to 30° B. On cooling, the boric acid crystallises out and very pure sodium sulphate is obtained by concentration of the mother liquors (Heidlberg, Chem. Zeit. 1907, 31, Rep. 48).

Chenal Douilhet & Co. (D. R. P. 110421, 1899) produce boric acid by taking advantage of the fact that when a borate is boiled with ammonium chloride, ammonia and boric acid are produced. If the concentration is too high, there is a tendency to recombination; the boric acid is therefore removed frequently by crystallisation from portions of the liquid, the mother liquors being returned to the main volume. By this process it is claimed that 98–99 p.c. of the boric acid in combination is recovered.

In another process chlorine is passed into water at 70° containing finely powdered calcium borate in suspension. Calcium chloride and chlorate and boric acid are produced. The boric acid is removed by cooling, and the mother liquors used again until sufficiently concentrated for convenient extraction of the chlorate (G. C Moore, Eng. Pat. 20384, 1899).

METALLIC BORATES.

Borates are obtained by the action of boric acid on metallic oxides or their salts, in either the dry or wet way.

In solution boric acid is a very weak acid, being expelled by almost all acids from its combinations, partially so even by carbonic and hydrosulphuric acids. A boiling concentrated solution, however, decomposes carbonates and soluble sulphides and manganese sulphide.

In the dry way, at high temperatures, it is capable of decomposing the salts of all more volatile acids.

Alkaline borates are soluble in water, but are precipitated by alcohol. The remaining borates are insoluble, or very sparingly soluble in water. The soluble borates produce precipitates in solutions of salts of calcium, barium strontium, nickel, and cobalt, and of ferric salts which are readily soluble in ammonium chloride.

Anhydrous borates are produced by fusing together, in a special furnace at 1350°–1400° for three hours, boric oxide with the necessary quantity of oxide, carbonate, or nitrate of the metal. With large excess of boric acid, lithium, potassium, sodium, rubidium, cæsium, thallium, and silver produce clear fusions which either crystallise or leave clear glasses on cooling. Cuprous oxide, and oxides of lead, bismuth, antimony, arsenic, titanium, molybdenum, and tungsten produce clear fusions at the high temperatures which form emulsions on cooling. The oxides of calcium, strontium, barium, magnesium, zinc, cadmium, manganese, iron, cobalt, and nickel, do not give homogeneous fusions, but separate into two layers (W. Guertler, J. Soc. Chem. Ind. 1908, [illegible]58).

Borates have also been prepared electrolytically by Levi and Castellani by electrolysing boric acid and an alkaline earth chloride in a special type of divided cell (J. Soc. Chem. Ind. 1909, 248).

Ammonium borates. *Laderellite*

$$(NH_4)_2B_{10}O_{16},5H_2O$$

occurs in the Tuscan lagoons in small crystalline rhomboidal plates (D'Achiardi, Chem. Soc. Abstr. 1900, 600). Atterberg (Zeitsch. anorg. Chem. 1906, 48, 367) distinguishes a *diborate* $(NH_4)_2B_4O_7,5H_2O$, crystallising in tetragonal pyramids, besides the *pentaborate*

$$(NH_4)_2O,5B_2O_3.3H_2O,$$

crystallising in rhombic double pyramids previously prepared by Rammelsberg. *Cf.* Sborgi (Atti R. Accad. dei Lincei, 1912, 21, ii. 855; 1913, 22, i. 90).

Barium borates. The interaction of barium hydroxide and boric acid in aqueous solution has been studied by Sborgi (Atti R. Accad. dei Lincei, 1914, 23, i 530, 717, 854). The only stable compounds which appear to exist are the triborates $(BaO,3B_2O_3, + H_2O)$ and the metaborate $(BaO.B_2O_3 + H_2O)$.

Calcium borates $Ca_2B_6O_{11}$. There are three varieties of calcium borate, which correspond to the three varieties of calcium carbonate, calc spar, marble, and chalk—viz. *boracite* or *pandermite*, *colemanite*, and *pricite*—each found in different parts of the world in large quantities, and of a well-defined and constant composition. Meyerhoffer and van 't Hoff (Annalen, 351, 100), [illegible] attempting to prepare compounds of similar composition artificially, have obtained several other calcium borates. These authors assign different compositions to colemanite and pandermite. *Boracite*, in outward appearance, closely resembles a snow-white, fine-grained marble; *colemanite* is of a crystalline nature like calc spar, or Iceland spar, and has been termed *borate spar*; *pricite*, or *bechilite*, is a very fine, white, soft, chalky mineral of a cohesive nature, easily rubbed to powder, and resembling chalk. Chemically speaking, they are all hydrated calcium borates, differing only in their composition in respect to the water of combination, their composition being given in table below.

—	$Ca_2B_6O_{11},3Aq.$	$Ca_2B_6O_{11},4Aq.$	$Ca_2B_6O_{11},5Aq.$	$Ca_2B_6O_{11},6Aq.$

Water H_2O	14·2	18·3	21·9	25·1
	100·0	100·0	100·0	100·0

Cf. Sborgi (Atti R. Accad. dei Lincei, 1913, 22, i. 639, 715).

Boracite has been extensively mined at Sultan-Chairi, in the district of the Villayet of Broussa in Asia Minor, forty-five miles from Panderma, a port on the Sea of Marmora; the principal deposits, as far as yet known, exist near the Tschataldga Mountain, in long. 28° 2′ east of Greenwich and lat. 40° north. The Susurlu river runs from the Tschataldga Mountain to the Sea of Marmora: it is partly navigated to a point called Mohalitch; the field is situated in a basin of Tertiary age, surrounded by volcanic rocks, which vary from granite on the east to trachyte on the north, and columnar basalt on the west. Several basaltic hills and dykes protrude in different portions of the basin, and the presence of hot and mineral springs further testifies to the volcanic influences which have been at work and in which, doubtless, originated the boracic mineral. The latter occurs in a stratum at the bottom of an enormous bed of gypsum; its greater sp.gr. probably impelling it downwards, while the whole mass was yet in a soft state. Several feet of clay cover the gypsum bed, which is here 60 or 70 feet thick, though in places it attains to double that thickness. The borate strata vary in depth, and have been proved for a vertical distance of 45 feet. The mineral exists in closely packed nodules of very irregular size and shape, and of all weights up to a ton. It is easily separated from the dark-coloured gypsum in which it is embedded, and a number of people are employed at the pit mouth in picking and selecting the material. It is sold on a basis of 40 p.c. boric acid, which would be equal to 78·5 p.c. of the pure calcium borate with five molecules of water $Ca_2B_6O_{11},5Aq.$, the remainder consisting of calcium sulphate and other impurities.

Borate spar or *colemanite* has been extensively mined since 1883 at Calico, in San Bernardino county, California, 462 miles south-east of San Francisco. The geological formation of the surrounding hills consists of black lava, sandstones of different colours, gypsum, steatite, and calcium carbonate; it is found in veins and seams from 2 feet to 8 feet in thickness, in some cases dipping at an angle of 36°, and at others running into the hillsides almost horizontally. Its colour and streak is white-milky to transparent; hardness 3·5–4; sp.gr. 2·4; before the blowpipe it exfoliates, decrepitates violently, and melts imperfectly after considerable heating; it imparts a reddish-yellow colour to the flame, which changes to green. The fragments are obscurely rhombic and pulverise easily; it is wholly soluble in hot hydrochloric acid: from the solution boric acid crystallises on cooling. Lustre of the mineral is vitreous to adamantine. The veins and seams are interspersed with masses of calcium carbonate and magnesium silicate, from which, like the boracite, it has to be picked and selected.

Its formula is $Ca_2B_6O_{11},5Aq.$; it is sold on the basis of 40 p.c. boric acid. Average samples from the bulk vary in composition from 33·8 p.c. boric acid up to 41·2 p.c.; the following analyses may serve as examples of the general composition:—

BORATE SPAR.

Component parts	1	2	3	4	5
*Calcium borate $Ca_2B_6O_{11}5Aq.$ . .	66·2	70·4	75·0	78·00	80·80

* = to boric acid	33·8 p.c.	35·9 p.c.	38·2 p.c.	39·8 p.c.	41·2 p.c.

Borate spar is also found in the neighbourhood of Furnace Creek, Inyo county, California; its outward appearance is frequently so exactly like calc spar as often to be mistaken for that mineral. Priceite has hitherto not been so extensively mined as boracite and colemanite; a mine of this mineral, however, exists at Lone Ranch, Cheteo, Curry, county Oregon, from which source, since the first cargo was extracted by E. L. Fleming in 1888, several hundred tons have been taken. It is found embedded in boulders of different size, the nodules varying in weight up to one ton. It is of a soft chalky nature, purely white, can be easily rubbed to powder, but is of a cohesive character; it is very soluble in sulphurous acid, hydrochloric acid, or acetic acid, yielding boric acid. The following analysis from bulk shows its composition:—

Boric acid B_2O_3	44·24
Lime CaO	30·91
Water H_2O	23·00
Magnesia MgO	0·65
Silica SiO_2	1·20
	100·00

Bechilite is a calcium borate found in the lagoons in Tuscany.

Its composition is represented by the formula $CaB_4O_7,5H_2O$.

Boronatrocalcite, Ulexite, tiza, cottonballs, hayesine $Ca_2B_6O_{11}Na_2B_4O_7,16H_2O$, is a soft, fibrous, silky mineral of a brilliant white when pure, generally found in nodules of a yellowish-white colour, varying in size from that of a Brazil nut to a potato. This curious mineral was first found in the nitre beds of Peru in small quantities, and was examined by Ulex in 1836. It was discovered in Tarapaca, 30 miles from Iquique, under the crust that covers the nitrate of soda beds. It has since been discovered in Chile, Bolivia, California, Nevada, Nova Scotia, and Persia.

Its composition is constant, containing, when pure:

Boric acid B_2O_3	43·1
Lime CaO	13·8
Soda Na_2O	7·7
Water H_2O	35·4
	100·0

The nodules are frequently found incrusted with a coating of sodium sulphate and salt, from which cause the percentage of boric acid in large parcels varies considerably, the average being from 18 to 25 p.c.

Chile has hitherto been the principal source of supply of this borax material. Ulexite, when in a state of fine division, is difficultly soluble in boiling water.

Calcium borosilicate. Datolite (*Howlite*). A siliceous borate of lime, colour white, streak white, opaque, of a chalky nature, found at Calico, San Bernardino county, California, and at Brookville, Nova Scotia. Composition:

Boric acid B_2O_3	44·22
Lime CaO	28·69
Silica SiO_2	15·25
Water H_2O	11·84
	100·00

Copper borate is readily obtained by treating a soluble borate in solution with copper chloride or sulphate. It is blue, and used in certain oil paints and also in the colouring of porcelain.

Iron borate. A hydrated borate of iron, *lagonite* $Fe_2O_3,3B_2O_3,3H_2O$, is found in the Tuscan lagoons.

Lead borates. By mixing concentrated solutions of lead nitrate and borax, the metaborate $Pb(BO_2)_2,H_2O$ is precipitated, and by the use of solutions of smaller concentrations Rose obtained many basic salts. They all melt on strong heating to colourless or light-yellow, highly refractive glasses, the hardness increasing with the boron content. Glasses may be obtained by fusing together lead oxide and boric acid in any proportions greater than 0·0725 equivalent of PbO to 1 equivalent B_2O_3, but below this limit an emulsion is formed on cooling.

Magnesium borates. *Stassfurtite* (*Szaibelyte*). This mineral occurs crystalline and massive, colour white, streak white, fracture conchoidal uneven, subtransparent, translucent, lustre vitreous inclining to adamantine, hardness 7, sp.gr. 2·83, pyro-electric, soluble in acids. It is found at Stassfurt, Prussia, embedded in the kainite beds, the composition being:

Boric acid B_2O_3	62·33
Magnesia MgO	27·03
Chlorine Cl	7·91
Magnesium Mg	2·73
	100·00

It is also found in nodules in grey limestone at Werksthal, Hungary, and at Danbury, Connecticut, United States.

Sussexite is a hydrated borate of manganese and magnesia found in Sussex county, New Jersey, United States. *Tourmaline*, found in different parts of the world in different colours, also contains a small percentage of boric acid.

Potassium borates. Atterberg distinguishes five different potassium borates: a monoborate $K_2O,B_2O_3,3H_2O$; three diborates $K_2O,2B_2O_3$ crystallising with 4, 5½, and 6 molecules of water respectively; and Laurent's pentaborate $K_2O,5B_2O_3,8H_2O$ (Zeitsch. anorg. Chem. 1906, 367).

Sodium borates. The only commercially important compounds are sodium diborate (*v. Borax*) and the perborate (*v. Perborates*). The metaborate $NaBO_2,4H_2O$ is readily obtained by fusing together the necessary proportions of boric acid and sodium carbonate, and crystallising.

Acid borates $Na_2O\cdot3B_2O_3$ and $Na_2O,4B_2O_3$ melting at 694° and 783° respectively may be obtained by fusing mixtures of borax and boron trioxide.

Sodium diborate, or Borax. Borax occurs in the crude state in what are termed borax marshes, which are generally the bottoms of dried-up lakes, or, where tincal is found, lakes that are nearly dried. The crude borax in the former instances is found lying on the surface of the plain, of a peculiar greyish-yellow colour, having a depth of from 1 inch to 18 inches. It is generally associated with other substances, both soluble and insoluble, as the table of analyses below shows.

At Jagadhri in Northern India, 37 miles S.E. of Umballa, there is a borax refinery, the product of which is shipped to Calcutta. The quantity of tincal and borax obtained from the districts of the Himalayan Mountains amounts to about 2000 tons per annum. The tincal deposits are of very ancient origin. In North America there are no less than ten deposits, five of them being in the State of California—at Saline Valley, Furnace Creek, and Armagora (in Inyo county), Slate Range (in San Bernardino county), and Lower Lake (in Lake county); the remaining five are in the State of Nevada—at Rhodes, Teels Marsh, Columbus, and Fish Lake (in Esmeralda county), and Salt Wells (Carson Lake, Churchill county).

COMPOSITION OF CRUDE BORAX FROM THE MARSHES.

Borax was first accidentally discovered in California, in 1856, by Dr. John A. Veatch, since which time the different deposits mentioned have been developed, and the available supply is practically unlimited, and is solely regulated by the demand. The exports of borax from America have increased very greatly of late years, and, to a large extent, have taken the place of the Italian product.

Commercially, borax is valued by evaporating to dryness a known weight of the sample with hydrochloric acid, and estimating the chloride volumetrically in the residue with silver nitrate. Any chloride present in the sample as impurity is estimated separately and allowed for, the percentage of borax being calculated from the equation

$$Na_2B_4O_7+2HCl+5H_2O=2NaCl+4H_3BO_3.$$

Properties.—Borax forms two varieties of crystals, (1) the *decahydrate*, which is produced by allowing solutions of borax to crystallise by cooling down to the ordinary temperature; (2) *octahedral borax*, which is a pentahydrate which separates out when the solution is allowed to crystallise above 50°.

1. *Ordinary or prismatic borax* $Na_2B_4O_7,10H_2O$ forms large transparent monoclinic prisms with truncated lateral edges. They effloresce when exposed to the air, have a rather sweet cooling alkaline taste, and a sp.gr. of 1·75. When heated they melt in their water of crystallisation, swell up, and leave a porous spongy mass, called burnt or calcined borax (*borax usta*), and fuse at a red heat to a colourless anhydrous glass (vitrified borax) with a sp.gr. of 2·36, which gradually absorbs water from the air, reforming prismatic borax. At 62° the decahydrate undergoes transition into the pentahydrate $Na_2B_4O_7,5H_2O$ At 130° the salt contains 3 mols. H_2O, at 150°, 2 mols. H_2O; at 180°, 1 mol. H_2O. At 318° it becomes anhydrous.

When borax is distilled with methyl alcohol, about 50 p.c. of the boric acid comes over fairly readily, and on longer treatment nearly 60 p.c. From the liquor remaining in the flask, crystals of $NaBO_2,5CH_3OH$ separate (Polenske, Analyst, 1902, 34).

Borax dissolves in water, but is insoluble in alcohol. The aqueous solution has an alkaline reaction, and changes the colour of an alcoholic solution of turmeric to brown; a small quantity of a mineral acid restores the original yellow colour, but a larger quantity liberates boric acid in sufficient quantity to produce the characteristic brown colouration. The following determinations of its solubility are those of Horn and van Wagener (Amer. Chem. J. 1903, 346):—

t°	100 grams H_2O dissolve of anhydrous borax $Na_2B_4O_7$	t°	100 grams H_2O dissolve of anhydrous borax $Na_2B_4O_7$
5°	1·3 gram	60°	19·9 grams
21·5°	2·8	70°	24·4
30°	3·9	80°	31·4
45°	8·1	90°	40·8
50°	10·5	100°	52·3
55°	14·2		

For conditions determining the crystallisation of borax, *see* Levi and Castellani (Gazz. chim. ital. 1901, 40, i. 138).

At the temperature of 27°, borax solutions hold 1 lb. of borax to the imperial gallon, and have a sp.gr. of 1·500, or 10° Tw. The general crystallising strength is 1·160 sp.gr., or 32° Tw., when the solution holds [illegible] lbs. of borax to the gallon, crystallisation commencing at 65·5°.

Borax is easily decomposed by acids. *Hydrochloric acid* leaves, on evaporation, sodium chloride and free boric acid. *Carbonic acid* is absorbed by a solution of borax from the air, and no borax is precipitated on the addition of alcohol. Saturated with *sulphuretted hydrogen* and mixed with alcohol, the liquid separates on the addition of ether into two layers, the lower containing sodium sulphide, the upper free boric acid.

It forms double salts with arsenious acid of the empirical formula.

$$3Na_2O{\cdot}6B_2O_3{\cdot}5As_2O_3+10Aq$$

(Schweizer, J. 1850, 257). With *sodium fluoride* it forms sodium fluorborate. When 1 pt. tartaric acid is mixed with 2 pts. of a hot solution of borax, boric acid separates out on cooling. If the tartaric acid be increased, the separation of boric acid likewise increases up to a certain point, after which it diminishes, and ultimately is no longer separated. *Acid tartrate of potassium* forms a double salt with borax. *Silicic acid* is insoluble, or nearly so, in solutions of borax.

Benzoic, tartaric, and gallic acids dissolve more readily in borax than in water. Many fatty acids and resins dissolve as readily in borax as in alkaline leys, the borax behaving like a mixture of boric acid and free soda.

Borax fuses at 730° and readily dissolves and unites with metallic oxides, forming a fusible glass of a double salt, which property renders it of great use in soldering and in metallurgical operations and in blowpipe analysis, the glasses thus formed often exhibiting characteristic colours. It is used also in the preparation of easily fusible glass fluxes for enamels and glazes.

2. *Octahedral borax* $Na_2B_4O_7,5H_2O$ is obtained by allowing a saturated solution of borax to cool down to about 60° in a warm place and removing the crystals.

The crystals are regular, transparent octahedra, harder than the ordinary borax. They have a conchoidal fracture and a sp.gr. of 1·8. They do not change in dry air, but absorb moisture very readily and become prismatic. They fuse more readily than the prismatic crystals, and with less intumescence, and without splitting. Octahedral borax is therefore better adapted for soldering and as a flux than common borax, and the smaller quantity of water (a difference of 17 p.c.) diminishes the cost of transport. The prismatic variety is, however, generally preferred, probably because it is cheaper weight for weight.

The commonest impurities in borax are sodium carbonate and small quantities of chlorides and sulphates of sodium, calcium, and magnesium. It is occasionally adulterated with earthy matters, alum, and sodium chloride. It should dissolve in two parts of boiling water and should not effervesce with acids. The aqueous solution should not be rendered turbid when treated with an alkali, or with barium chloride or silver nitrate in presence of nitric acid.

The manufacture of borax from boric acid.

This industry is chiefly associated with the production from the Tuscan lagoons. The crude acid, packed in large casks weighing about 13 cwts., on arrival at the borax works is first of all manipulated in the casks themselves. For this purpose, the cask is placed on what is termed a stillage, the head taken off, the acid loosened with a spade and treated with small quantities of water for the purpose of washing out the sulphates of ammonia and magnesia, which, on account of their greater solubility, easily separate from the less soluble boric acid, the washings being used for the recovery of the ammonia and magnesia they contain, whilst the acid, which formerly contained 83·46 p.c. $B_2O_33Aq.$ or equivalent to 128·5 p.c. borax, is brought up to a strength of 96 67 p.c $B_2O_33Aq.$ or equivalent to 148·87 p.c. borax. The acid, after draining for twenty-four hours, is then placed in wicker baskets and transferred to the saturators. These are made of wrought-iron ⅜ plates, having a diameter of 10 feet, egg-ended, height 9 feet 6 inches, provided with hopper and swivel discharge, still head, inspection glasses, run-off stop-cocks, and connected by steam pipes with a perforated iron coil in the bottom of the pan for the purpose of boiling the borax liquor with injected steam. There is also a manhole with movable cover. When the saturator is ready for charging, liquor is pumped in to the height of 4 feet, or 2300 gallons, which is then boiled with steam and soda ash. Anhydrous sodium carbonate is then added, about 23 cwts. being generally required to 60 cwts. of acid. When the soda ash is all dissolved, the manhole lid is placed on, and the boric acid is put in by degrees through a hopper, half a hundredweight at a time. At each addition of acid a brisk ebullition of carbonic acid takes place, which passes along the still head, and after being deprived of its ammonia may be utilised for making bicarbonate of soda.

After the saturator has received its charge of soda ash and acid, the liquor is thoroughly boiled for five hours and allowed to settle, in order that the solid impurities may subside. This generally occupies from eight to ten hours, after which the liquor is run into large wrought-iron vats 12 feet long, 6 feet wide, 4 feet deep, into which the wires made of iron, technically called 'straps,' are suspended over bars of wood laid across the top of the vat. The liquor on cooling crystallises on the wires, sides, and bottom of the vat, and when the temperature has fallen to 26° (80°F.), the liquor is siphoned off from the vats, and men get in, and, by the aid of iron bars terminating in a chiselled end, first remove the crystallised borax from the straps, then cut up the borax crystallising on the bottom of the vat, and lastly knock down the sides. This borax is not of sufficient purity for the market, and is, therefore, subjected to a second refining, and, if necessary, bleaching. For this purpose a series of pans, called refining pans, are employed; they are also of wrought iron, circular, 9 feet diameter, egg-ended, 8 feet deep open at the top and provided with cradles of wrought iron perforated with holes, suspended by iron chains from a patent block overhead in such a manner as to be raised or lowered in the pans as required. The pans are boiled with steam issuing from a perforated pipe in the bottom. They are first half filled with water, or some of the clearest liquor from a previous operation, and when the liquor is boiling crude borax is thrown into the cradle and allowed to dissolve. The right amount of borax is tested by means of the Twaddell hydrometer, which should read 30° when the liquor is of the required strength. About 5 cwts. of sodium carbonate is added, and a little chloride of lime, and the whole thoroughly boiled. The saturated liquor is then allowed to settle in the pans for ten hours, covers being placed on them to prevent the liquor chilling; the pans are run off into vats of similar size and shape to those employed in the first process, and the borax allowed to crystallise, which takes six days. Upon the expiration of that time, the liquor is siphoned off to a well, made by sinking a wrought-iron tank in the ground below the level of the vats, and, if impure, is pumped up to the refining pans to be used over again, and if sufficiently pure is pumped to boiling-down pans, to be concentrated to such a degree as to yield a further crop of borax.

The liquors from the first vats are also pumped to the boiling-down pans, where they likewise undergo a process of concentration. These boiling-down pans are made of wrought iron, and are capable of holding about 4000 gallons. They are provided with dry-steam coils, and are superior to other means of concentration from the fact that they are completely under control, and the evaporation of the liquor can be regulated as fast or as slow as may be necessary. The liquors in these pans are concentrated until they reach a sp.gr. of 1·300, or 60° Tw., when they are run off into vats to yield first a crop of borax, and then upon reaching a temperature of 80°F. they are siphoned off into other vats, where they yield a crop of Glauber salts, or sodium sulphate, after which the liquors, being rich in sodium carbonate, are used again in the saturators for making up a fresh batch of borax with acid and soda ash. The mother liquors, strong in common salt and weak in sodium carbonate, are further concentrated in jacketed pans, where, on continued boiling, the salt falls to the bottom, is collected by means of rakes, and fished out with perforated scoops provided with long wooden handles, and the salt is ladled into iron baskets set over the pans and allowed to drain. By this means all the salts contained in the soda ash and boric acid are saved, and nothing is run to waste.

The washings from the boric acid in the first process, containing the ammonium sulphate and magnesium sulphate, are collected together, and placed in a wrought-iron still provided with a dry-steam coil. The requisite amount of sodium carbonate is then added, and the ammonium carbonate is distilled off, yielding a highly concentrated and very pure carbonate of ammonia liquor, which is either sold in that state or utilised for making the purest volcanic ammonia salts.

The borax from the refined vats, consisting of the straps and sides, is carried to the packing room, there to be picked, selected, and packed in casks, whilst the borax bottoms, not being in the form of merchantable borax, are refined again.

Manufacture of borax from borate of lime.

The mineral is first crushed in a stone breaker, the size of jaw being 8 inches and known as No. 4, easily capable of crushing 12 tons in twenty-four hours. As the mineral passes through it is taken up by an elevator and run through millstones, 30 inches in diameter, and placed by the side of the crusher. There are two pairs, one grinding fresh ore and the other grinding the tailings. The millstones deliver the powdered ore into another elevator, which passes it through a bolting or sifting machine, 10 feet long and 30 inches in diameter, having octagonal sides, the bolting cloth being of silk known as No. 8. As considerable fine and impalpable dust arises from the sifting, it is kept down by means of an exhaust fan blowing the dust into a dust room. The fine mineral is conveyed by means of an Archimedean screw and elevator into bins, each holding a certain quantity and placed over the saturators. These are wrought-iron tanks capable of holding a charge of 2500 gallons, and provided with suitable agitators and either dry or wet steam coils, the bottom of the saturators being connected by 3-inch wrought-iron valves and pipes to a powerful pump for the purpose of removing the contents of the saturator when desired. The saturators are grouped together in sets of four for facilitating the lixiviation of the contents by means of repeated washings, after the first decomposition of the mineral. The saturators, as in the case of the manufacture of borax from boric acid, are first charged with liquor and brought to the boil; a charge of soda ash, usually about 30 cwts., being put in, which is sufficient to decompose three tons of the borate of lime which is gradually added after the soda ash is all dissolved. The soda ash gradually but completely decomposes the sesquiborate forming calcium carbonate, borate of soda, and biborate of soda:

$$Ca_2B_6O_{11}+2Na_2CO_3 = 2CaCO_3+Na_2B_4O_7+2NaBO_2.$$

After boiling five hours the steam and agitators are stopped, and the muddy liquor allowed to settle for ten hours, after which time the clear supernatant liquor is run off to vats to crystallise, and the residue is again washed with weaker liquor from the saturator previously washed, the operation being repeated of boiling and washing with the gradually weaker liquors from the other saturators in rotation. By the time the mud has received eight washings, the last being with water, the whole of the borax will have been removed, and the chalk which is left is then pumped through an iron filter press, which completely presses out the remaining weak liquor and leaves the chalk in a solid cake, which is generally thrown to one side, being too impure for any purpose. The first liquor run to the vats contains the biborate and borate of soda, together with carbonate and sulphate of soda in solution. The biborate of soda or borax crystallises out after cooling in the vats for about six days, leaving the borate of soda in solution. The liquor is then siphoned off into the well and pumped to the boiling-down pans, where it undergoes the process of concentration until it reaches a sp.gr. of 1·350 to 1·400 (70° to 80° Tw.), when it is run off into vats and allowed to throw a further crop of borax. The mother liquor is now of a syrupy consistence, and is pumped into a decomposing tank, where carbon dioxide is blown through it. The following decomposition takes place:— a finely divided state, whilst the sodium carbonate remains in solution, and can be used over again in the saturators for the first operation. The refining of the borax from the first process is the same as that employed in the boric acid process, and therefore need not be further described. The only precaution necessary is the addition of a little bicarbonate of soda in the pans to decompose any borate of soda that might be associated with the borax. Three tons of borate of lime produce 2 tons of borax and 1 ton of borax in the state of metaborate of soda. Metaborate of soda may be formed by mixing the concentrated solutions of borax and caustic soda together in their equivalent quantities, and evaporating to 70° Tw.:

$$Na_2B_4O_7+2NaHO=4NaBO_2+H_2O$$

from which the metaborate of soda crystallises in needle-shaped crystals having the formula $NaBO_2,4H_2O$.

100 parts of metaborate of soda, when decomposed by carbonic acid, produce 65·6 parts of borax and 34·4 parts of sodium carbonate; about 30 cwts. of borate of soda thus produce 20 cwts. of borax.

The following process is used by Masson, Gembloux, and Tillière, Brussels. An ammonium salt is treated with lime in a distilling column and the ammonia set free is passed into water contained in a digester, and the digester is then charged with carbonic or sulphurous acid. The digester is gently heated and pandermite is introduced. It is then closed and more strongly heated for several hours, whilst the contents are mechanically agitated and are transferred, when the action is complete, to filter presses, whence the liquor passes to a reaction chamber where it is agitated with sodium chloride and, after addition of a little ammonia, is discharged into crystallisers. After removal of the borax which crystallises out, the mother liquor is used instead of water in the succeeding operation. After several operations, the mother liquor requires a special treatment.

In this process, an ammonium biborate is first obtained by the ammonium carbonate treatment of calcium borate, and from this ammonium salt borax is obtained by double decomposition with sodium chloride. Boronatrocalcite may be used instead of pandermite if the process is slightly modified.

Manufacture of borax from ulexite.

Borax is manufactured from this mineral at the various deposits, and also in England, France, and Germany, to which places it is exported from Chile and California, selected and packed in sacks.

The first operation consists in reducing the material to a state of fine division, and for this purpose a mill is used so constructed as to tear the borate to pieces instead of grinding it, which, owing to its fibrous silky nature, is found preferable.

The borate is then mixed with its proper proportion of soda ash and bicarbonate of soda, or soda ash and boric acid, having regard to the fact that, if associated with much gypsum, a proportionate additional allowance of soda ash must be made, as the gypsum decomposes the and chalk. The composition of ulexite being $Ca_2B_6O_{11}\cdot Na_2B_4O_7$, it requires one equivalent of bicarbonate of soda and one equivalent of carbonate of soda to decompose it:

$$2(Ca_2B_6O_{11}Na_2B_4O_7)+2NaHCO_3+2Na_2CO_3$$
$$=5Na_2B_4O_7+4CaCO_3+H_2O.$$

These ingredients are all mixed together in the dry state. The process adopted is similar to the processes already described—namely, that of first boiling the liquor in the saturator, then gradually adding the crude material, boiling, settling, lixiviating.

100 parts of the ulexite, testing 43 p.c. boric acid, require 10 parts of bicarbonate of soda and 12 parts of carbonate of soda, for its conversion into 117 parts of borax.

Manufacture of borax from crude borax.

This branch of the industry is generally carried on at the borax marsh. It may be desirable to give a description of the Saline Valley, Inyo county, California, where the most extensive deposit of natural borax exists in North America, before entering into the details of refining.

The valley, situated on the eastern slope of the Sierra Nevada Mountains, 11 miles from the Carson and Colorado railroad, is 18 miles long and 12 miles wide, surrounded with mountainous hills which afford no outlet, and therefore the valley may be said to be the bottom of a dried-up lake. At the point of deepest depression an area of over 1000 acres is covered with crude borax from 6 to 18 inches in depth. The colour of the crude material as it lies upon the level plain is a peculiar grey yellow. The borax in Saline Valley is mixed with sand, which is volcanic ash and decomposed lime rock, sodium sulphate, sodium carbonate, and sodium chloride. The surrounding hills consist of granite, marble, dolomite, black lava, and felspar. The composition of the crude material varies in strength from 10 p.c. of borax up to 90 p.c., whilst in some places on the marsh—under a crust composed of sodium sulphate, sodium carbonate, and common salt—beds of tincal, or large crystals of borax, some two feet in thickness, are found; whilst below the tincal there is a strong saturated yellowish liquor containing 1 lb. of borax to the gallon. All the manipulation that is required is to shovel off the surface of the marsh to a depth of 18 inches and cart the material to long hemispherical wrought iron pans set on arches of stone, fired beneath with wood fuel obtained in the neighbourhood. The pans are charged with water, and the crude material thrown in and vigorously stirred with long poles, until, with the aid of heat, all the soluble salts are dissolved. The fires are then withdrawn, and the contents of the pans allowed to settle for ten hours, when the liquor is drawn off into vats, where the borax crystallises out. The mother liquor after six days is drawn off, and the borax is taken out and packed into sacks for shipment.

Borax and boric acid are applied in the manufacturing industries as follows:—

Brick and tile makers. Glazed surfaces.

Candle makers. Preparation of wicks.

Cement. Making the finest kinds, which take a polish.

China and earthenware. In preparing a frit used for glazing what is technically termed 'biscuit ware' in pottery of all descriptions.

Colour makers. In preparing Guignet's green and borate of manganese (a drier).

Coppersmiths. In brazing.

Druggists. Pharmaceutical preparations.

Enamelled iron. An enamelled coating to cast and wrought iron.

Glass. Making pastes and as an ingredient.

Hat makers. Dissolving shellac for a stiffener.

Ironsmiths. In welding.

Jewellers. In soldering. (Ancient name for borax, 'chrysocolla,' gold-glue.)

Laundresses. As a starch-glaze for linen.

Paper makers. Superfine note and highly glazed paper and cards.

Pork packers. Curing and preserving hams and bacon.

Safe makers. Lining safes to resist fire.

Soap makers. As an emollient.

Tanners. Dressing leather.

Textile manufacturers. Solvent-bleach; mordant; fireproofer.

Timber merchants. In preparation of hard from soft wood.

Zinc borate is formed by adding borax in slight excess to a solution of a zinc salt. For conditions of formation, *see* Borchers (Zeitsch. anorg. Chem. 1910, 68, 269).

Perborates are salts of the acid HBO_3 or

$$HO\cdot B\begin{matrix}\diagup O\\ \mid\\ \diagdown O\end{matrix}$$

which has not been prepared in the free state on account of its instability. The alkali and alkaline earth salts are soluble in water and have an alkaline reaction. They behave in solution like mixtures of borates with hydrogen peroxide; the active oxygen being liberated by heat, by acidifying the solution, or by large dilution. Oxydases, reductases, and manganese dioxide cause them to give up the whole of their reactive oxygen. They convert chromic acid and molybdates into perchromic acid and yellow permolybdates. They readily oxidise protoxides and their salts into higher oxides, but do not always form perborates with them. Ferrous, mercurous, manganous, and lead salts yield higher oxides; the salts of other metals yield perborates of an indefinite or basic composition. Perborates of the alkali metals may be obtained by careful precipitation of solutions of alkali borates with alcohol in the presence of hydrogen peroxide.

Ammonium perborate NH_4BO_3,H_2O is the best characterised of the several perborates resulting from the action of ammonia and hydrogen peroxide on ammonium borate. It contains 16·84 p.c. of active oxygen.

Potassium biperborate $KB_2O_5,2H_2O$ is obtained by the action of hydrogen peroxide on potassium borate.

Sodium perborate $NaBO_3,4H_2O$. When 248 grams of boric acid are mixed with 78 grams of sodium peroxide and added gradually to 2 litres of cold water, the mixture dissolves at first, but later a crystalline substance separates out which may be filtered off and dried. This substance, which has a composition $Na_2B_4O_8,10H_2O$, is called '*perborax*,' and is soluble in water to the extent of 42 grams per litre at 11°. When one-half of its sodium is displaced by a mineral acid, a crystalline precipitate of *sodium*

perborate, $\mathrm{NaO{\cdot}O{\cdot}B}\left\langle\begin{matrix}\mathrm{O}\\|\\\mathrm{O}\end{matrix}\right. + 4\mathrm{H_2O}$ separates out. This is a very stable substance, and can be preserved indefinitely at ordinary temperatures. It dissolves readily with slight decomposition in water at 50°–60°, and a vigorous ebullition of oxygen takes place at 100°. The cold aqueous solution possesses all the properties of hydrogen peroxide. When powdered sodium perborate is added gradually to 50 p.c. sulphuric acid, and the solution filtered through guncotton a very strong (150–200 vols.) solution of hydrogen peroxide is obtained.

For the constitution of the perborates, *see* Bosshard and Zwicky, Zeitsch. angew. Chem. 1912, 25, 993.

ORGANIC DERIVATIVES OF BORIC ACID.

Aniline borate, and compounds of *piperidine, conine, tetrahydroquinoline*, and *tetramethylammonium hydroxide*, have been prepared by L. & T. Spiegel (J. Soc. Chem. Ind. 1905, 103). The *menthyl* and *bornyl* esters are readily prepared by heating menthol and borneol with boric acid, xylene being used as a medium in the latter case (Verein Chininfabriken, Zimmer & Co., Eng. Pat. 11574, 1906).

Ethyl borosalicylate, or '*boryl*,' is prepared by boiling together 62 grams of boric acid and 138 grams of salicylic acid with 200 c.c. of water. The resulting borosalicylic acid is esterified by adding 60 grams of 95 p.c. alcohol and heating with 40 grams of sulphuric acid. It forms needle-shaped crystals which are more convenient than oil of winter-green for many medicinal purposes (Cohn, Chem Zentr. 1911, 1; 1806).

Zinc boropicrate, or '*chrysyl*,' is the product obtained by boiling together boric and picric acids, and saturating the mixture with zinc oxide. It is a yellow powder used as a medicinal antiseptic (Monteil, J. Soc. Chem. Ind. 1908, 354).

Phenyl borate $\mathrm{B(OPh)_3}$, *diphenylboric acid* $\mathrm{B(OH)(OPh)_2}$, *m-tolyl borate* $\mathrm{B(OC_6H_4Me)_3}$, and *β-naphthyl borate* $\mathrm{B(C_{10}H_7O)_3}$, together with several other aryl halogen boron compounds and *p-borobenzoic acid* $\mathrm{CO_2H{\cdot}C_6H_4{\cdot}B(OH)_2}$, have been prepared by Michaelis (Annalen, 315, 19–43).

Borcitrates are valuable as remedies in cases of kidney disease and urinary calculi. Their solvent power for urates and phosphates is greater than that of lithium benzoate. The diborocitrates are best adapted for the purpose. The following are known:—

Magnesium triborocitrate $\mathrm{(C_6H_5O_7)_2Mg_3(B_3H_3O_6)_2}$
" diborocitrate $\mathrm{(C_6H_5O_7)_2Mg_3(B_2H_2O_4)_2}$
" monoborocitrate $\mathrm{(C_6H_5O_7)_2Mg(BHO_2)}$

Lithium, potassium, sodium, and ammonium, mono-, di-, and tri-borocitrates of similar constitution have been prepared. Iron salts have also been obtained containing respectively 8 and 16 p.c. of iron by acting on sodium di- and mono-borocitrate with ferric hydrate (Scheile, Pharm. J. [3] 11, 389).

The magnesium compounds possess strong antiseptic properties.

DETECTION AND ESTIMATION OF BORON.

Boron almost always occurs in the form of boric acid. When the acid is in the free state it can readily be recognised by the green colour which it gives to the flame, and by its action upon turmeric.

Turmeric paper, when moistened with a solution of boric acid and dried, acquires a cherry-red colour, which is changed to olive-green on moistening with an alkali. Acid solutions of zirconic, tantalic, niobic, and molybdic acids also colour turmeric brown. Cassal and Gerrans (Chem. News, 1903, 27) find that the sensitiveness is greatly increased by the addition of oxalic acid, and base a colorimetric method of estimation of boric acid on this reaction.

The green colour imparted to flame is a very delicate test for boron (according to Merz, J. pr. Chem. 80, 487, 1 part in 1400 may be detected by means of it). It is, however, to be noted that salts of copper likewise colour flame green, as well as certain compounds of chlorine and barium and thallium. When the boric acid is combined with a base the compound in the state of powder is decomposed by means of sulphuric acid, and the boric acid extracted by alcohol. Compounds not decomposed by sulphuric acid are fused with potash and digested with alcohol and sulphuric acid.

The presence of boron in minerals may be detected by mixing the mineral in powder with a flux containing 1 part fluor-spar to 4½ parts hydrogen potassium sulphate, made into a paste with water, and heating the mixture in the inner blowpipe flame, when boron chloride is given off which tinges the flame green; or by mixing the suspected substance with fluor-spar moistening with concentrated sulphuric acid, and passing the escaping gas through a tube drawn to a fine point into the non-luminous bunsen flame, which it colours green.

The spectrum of boron shows three bright lines in the green and one in the blue. Hartley finds in the spectra of boric acid and borax the lines λ3450·3, λ2497, and λ2496·3, which he considers characteristic of boron (Roy. Soc. Proc. 35, 301). (For the measurement of the intensity of these bands, *v.* Lecoq de Boisbaudran, Compt. rend. 76, 883.)

The quantitative estimation of boron is difficult, as all borates are soluble to some extent in water and alcohol, and boric acid cannot be heated without loss in contact with water.

One method of direct determination is to precipitate the boron as potassium borofluoride, which is quite insoluble in alcohol (Berzelius, Lehrbuch, 3 ed. 10, 84; Stromeyer, Annalen, 100, 82; Thaddeeff, J. Soc. Chem. Ind. 1898, 953). This method has been adversely criticised by Gooch and others, and has been almost entirely superseded.

The most trustworthy method of estimating boron is due to Gooch. If the boron is not present as boric acid, it is brought into that state by heating for some hours in a sealed tube with nitric acid. The resulting solution is repeatedly distilled with methyl alcohol, the boric acid passing over in the vapour. The distillate is then treated with an exactly weighed excess of pure lime, transferred to a platinum crucible, evaporated to dryness on the water-bath and strongly heated. The increase in weight represents the boric anhydride.

Volumetrically, boric acid may be estimated accurately by titration with caustic soda, using phenolphthalein as indicator, if about one-third of the bulk of the solution of glycerol is added (Thomson, J. Soc. Chem. Ind. 1894, 432; *v.* also ANALYSIS).

A freshly prepared solution of manna may replace the glycerol (Iles, Analyst, 1918, 43, 3257). Tropaolin O (sodium-*p*-benzene-azoresorcinol sulphonate) may be used for the direct titration of boric acid without the addition of mannitol or glycerol. Soda is first neutralised by standard hydrochloric acid in the presence of methyl orange or *p*-nitrophenol, excess of sodium chloride not materially interfering with the accuracy of the method. The indicator is introduced as 0·04 p.c. solution (Prideaux, Zeitsch. anorg. Chem. 1913, 83, 362).

Boron may be estimated indirectly by digesting a weighed quantity of the finely divided compound in a platinum vessel with hydrofluoric acid, and then with concentrated sulphuric acid. On warming gently, the boron present is expelled as fluoride, and after driving off the excess of sulphuric acid, the quantity of bases in the residue is determined. Their weight, deducted from the weight of the original substance, gives the quantity of boric anhydride.

When combined with potash or soda, boric acid may be determined by evaporating the solution of the previously weighed salt with hydrochloric acid, and determining the chlorine in the dry residue (Schweizer, Pharm. Centr. 1850, 372; J. 1850, 590)

Crude boric acid (Italian) is usually valued by determining the water and the substances insoluble in alcohol, and taking the rest as being boric acid. According to Zschimmer (Chem. Zentr. 1901, [5] 44, and [7] 67), the results are inaccurate, on account of the water not being completely driven off under the conditions used (2 hours drying at 45° and 2 hours in desiccator).

Boron is best estimated in the presence of silicates; *e.g.* in tourmaline, by the method of G. W. Sargent, who has submitted all the processes published to examination and criticism (J. Amer. Chem. Soc. 1899, 858–888). The mineral is fused with alkali carbonates, and, after lixiviating and acidifying, the boric acid is volatilised from the solution as the methyl ester. A convenient form of apparatus for performing this operation is described. The boric ester is subsequently hydrolysed by a weighed quantity of pure lime, and estimated by Gooch's process.

A method for its estimation in insoluble silicates is also given by Wherry and Chapin (J. Amer. Chem. Soc. 1908, 1687–1701).

A solution of boric acid produces no change of colour in solutions of helianthin, tropæolin, and methyl orange, but a drop of hydrochloric acid immediately changes the yellow colour into red. Borax may thus be titrated by the stronger acids (A. Joly, Compt. rend. 100, 103).

(For the estimation of boric acid in mineral waters, *v.* Fresenius, Zeitsch. anal. Chem. 25, 202.)

To detect boric acid in milk, baryta is added to 100 c.c. of milk till alkaline. After incineration, the ash is dissolved in a little strong hydrochloric acid, evaporated to dryness, and a solution of turmeric with a drop of dilute hydrochloric acid added, and the solution evaporated on a water-bath. 0·001 c.c. boric acid gives a distinct colour to turmeric in this manner (J. Soc. Chem. Ind. 1887, 563).

Boric acid may be rapidly determined in butter by stirring a weighed quantity with a known volume of warm standard sulphuric acid till melted, allowing to settle, and titrating a portion of the aqueous part with caustic soda, using phenolphthalein. The pink colour appears when the sulphuric acid has been neutralised; glycerol is then added and caustic soda run in till the colour reappears. The second titration represents the boric acid (Richmond and Harrison, Analyst, 1902, 179).

BORONATROCALCITE. An early name (G. L. Ulex, 1849) for the mineral ulexite, a hydrated borate of sodium and calcium $NaCaB_5O_9,8H_2O$. Most of the natural borates exported from South America (Chile, Bolivia, and Argentina) are of this species; it is also abundant in the borate deposits of California and Nevada. L. J. S.

BOROVERTIN *v.* SYNTHETIC DRUGS.

BORSALYL. Trade name for sodium borosalicylate.

BORYL. Trade name for ethyl borosalicylate. Prepared by boiling together solutions of boric acid and salicylic acid and esterifying by the addition of alcohol and sulphuric acid. Needle-shaped crystals. Used in medicine as a substitute for ethyl salicylate (Monteil, J. Soc. Chem. Ind. 1908, 354).

BOSCH. An inferior butter prepared in Holland. The term is sometimes used as synonymous with margarine (*q.v.*).

BOSTONITE. A trade name formerly in use for the Canadian serpentine-asbestos (*v.* ASBESTOS). L. J. S.

BOSWELLIA SERRATA (Roxb.) or **GUGAL.** The gum of this plant (ord. *Burseraceæ*) is used as an incense. It is often confounded with bdellium and olibanum (Dymock Pharm. J. [3] 7, 190).

BOTANY BAY RESIN *v.* BALSAMS.

BOTRYOLITE *v.* CALCIUM.

BOTTLE-NOSE OIL. An oil obtained from the bottle-nosed whale, closely resembling sperm oil; its sp.gr. varies from 0·876 to 0·880 (Allen, J. Soc. Chem. Ind. 2, 53).

BOUILLON NOIR. *Ferric acetate* (*v.* ACETIC ACID).

BOU-NEFA. The root bark of *Thapsia garganica* (Linn.), an umbelliferous plant growing in the South of Europe and Algeria. It contains a resin used as a medicine in France.

BOURNEENE or **VALERENE.** A liquid hydrocarbon isomeric with oil of turpentine, secreted by the *Dryobalanops aromatica* (Gaertr.), and holding in solution borneol or Borneo camphor. According to Wallach (Annalen, 230, 225; Chem. Soc. Trans. [2] 50, 70), it is a mixture of the decomposition products of camphene.

BOURNONITE. Sulphantimonate of copper and lead $CuPbSbS_3$, crystallising in tabular orthorhombic crystals; these are frequently twinned and show re-entrant angles at the edges, hence the names 'cogwheel-ore' and 'wheel-ore.' It is found in Cornwall, Harz, &c.; and in Bolivia. It sometimes occurs in sufficient abundance to be used as an ore of copper and lead. L. J. S.

BOVEY COAL *v.* FUEL.

BRAGA. An alcoholic beverage used in Roumania, prepared by the fermentation of millet. The seed is boiled with about 12 times its weight of water for 14 hours, the resulting viscous mass cooled, stirred with water and allowed to ferment. The liquid is filtered and mixed with water, when it is ready for sale. It is somewhat sweet, and contains about 1·3 p c. of alcohol by weight.

BRAIN'S POWDER. An explosive consisting of 60 parts of a mixture of potassium chlorate, potassium nitrate, wood charcoal, and oak sawdust saturated with 40 parts of trinitroglycerine (Wagner's Jahr. 22, 470).

BRAN. The name given to the coarser fragments, consisting mainly of the outer layers, which are produced in the grinding or milling of cereal or other seeds. When the term is used without any descriptive adjective, the product from wheat is usually understood; but maize, barley, buckwheat, rye, oats, even peas and earth nuts, when milled, yield products which are described as 'bran.'

The following analyses, compiled chiefly from German and American sources, show the general average composition of various 'brans':

—	Water	Protein	Fat	Sol. carbohydrates	Fibre	Ash
Wheat bran, fine	13·2	15·5	4·8	54·0	8·0	4·5
„ „ coarse	13·2	14·3	4·2	52·2	10·2	5·9
„ „ spring wheat	11·5	16·1	4·5	54·5	8·0	5·4
„ „ winter wheat	12·3	16·0	4·0	53·7	8·1	5·9
Rye bran (German)	12·5	16·7	3·1	58·0	5·2	4·5
„ „ (American)	11·6	14·7	2·8	63·8	3·5	3·6
Barley bran	10·5	14·8	3·6	57·6	8·5	5·0
Oat bran	9·6	7·6	2·7	53·8	21·6	5·7
Maize bran	12·5	9·9	3·6	61·5	9·5	3·0
Rice bran	9·7	12·1	8·8	49·9	9·5	10·0
Buckwheat bran, fine	12·0	15·2	4·5	50·0	11·3	7·0
„ „ coarse	15·6	8·0	1·8	34·2	37·6	2·8
Pea bran	11·7	16·8	1·7	46·2	20·1	3·5
Earth nut bran	10·5	21·8	18·1	24·7	19·5	5·4

The digestion coefficients for the constituents of most varieties of bran are low, so that their food value is in general not so high as the analyses would indicate.

The character and composition of the bran from any particular grain is liable to considerable variation, according to the method of milling adopted. As a rule, the less perfectly the corn is ground, the richer is the bran in meal and therefore in feeding value.

It will be noticed that bran is much richer in protein, fat, ash, and fibre than the fine portions of the meal from the same grain.

In the case of wheat, the finer portions of the bran are known as 'middlings' and 'sharps' or 'shorts.' Usually the last term denotes the portions which most nearly resemble bran, while 'middlings' refers to an intermediate product more approximating to flour in composition, though much richer in protein, ash, and fibre.

The processes employed in the milling of wheat, however, are so complex that about 80 or 100 products are separated. For a study of the composition of the various products of a modern roller mill, *see* Clifford Richardson (Bull. No. 4, U.S. Dept. of Agric. Div. of Chemistry, reproduced in part 9, Bull. 13, [1898]). Usually, about 70 to 75 p.c. of the wheat is obtained as flour of various grades, about 20 p.c. as bran, 3 or 4 p.c. as 'shorts,' and the remainder as screenings and loss.

Weinwurm (Oesterr-Ungar. Zeits. Zucker-ind. u. Landw. 1890) found that from Hungarian wheat, 20 p.c. of bran of three degrees of fineness were obtained, possessing the following composition:—

—	Yield p.c.	Water	Composition of dry matter					
			Protein Insol. in dil. acetic acid	Protein Sol. in dil. acetic acid	Fat	Sol. carbohydrates	Fibre	Ash
Fine bran	16	11·35	13·50	3·06	4·54	63·64	8·71	6·55
Medium bran	2	11·55	13·38	2·72	3·96	63·97	9·08	6·89
Coarse bran	2	12·37	13·44	3·17	3·46	62·13	9·79	7·01

Snyder (Studies on Bread and Bread-making at the University of Minnesota, 1901) examined the products from the milling of wheat by the American methods, using a hard Scotch Fife wheat.

The shorts and bran obtained had the following composition:—

	Water	Protein (N×5·7)	Fat	Total carbohydrates	Ash	Acidity
Shorts	8·73	14·87	6·37	65·47	4·56	0·14
Bran	9·99	14·02	4·39	65·54	6·06	0·23

The acidity is expressed in terms of lactic acid.

The carbohydrates of bran have been investigated by Sherman (J. Amer. Chem. Soc. 1897, 19, 291). He found the following average percentages in wheat bran:—

Total soluble carbohydrates calculated as dextrin	7·2 p.c.
Starch	17·7
True pentosans	17·5
Lignin and allied substances	11·6
Cellulose	8·5
Total carbohydrates	62·5

Other investigators — Tollens, Chalmot, Günther and Stone—have found from 22 to 25 p.c. of pentosans in wheat bran, while maize bran contains about 40 p.c.

Girard (Compt. rend. 1897, 124, 926) gives the results of the examination of by-products from wheat—presumably shorts and bran—by a method different from the conventional one.

In estimating the amount of water-soluble matter in products from seeds, he points out the necessity of using ice-cold water, otherwise the enzymes present may act upon the constituents of the seed, and greatly increase the amount of matter soluble in water.

The following are the mean figures calculated from analyses of the by-products from four French wheats :—

Water	Soluble in water	Insoluble in water
14·72	10·63	74·65

The matter soluble in water consisted of—proteids 2·70, carbohydrates 6·16, inorganic matter 1·77. The matter insoluble in water consisted of—gluten 4·55, starch 28·08, nitrogenous woody matter 5·70, fats 3·17, cellulose 30·22, inorganic matter 1·94, loss and undetermined 0·99.

The mineral matter in bran is very high as compared with that in the rest of the seed, being usually between 5 and 6 p.c., whilst that in flour is usually less than 0·5 p.c.

The ash of bran is particularly rich in phosphoric acid, but poor in lime. The following analysis by Wolff gives its usual composition :—

K_2O	Na_2O	MgO	CaO	P_2O_5	SiO_2
24·0	0·6	16·8	4·7	51·8	1·1

There is a widespread belief that bran is particularly well fitted, because of its richness in mineral matter, to supply the needs of animals with reference to the development and nutrition of bone. But from a study of a bone disease among horses and mules in South Africa, it has been deduced that for normal bone nutrition it is necessary that animals be supplied, in their rations, with phosphoric oxide and lime in approximately equal proportions by weight (Ingle, Jour. Comp. Path. and Therapeutics, 1907, March, also Jour. Agric. Science, 1908, 3, 22). From this point of view, bran is particularly ill suited to aid bone development, since it contains an overwhelming preponderance of phosphoric acid over lime, being in the ratio of 100 to 9 in the above analysis, while in some samples it is as high as 100 : 5·5. That bran has an injurious action upon bone nutrition when used in large quantities, is shown by the occurrence of a peculiar bone disease in horses known as 'bran rachitis' or 'millers' horse rickets,' observed in animals fed largely on bran.

The phosphoric acid in bran, however, does not exist entirely as metallic phosphates. According to Patten and Hart (Bull. 250, New York Agric. Expt. Station, 1904) about 68 p.c. of the total phosphorus is extracted by 0·2 p.c. hydrochloric acid solution, and of this, nearly the whole exists as anhydro-oxymethylene diphosphoric acid $C_2H_8P_2O_9$

$$=(OH)_2OPO-CH_2-O-CH_2-OPO(OH)_2$$

a substance first isolated by Posternak (Revue General de Botanique, 1900, 12, 5 and 65; Compt. rend. 1903, 137, 439). In bran, this acid exists in combination with magnesium, calcium, and potassium.

According to more recent views (Anderson, J. Biol. Chem. 1915, 20, 463, 475, 483, and 493; Robinson and Mueller, Biochem. Bull. 1915, 4, 100; Clarke, Chem. Soc. Trans. 1915, 360) the phosphorus in bran is mainly in combination with inositol, the triphosphate $C_6H_{15}O_{15}P_3$ and the hexaphosphate $C_6H_{18}O_{24}O_6$ being the most important. Anderson (*l.c.*) finds that wheat bran contains about 0·1 p.c. of inorganic phosphorus, *i.e.* about 11 p.c. of the total soluble phosphorus.

The free acid, when heated with mineral acids, or with the enzyme-*phytase* (*q.v.*), is hydrolysed, yielding inositol and phosphoric acid $3C_2H_8P_2O_9+3H_2O=C_6H_{12}O_6+6H_3PO_4$.

Bran is largely used as a food for farm animals, but has a weakening effect upon digestion if used in large quantities. It is more suitable as a food for fattening than for working animals. Owing probably to its mechanical action on the bowels, it has a purgative effect. If used largely for milch cows, it tends to make the butter soft. Similarly, large quantities of bran given to fattening animals tend to lower the melting-point of the body-fat. This is an advantage in the production of mutton or beef, but a disadvantage with bacon.

Bran is also largely used in tanning leather. (For a description of the process and of the changes occurring in the fermentation of bran so employed, *see* Wood and Wilcox, J. Soc. Chem. Ind. 1893, 422, and 1897, 510.) H. I.

BRANDY. (*Eau-de-vie*, *Fr.*; *Branntwein*, Ger.) The term 'brandy' is an abbreviation of 'brandy-wine' the original English form of the word, which occurs also in all the Teutonic languages of Northern Europe, and signifies burnt or distilled wine. The latter term (wine) in its widest sense includes the product obtained by fermentation of all natural fruit juices or extracts from grain, and not fermented grape juice only. Old English Acts of Parliament refer to 'brandy' and 'aqua vitæ' made from malted corn, whilst the German word *branntwein* is applied to strong potable spirits generally without implying that such spirit is necessarily derived from wine. At the present time, however, the 'brandy' of commerce is almost universally understood to be a spirit derived exclusively from the grape.

Besides alcohol and water, the principal constituents of brandy are acetic, butyric, œnanthic, and valerianic esters, acetic acid, a small quantity of a volatile oil, and a little fixed acid, tannin, and colouring matter. When new, brandy is colourless, but gradually acquires a yellowish-brown colour by storage in oak casks. The required colour for particular brands is, however, usually obtained by the addition of a solution of caramel or burnt sugar. Genuine brandy of good quality has a sweet mellow ethereal flavour, without any suspicion of the 'fiery' or 'earthy' taste common to inferior or fictitious brandies.

The *bouquet* of brandy depends upon (*a*) the nature and quality of the wine from which it has been produced; (*b*) the conditions under which the wine has been fermented; (*c*) the method of distillation employed; and (*d*) the age of the brandy. The characteristic flavour of brandy is said to be due chiefly to œnanthic ester (ethyl pelargonate), but it varies with the total amount and relative proportions of other volatile constituents present. According to Ordonneau, the peculiar fragrant odour of brandy is due to a very small quantity of a terpene which boils at 178°, and which, on oxidation, gives the characteristic flavour to old brandy.

Over 90 p.c. of the brandy imported into the United Kingdom comes from France, the finest grades being *Cognac* and *Armagnac*, so named from the French towns in which they were originally distilled. But little brandy is now distilled in Cognac itself, the greater part being produced on the brandy farms of the surrounding districts. Other brandies of less value commercially are those of the Midi and the districts of Aude, Gard, Hérault, and Pyrenées Occidentales, commonly known as the 'Trois-six de Montpellier.' Marc brandies are distilled from the fermented 'marc' or refuse of the wine-press as well as from the lees of the wine-casks.

Whilst the term 'Cognac' has by custom come to be used almost as a generic term for 'brandy,' it is, strictly speaking, applicable only to spirits made from wine grown in the Cognac region, which comprises a certain part of the two departments of Charente and Charente Inférieure, also Dordogne and Les Deux-Sévres. A strict delimitation of the Cognac area has been made by the French Government by decree dated 1st May, 1909, and the region is locally subdivided into the Grande or Fine Champagne, the Petite Champagne, the Borderies and the Bois, according to the quality of the wine produced.

The soil of the district is mainly calcareous, and the grape is a small white berry with very acid juice, producing a wine of inferior quality for drinking purposes. (For the extraction and fermentation of the grape juice, *see* WINE.)

As the reputation of the brandies of the Cognac and Armagnac districts depends so much upon their bouquet, they are submitted to slight rectification only, and distillation is therefore usually conducted in a simple 'pot' still by the professional distiller as well as by the farmer. The still, which varies in content from about 150 to 200 gallons, is usually enclosed in brickwork, with only a small bulbous head exposed, and is generally heated by means of a furnace, wood being considered the best fuel. In a few distilleries the stills are heated by steam. Occasionally, a subsidiary vessel, filled with wine and called a 'chauffe-vin,' is attached to the still, and through it the pipe conveying the spirit vapour to the refrigerator passes, heating the wine so that the latter is quickly raised to boiling-point when subsequently passed into the still, thereby effecting a saving of fuel. Two distillations are made, termed 'brouillis' and 'bonne-chauffe,' corresponding respectively with the 'low wines' and 'spirits' of the whiskey distiller.

In some distilleries the finished spirit is produced at one continuous distillation by means of a still described as 'à premier jet.' In this form of still, a vessel is attached to and above the head of the still, and through it the spirit of the first distillation is conveyed. This spirit is again vapourised by the heat of the spirit vapour rising from the still itself on its way to the refrigerator. The spirit produced in this way is not considered so fine as that obtained by the pot still, but it is of higher strength and more suitable for the manufacture of liqueurs.

The quality of the spirit depends greatly on the care with which the distillation process is carried out. The stills should be worked slowly and regularly, the normal time for the complete distillation of a charge being about ten hours.

The quantity of wine used in the process of manufacture is relatively very great, the amount of brandy produced from a given measure being only from 10 to 15 p.c. The strength of the wine varies from 4·5 to 9 p.c. by weight of pure alcohol, or approximately from 10 to 20 p.c. of proof spirit, the average being 6·5 p.c. of alcohol, or 14 p.c. of proof spirit. The finished spirit as run from the still contains about 64 p.c by weight of alcohol, equivalent to a strength of about 25 over-proof. The brandy, as received from the farmers, is blended and diluted in vats, sweetened with cane sugar, slightly coloured with caramel, and filtered (if necessary) into storage vats in which it is matured.

The French Government has by various laws and decrees of the years 1905 to 1909 prohibited the description 'Cognac' to be applied to any mixture of Cognac or other wine spirit, with grain or beet spirit, and has further provided that labels, marks, &c., bearing the word 'Cognac' should signify that the spirit in question is solely the product of the Cognac region (*vide supra*).

The simple pot stills and the modified stills known as 'à premier jet,' above referred to, as being used in the Charente districts, are not suitable for wines having a strong earthy flavour ('terroir') or other undesirable qualities. In such cases, as in the brandies of the Midi, the Rochelle district, and the marc brandies of Burgundy, stills of a more complicated nature are employed, owing to the necessity for a greater degree of rectification. In these the distillation is continuous, and in the Rochelle district and the islands of the N.W. coast, a pot still with a rectifying head, known as the 'Alembic des Iles,' is employed, whilst in the south the distilling column consists of a series of compartments separated by plates or 'plateaux,' connected with taps by means of which it is possible to take off the spirit at a higher or lower strength as desired. These stills are generally heated by direct fire.

Immense quantities of wine are produced in the Midi for conversion into brandy, the grapes of this region being unsuitable for making good wine. This is attributed to the effects of the *Phylloxera*, which devastated the whole of the Charente district in the years 1875–1878. Before this time, most of the brandy exported to the United Kingdom was genuine Cognac, but the destruction of the Charente vineyards stimulated the production of brandy in other parts of France as well as in other countries. The vineyards of the Cognac district were replanted with American stocks, on which Charente vines were grafted, and the result has been highly successful; but in the south of France the vineyards ravaged by the phylloxera were replanted with vines which were not appropriate to the soil, and which yielded wine in great quantity but at the sacrifice of good quality. Hence the use of the rectifying stills in the Midi and the large quantity of brandy produced. Most of this is consumed in France. The spirit derived from diseased or unsound wines is highly rectified and used for industrial purposes. The cheapness of wine, therefore, affords little or no inducement to the distillers of the Midi to use beet or grain as the raw material for the production of their brandies.

The relative values of the spirits above mentioned may be gathered from the average prices per proof gallon in 1909, which just before the war (1914) were from 7*s.* 6*d.* for brandy of the best Cognac district (Champagne) to 3*s.* for Bois brandy, the cheapest in the Cognac district, whilst Midi brandy was 2*s.*, and grain and beet spirit about 1*s.* 3*d.* (f. o. b.) per proof gallon.

Marc brandies or *eaux-de-vie de marc* are, as the name implies, derived from the marc or refuse of the grapes after the juice has been extracted. They have a strong earthy flavour, and usually are very rich in secondary products. They are therefore often added to other wine spirits to impart the brandy character, or admixed with neutral spirit from grain, beet, &c., in the preparation of fictitious brandies.

Algerian brandy is of high quality, resembling Cognac, and is generally sent to France, whence considerable quantities are reshipped from the Charente district to the United Kingdom.

Brandies are produced in most other wine-growing countries, especially when, owing to over-production of wine, or some defect in its quality, it becomes more profitable to convert it into spirit than to dispose of it as 'wine.' The most important commercially are from Spain, Egypt, Germany, South Africa, and Australia, but the quantities of these exported to the United Kingdom are small as compared with French brandies.

The Spanish brandies are similar in character to the French, and command a high price. Genuine Egyptian brandy is made from fresh grapes, although the wine grape is not cultivated in Egypt. The grapes are imported into Alexandria from Southern Turkey, Greece, Cyprus, and Asia Minor, and there made into wine from which the brandy is distilled. They have a strong characteristic flavour, much appreciated by consumers of the cheaper brandies. Spurious brandies of doubtful origin, but described as 'Egyptian,' are also on the market. They are probably made from the currant grape grown in Greece and Asia Minor, and have no right to the title of 'Egyptian,' beyond the fact that they are exported *viâ* Alexandria. Increasing quantities of brandy of fair quality are being produced in South Africa and Australia. The so-called 'dop' brandy of South Africa is produced in the same way as the French 'marc' brandies, and has similar characteristics.

The natural improvement observed in genuine brandies by 'ageing' is always accompanied by a rise in the quantity of the secondary constituents due to the formation of oxidation products (aldehydes and acids) and esters, as well as to concentration due to loss of alcohol and water. The higher alcohols also tend to increase, and furfural to diminish, with age. According to Duplais, the mellowness due to age may be imparted to new brandy, making it fit for immediate use, by adding the following to every 100 litres: old rum, 2·0 litres; old kirsch, 1·75 litres; syrup of raisins, 2·0 litres; and infusion of walnut hulls, 0·75 litre. Low wines which have been kept for some months in casks containing clear rain water preserved by the addition of 10 or 12 p.c. of strong brandy (85°) are also used for a similar purpose.

Whilst there is a legitimate use of colouring which has become practically an essential character of the brandy of commerce, the colour acquired by old brandies, owing to long storage in casks, is often simulated in order to give to new brandies a fictitious appearance of age by means of a tincture of oak extract obtained from chips, shavings, or sawdust of the white oak used at Cognac for making brandy casks.

Brandy was formerly described in the British Pharmacopœia, as 'Spiritus Vini Gallici,' thus implying the French origin of the spirit, and was defined as 'a spirituous liquid distilled from wine and matured by age, and containing not less than 36½ p.c. by weight, or 43½ p.c. by volume of ethyl hydroxide' (approximately 76 p.c. of proof spirit).

This definition, however, takes no cognisance of the nature, quantity, or relative proportions of the secondary products to which the peculiar medicinal properties of brandy are attributed and in view of the variations in these constituents even in the brandies of commerce known to be genuine, and the difficulty of arriving at any satisfactory standard, the British Medical Association eliminated 'brandy' in the last edition of the British Pharmacopœia published in 1914.

The following standards of purity are prescribed by the United States Pharmacopœia. Brandy should be at least 4 years old; its alcoholic content from 39 to 47 p.c. by weight (81–96 p.c. British proof spirit); specific gravity not exceeding 0·941 nor less than 0·925; the residue should not, on the volatilisation of the last traces of alcohol, evolve a marked disagreeable odour of fusel oil, and should not exceed 1·5 p.c.; also the residue from 100 c.c. should dissolve readily in 10 c.c. of cold water, and should be free from more than traces of tannin (*i.e.* should not give more than a pale-green colouration on the addition of a dilute solution of ferric chloride); and the acidity should require not more than 1 c.c. of decinormal alkali for neutralisation using phenolphthaleïn as an indicator.

Under the Sale of Food and Drugs Act, no standard for brandy is fixed beyond the limitation of strength (in common with whiskey and rum) to a minimum of 25 p.c. under proof, below which it may not legally be sold without the fact of dilution being declared. This is now (during the war) superseded by special legislation, which permits of spirits being reduced to a minimum strength of 50 p.c. under proof and 30 p.c. under proof as a maximum strength at which they may be sold as a beverage. The strength of brandy as imported into the United Kingdom varies considerably, but the average is about 5° below proof, or 46·5 p.c. of alcohol by weight.

Ordonneau (Compt. rend. 102, 217) subjected 100 litres of 25-year-old brandy to fractional distillation, and obtained the following substance estimated in grams per hectolitre :—

Aldehyde	3·0
Normal propyl alcohol	40·0
Normal butyl alcohol	218·6
Amyl alcohol	83·8
Hexyl alcohol	0·6
Heptyl alcohol	1·5
Acetic ester	35·0
Propionic, butyric, and caproic esters	3·0
Œnanthic ester (about)	4·0
Acetal and amines	traces

Morin (Compt. rend. 105, 1019) distilled 92 litres of pure cognac in Claudin and Morin's apparatus. The first portion of the distillate contained the more volatile bodies; the second consisted of tolerably pure ethyl alcohol; the third, the higher-boiling alcohols, &c. The residue, chiefly water, was tested for free acids, *iso*butylglycol and glycerol.

The first three portions were then fractionated, 5 litres of light alcohol, 55 litres of pure ethyl alcohol, and 3·5 litres of higher-boiling compounds being obtained. The latter fraction smelt strongly of fusel oil, and possessed a burning taste. The water remaining behind was added to that already obtained. The fractions were then redistilled in Le Bel and Henninger's apparatus. The fusel oil portion, which after dehydration by potassium carbonate weighed 352 grams, gave:

	grams
Water	7
Ethyl alcohol	130
Normal propyl alcohol	25
*Iso*butyl alcohol	6
Amyl alcohol	175
Furfural	2
Wine oils	7

The water contained a little acetic and butyric acids, and a small quantity of a viscous liquid which distilled undecomposed under diminished pressure, and appeared to consist of *iso*butyl alcohol and glycerol. The residue contained tannin, together with substances extracted from the wood.

In the following table: 1 shows the compounds contained in 100 litres of the cognac; 2 shows the same obtained by the fermentation of 100 kilos. of sugar :—

	1 grams	2 grams
Aldehyde	trace	trace
Ethyl alcohol	50,837·00	50,615·0
Norm. propyl alcohol	27·17	2·0
*Iso*butyl alcohol	6·52	1·5
Amyl alcohol	190·21	51·0
Furfural bases	2·19	—
Wine oil	7·61	2·0
Acetic acid	trace	—
Butyric acid	trace	—
*Iso*butyl glycol	2·19	—
Glycerol	4·38	—

Butyl alcohol was absent; furfural was detected directly by the addition of aniline to the cognac, a red colouration being produced in the presence of acetic acid. It will be observed that *iso*butyl alcohol is present only in small quantity, whilst in Ordonneau's results it is absent altogether.

The analytical data usually relied upon for discriminating between genuine brandies and those blended with neutral spirit are (*a*) volatile acids; (*b*) aldehydes; (*c*) esters; (*d*) higher alcohols; and (*e*) furfural. The results are calculated in parts per 100,000 of absolute alcohol, *e.g.* in milligrams per 100 c.c., or grams per hectolitre. The total amount of the secondary products expressed in this manner is termed the 'coefficient of impurities,' or preferably the 'coefficient non-alcohol.' The standard coefficient suggested by Girard and Cuniasse for genuine brandy is 300, of which not less than 80 should be esters. In calculating the proportion of neutral spirit in a mixture, allowance should be made for the small amount of secondary products present in neutral spirit. The average coefficient for industrial alcohol, as shown by the analyses of Girard and Cuniasse, is 17 and the esters 8.

(For a detailed description of the methods of analysis employed, *see* Thorpe, Minutes of Evidence taken by the Royal Commission on Whiskey and other Potable Spirits, ii. Appendix Q, xii. 1909.)

The causes which affect the characteristic bouquet of the wine naturally influence the proportion as well as the character of the volatile matters included in the 'coefficient' of the brandy. Thus the proportion of acids and esters is considerably augmented if the wine becomes sour, and, speaking generally, the aldehydes are higher in white than in red wines. Also in regard to distillation, the aldehyde and more volatile esters are found mainly in the first runnings ('produits de tête'), whilst the higher alcohols and furfural occur in largest quantity in the tailings ('produits de queue').

In the brandies of Charente and Armagnac the coefficient is usually rather high, but ordinarily, in cognacs and *fine champagne*, it ranges between 275 and 450, although occasionally it falls considerably beyond these limits. Brandies obtained from wines of the Midi and from Algeria show much wider variations, ranging from 25 (indicating strong rectification) to 500. Marc brandies have almost invariably a very high coefficient, ranging from 500 to nearly 1500, and in these, aldehydes often form a large proportion.

Attempts have been made to fix minimum and maximum values for the coefficient, but without much success, the former with a view to the detection of the admixture of neutral spirit, and the latter to restrict the amount of secondary products for hygienic reasons. The effect of such limits would be to condemn many brandies that are undoubtedly genuine and even of high commercial value.

From the hygienic point of view, the esters, furfural, and especially the aldehydes, have a much more deleterious action on the human system than the higher alcohols, whilst the acids, particularly acetic, which frequently forms a large proportion of the coefficient, cannot be said to have any detrimental influence.

The French Government, in 1904, instituted an inquiry by the Technical Committee of Œnology into the possibility of fixing standards for the total amount of secondary products ('coefficient non-alcohol') of genuine brandy, but the conclusion arrived at was that neither a minimum nor a maximum limit could be recommended owing to the extremely variable character of brandy, not only with respect to the coefficient as a whole, but also in regard to the proportions of the volatile constituents relatively to each other. Chemical analysis should not be relied upon alone, but should be supplemented and its results confirmed by expert tasting ('degustation').

British brandy is usually made from grain spirit distilled with certain flavouring materials, or by adding flavouring ingredients to the spirits. It is frequently mixed with foreign brandy, and is largely used for cooking purposes.

Amongst the flavouring ingredients used in the manufacture of artificial brandies (including British brandy) may be mentioned the following: œnanthic ester, tincture of catechu, balsam of tolu, acetic ester, argol, cognac oil, essence of cognac, infusions of bitter almond shells, tea, and walnut hulls, liquorice root, prune juice, rum, syrup of raisins, vanilla, &c. So-called 'cognac essences' contain mixtures of the aromatic compounds just mentioned, whilst 'cognac oil' is made by the distillation of a mixture of alcohol, coco-nut oil, and sulphuric acid, œnanthic ester being one of the products.

Cider brandy is manufactured in the United States and Canada from cider and perry.

Danzig brandy is made from rye ground with the root of *Calamus aromaticus*.

Guernsey brandy is the spirit of beet root flavoured to imitate true brandy.

Hamburg brandy is said to consist of potato or beet-root spirit as a basis, flavoured with essences or by the addition of inferior brandy, and coloured to represent genuine brandy. Similar imitation brandies appear to be made in the north of France, in Belgium, and in other foreign countries. (Girard and Cuniasse, Man. pratique de l'Analyse des Alcools et des Spiritueux; Schidrowitz, Analyst, June, 1905, and June, 1906; Thorpe, Nature, 3 Nov. 1904; and Report of Royal Commission on Whiskey and other Potable Spirits, 1908–9.) J. C.

BRASS *v.* Zinc.

BRASSIC ACID *v.* Brassidic acid.

BRASSIDIC ACID (*Brassic acid*)

$$\begin{matrix}H\\C_8H_{17}\end{matrix}\!\!>C:C<\!\!\begin{matrix}H\\C_{11}H_{22}\cdot CO_2H\end{matrix}$$

is isomeric with erucic acid (*q.v.*), from which it may be obtained by the action of nitrous acid (Hausknecht, Annalen, 143, 54; Reimer and Will, Ber. 1886, 3321; Websky, Jahrb. Chem. 1853, 444; Fitz, Ber. 1871, 444); by treatment with hydrogen bromide in acetic acid solution, monobrombehenic acid $C_{22}H_{42}O_2Br$, being also formed (Ponzio, Gazz. chim. ital. 35, ii. 394); and by heating with concentrated sulphurous acid at 200° (M. K. and A. Saytzew, J. Russ. Phys. Chem. Soc. 24, 482; J. pr. Chem. 50, [2] 78). It may also be obtained by heating behenolic acid with zinc and acetic acid, and a few drops of hydrochloric acid (Holt. Ber. 1982, 962), and by the reduction of monobrombrassidic acid, which is obtained by treating behenolic acid with hydrogen bromide (Hasse and Stutzer, Ber. 1903, 3601). Brassidic acid crystallises from alcohol in plates, m.p. 65°–66° (Saytzew, *l.c.*), b.p. 282° (30 mm.), 265° (15 mm.), 256° (10 mm.), 180° (0 mm.), (Krafft and Weilandt, Ber. 1896, 1325); sp.gr. 0·8585 at 57·1°/4°; is less soluble than erucic acid in alcohol and ether. (For relationship to erucic acid and comparison of their behaviour towards various reagents, *v.* Albitzky, J. Russ. Phys. Chem. Soc. 31, 76; 34, 788; J. pr. Chem. 61, [2–3] 65; Mascarelli, Atti. R. Accad. Lincei, 1917, [v.] 26, i. 71). By fusing brassic acid with potash, *arachidic acid* $C_{20}H_{40}O_2$ is obtained (Goldschmidt, Jahrb. Chem. 1877, 728); oxidation with potassium permanganate yields a dihydroxybehenic acid (Jukovsky, J. Russ. Phys. Chem. Soc. 24, 499; Albitzky, *l.c.*). Treatment with hydriodic acid in glacial acetic acid yields iodobehenic acid (Bayer and Co., D. R. P. 180087; Chem. Soc. Abst. 1907, i. 380).

BRASSIL. A local name for iron pyrites.

BRASSYLIC ACID $C_{13}H_{24}O_4$. Obtained, together with other products, by acting on behenolic acid $C_{22}H_{40}O_2$, with fuming nitric acid (Hausknecht, Annalen, 143, 45; Grossmann, Ber. 1893, 644) May be prepared by the action of nitric acid on erucic acid (Fileti and Ponzio, Gazz. chim. ital. 23, ii. 393), and from ικ-undecenoic acid (Krafft and Seldis, Ber. 1900, 3571). Flat needles; m.p. 113°–114°; readily soluble in alcohol and ether, sparingly soluble in water.

BRAUNITE. A manganese mineral classed with the oxides, but containing an appreciable amount of silica (8–10 p.c.), the formula being $3Mn_2O_3\cdot MnSiO_3$ or $4Mn_2O_3\cdot MnSiO_3$. The manganese is usually isomorphously replaced by small amounts of iron, calcium, barium, &c. It is generally found in compact masses, but sometimes as tetragonal pyramids, the angles of which are very near to those of the regular octahedron. The crystals possess a perfect pyramidal cleavage. The colour is black with a sub-metallic to metallic lustre. Sp.gr. 4·8; H. 6–6½. The mineral i found in the manganese-mines in Sweden; and with the exception of psilomelane, it is the mos abundant of the manganese ores in India (L. L. Fermor, Mem. Geol. Survey, India, 1909 xxvii). L. J. S.

BRAZILITE. A synonym of baddeleyite (*q.v.*). The same name has also been applied to an oil-bearing rock from Bahia, Brazil. L. J. S.

BRAZIL NUTS are the fruits of *Bertholletia excelsa* (Humb. and Bonp.). They yield 73 p.c. of a fatty oil of pale yellow colour, of a taste similar to that of the nuts themselves. In South America an edible oil is expressed from the fresh nuts, but the oil known in Europe is derived from mouldy nuts, and is only fit for the manufacture of soap. The oil deposits a large amount of 'stearine' on standing. It is a 'semi-drying' oil; iodine value about 106; m.p. of fatty acids 28°–30° (De Negri and Fabris). J. L.

BRAZILETTO. An inferior kind of Brazil-wood obtained from *Cæsalpinia braziliensis* (Linn.), growing in th West Indies.

BRAZILWOOD. Under the name of Brazilwood certain varieties of the so-called 'soluble' red woods are known, the term 'soluble' being employed to distinguish them from the dyestuffs of the barwood class, which only with difficulty yield their colouring matters to boiling water. These soluble red woods give with aluminium mordanted fabrics, a bright-red shade, which in each case is derived from one and the same colouring matter, and all are botanically allied, in that they consist of the wood of various species of *Cæsalpinia*. About nine varieties have been employed as dyestuffs, of which the following are the best known:—

Fernambuco or *Pernambuco wood* is considered to be the richest in colouring matter, and is the product of the *Cæsalpinia crista*, a tree which is abundant in Jamaica and Brazil.

The true *Brazilwood* is derived from the *Cæsalpinia braziliensis*, and is said to contain only one-half the colouring matter which is present in the Fernambuco variety. It is obtained exclusively from Brazil.

Sappanwood is obtained from the *Cæsalpinia sappan*, a tree which is common to the warmer regions of Asia. The so-called *Limawood* is a variety of sappan, and the dyewood imported from the Philippine Islands is an inferior quality of this product.

Peachwood is the product of the *Cæsalpinia echinata*, which occurs in Central America and the northern parts of South America.

These woods, which are very hard, and of a deep-red colour, come into the market in the form of billets varying in weight from a few pounds up to a hundredweight. If freshly cut, the internal colour of the wood is seen to be light-yellow, but this soon changes to deep-red in contact with air.

Some varieties of these woods were employed for dyeing purposes in India long before the discovery of America, and it is stated that when South America was discovered by the Spaniards, in 1500, the northerly portion of the country was named Brazil (from *braza*, fiery red), because this red dyewood was found there in such immense quantities.

Owing to the fugitive character of the colours yielded by Brazilwood, it is now only employed to a somewhat limited extent.

Brazilin $C_{16}H_{14}O_5$, the colouring principle of Brazilwood, was first isolated in a crystalline condition by Chevreul (Ann. Chim. Phys. [1] 66, 225); but was not further examined until 1864, when Bolley (Schweiz. polv. Zeitsch. ix. 267) assigned to it the formula $C_{22}H_{20}O_7$ Subsequently Kopp (Ber. 6, 446) proposed the formula $C_{22}H_{18}O_7$, but it was left to Liebermann and Burg (Ber. 9, 1883) to determine the exact composition of this substance, and their formula, $C_{16}H_{14}O_5$, is in use at the present time. To prepare brazilin from the wood itself, it is best to employ the commercial extract. This is stirred up with a considerable quantity of sand, the product extracted with cold ether, the ethereal liquid evaporated to a small bulk, treated with a little water, and allowed to stand for some days. Crystals slowly separate, and these are purified by crystallisation from a little water.

This method is, however, tedious, and the usual source of brazilin consists of the crude crystalline crusts of this substance which are frequently deposited from Brazilwood liquor, and intermediate product in the manufacture of Brazilwood extract. The crude substance is best purified by two or three crystallisations from water, to which a little sulphurous acid has been added (Gilbody, W. H. Perkin, and Yates, Chem. Soc. Trans. 1901, 79, 1396). Brazilin crystallises in two forms, either as colourless needles containing $1\frac{1}{2}H_2O$, or as colourless prisms with $1H_2O$. It is readily soluble in alcohol and water, and dissolves in a dilute solution of sodium carbonate with a beautiful carmine-red colour.

Tetraacetylbrazilin $C_{16}H_{10}O_5(C_2H_3O)_4$, colourless needles, m.p. 149°–151° (Liebermann and Burg); *triacetylbrazilin* $C_{16}H_{11}O_5(C_2H_3O)_3$, needles, m.p. 105°–106° (Buchka and Erck, Ber. 18, 1139); *brombrazilin* $C_{16}H_{13}BrO_5$, brown-red leaflets (B. and E.); *dibrombrazilin* $C_{16}H_{12}Br_2O_5$, leaflets (Schall and Dralle, Ber. 23, 1550); *tetraacetylbrombrazilin* $C_{16}H_8Br_2O_5(C_2H_3O)_4$, needles, m.p. 203°–204° (Buchka, Annalen, 17, 685); *tetraacetyldibrombrazilin* $C_{16}H_6Br_2O_5(C_2H_3O)_4$, m.p. 185° (S. and D.); *tribrombrazilin* $C_{16}H_{11}Br_3O_5$ (S. and D); *dichlorbrazilin* $C_{16}H_{12}Cl_2O_5$ (L. and B.); and *tetrabrombrazilin* $C_{16}H_{10}Br_4O_5$, fine red needles (B. and E) have been prepared.

When brazilin is methylated with methyl iodide in the usual manner, it gives *brazilin trimethyl ether* (S. and D., Ber. 20, 3365; Herzig, Monatsh. 14, 56; and Schall, Ber. 27, 525) $C_{16}H_{11}O_2(OCH_3)_3$, prisms, m.p. 138°–139°, which on acetylation yields *acetylbrazilin trimethyl ether* $C_{16}H_{10}O_2(OCH_3)_3(C_2H_3O)$, m.p. 171°–173° (Herzig, Monatsh. 15, 140; Schall, Ber. 27, 236).

According to Gilbody, W. H. Perkin, and Yates (Chem. Soc. Trans. 79, 1403), large quantities of the trimethyl ether are conveniently prepared as follows: 143 grams of brazilin dissolved in the smallest possible quantity of methyl alcohol are treated with 35 grams of sodium in methyl alcohol and methyl iodide (250 grams), and the mixture is heated 50 hours to 60°–65° in absence of air. A second method employed also by v. Kostanecki and Lampe (Ber. 35, 1669) consists in methylating brazilin with excess of dimethyl sulphate and alkali.

The difficulty experienced in fully methylating brazilin is evidence of the presence of an alcoholic group; but the *tetramethyl ether* $C_{16}H_{10}O(OCH_3)_4$, m.p. 137°–139°, has been prepared by Schall by treating the sodium compound of the trimethyl derivative suspended in benzene with methyl iodide at 120° (compare also Herzig, *l.c.*). From this substance the following derivatives have been prepared:—

Brombrazilin tetramethyl ether $C_{16}H_9BrO\cdot(OCH_3)_4$, prisms, m.p. 180°–181° (S. and D., Ber. 21, 3014); and *dibrombrazilin tetramethyl ether* $C_{16}H_8Br_2O\cdot(OCH_3)_4$, m.p. 215° (S and D. Ber 23, 1432).

When brazilin is submitted to dry distillation, it gives *resorcin* (Kopp, *l.c.*), and by fusing it with potassium hydroxide, Liebermann and Burg obtained resorcin, and Herzig (Monatsh. 27, 739) also *protocatechuic acid*. With nitric acid brazilin yields *trinitroresorcinol* (Reim, Ber. 4, 334).

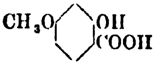
When brazilin, the colouring principle, is oxidised under suitable conditions, it is converted into *brazilein*, the true colouring matter

$$C_{16}H_{14}O_5+O=C_{16}H_{12}O_5+H_2O$$

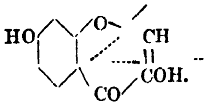
and for this purpose the action of air on an alkaline brazilin solution, alcoholic iodine (Liebermann and Burg), potassium nitrite, and acetic acid (Schall and Dralle), nitric acid in the presence of ether (Buchka and Erck), and sodium iodate (Mayer, Zentr. 1904, i. 228) have been employed. It can, however, be more economically prepared from Brazilwood extract in the following manner (Hummel and A. G. Perkin, Chem. Soc. Trans. 1882, 41, 367):—

To an aqueous solution of the extract of the wood, an excess of ammonia is added, and air is aspirated through the liquid. A precipitate of the impure ammonium salt of brazilien gradually separates, and this is collected, dissolved in hot water, and treated with dilute acetic acid (sp.gr. 1·04). A brown viscous precipitate of the crude colouring matter is thus obtained, which is extracted with hot dilute acetic acid, and the extract evaporated on the water-bath. Crystals of brazilein separate, which are collected and washed with acetic acid.

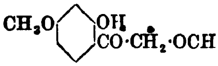
Brazilein consists of minute plates possessing a strong metallic lustre, and by transmitted light a reddish-brown colour. It is very sparingly soluble in all the usual solvents, and cannot be recrystallised in the ordinary manner. It is in reality the colouring matter of Brazilwood, and possesses strong tinctorial property. Alkaline solutions dissolve it with a deep-red colouration, which on standing in air passes gradually to brown. A study of this oxidation was carried out by Schall and Dralle, with interesting results. 2·7 grams of brazilin dissolved in 150 c.c. of water was treated with 10 c.c. of sodium hydroxide solution (sp gr. 1·37), and air aspirated through the liquid for 36 hours. Ether extracted from the acidified solution *β-resorcylic acid*, and a substance $C_9H_6O_4$, crystallising in brownish-yellow needles, m.p 271°, which gave a *diacetyl* compound, m.p 148°-149°, and a *dimethyl* ether, m.p. 169°-170°. When the latter was oxidised in acetic acid solution, with potassium permanganate *β-resorcylic acid monomethyl ether* was produced :



Schall and Drallo considered that this compound was probably a pheno-γ-pyrone derivative, and Feuerstein and Kostanecki (Ber. 32, 1024) proved that this was in reality the case, and assigned to it the following constitution :—



Thus the dimethyl ether, when hydrolysed with alcoholic potash, gave *fisetol dimethyl ether*



a substance which had already been obtained in a similar manner by Herzig from fisetin tetramethyl ether (*see* Young Fustic).

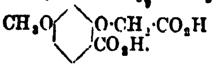
Our chief knowledge of the constitution of brazilin is due to the elaborate investigations of W. H. Perkin and his pupils, who obtained most important results by the oxidation of brazilin trimethyl ether with potassium permanganate, and also with chromic acid.

Gilbody, Perkin and Yates (Chem. Soc. Trans. 1901, 79, 1465) found that when brazilin trimethyl ether is oxidised with permanganate, it gives, in addition to oxalic, acetic, and formic acids, the following compounds :—

1. *m-Hemipinic acid*

The isolation of this substance was important, since it showed that brazilin contains a catechol nucleus and two orthohydroxyls, and as a result of these latter no doubt in part its tinctorial properties are due.

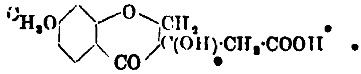
2. 2 *Carboxy-5-methoxyphenoxyacetic acid*



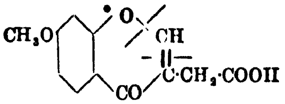
On fusion with alkali, this compound yields resorcinol, and on heating with water to 200° is converted into *methoxyphenoxyacetic acid*

This can be synthesised by the interaction of ethylbromacetate and the sodium compound of resorcinol monomethyl ether and subsequent hydrolysis.

3. *Brazilic acid*



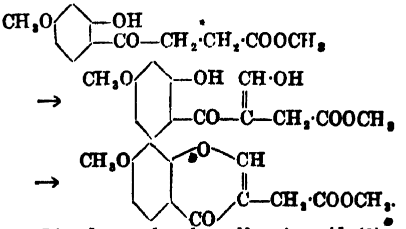
when fused with alkali, gives resorcin, and on warming with sulphuric acid is converted into *anhydrobrazilic acid*



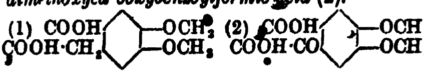
Boiling baryta water hydrolyses anhydrobrazilic acid, with production of *formic acid* and 6-*hydroxy*-4-*methoxybenzoylpropionic acid*

On methylation this is converted into the dimethyl ether, and the latter can be produced by the interaction of dimethyl resorcinol and the half-chloride of succinic acid monoethyl ester, and subsequent hydrolysis. It is also formed when resorcinol dimethyl ether and succinic acid are treated with aluminium chloride without employing a solvent.

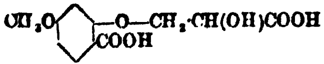
Finally, when the methyl ester of this hydroxymethoxybenzoylpropionic acid is dissolved in ethyl formate and treated with sodium, the *methyl ester* of *anhydrobrazilic acid* is produced. This interesting synthesis may be represented as follows :—



Dimethoxycarboxybenzylformic acid (1), and *dimethoxycarboxybenzoylformic acid* (2).

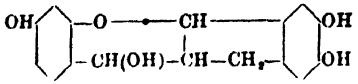


represent intermediate stages in the formation of *m*-hemipinic acid from brazilin trimethyl ether, whereas the acid



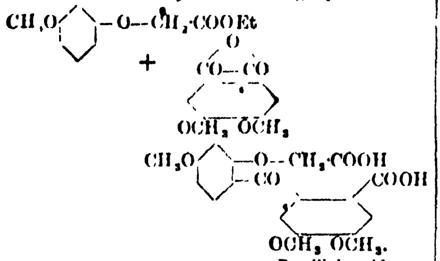
also isolated, is, no doubt, that product of the oxidation which is anterior to the formation of carboxymethoxyphenoxyacetic acid (*see* above)

The earlier work suggested the following probable constitution for brazilin :—



but this, as a result of the investigation of brazilinic acid, a very important substance, also produced by the oxidation of brazilin trimethyl ether, was subsequently discarded.

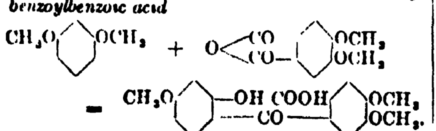
Brazilinic acid. The constitution of this acid has been conclusively demonstrated by its synthesis, which has been effected by the interaction of *m*-hemipinic anhydride with ethyl methoxyphenoxyacetate in the presence of aluminium chloride. This is illustrated by the following equation.—



Brazilinic acid.

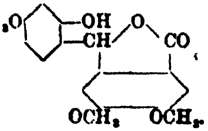
When brazilinic acid is reduced with sodium amalgam, it is quantitatively converted into *dihydrobrazilinic acid* $C_{19}H_{20}O_9$, which at once loses water with the formation of the *lactone* $C_{19}H_{18}O_8$.

To synthesise the latter compound, *m*-hemipinic anhydride is condensed with resorcinol dimethyl ether to form *2-hydroxy-4.5'.4'-trimethoxy benzoylbenzoic acid*

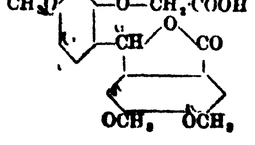


When reduced with sodium amalgam, this acid gives *2-m-meconyl-5-methoxyphenol* (1), and this by the action of chloracetic acid and potassium hydroxide is converted into the lactone of dihydrobrazilinic acid (2)

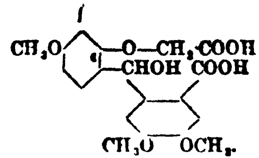
(1)



(2)

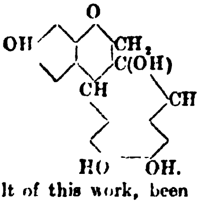


(3)



Dihydrobrazilinic acid itself is accordingly represented by formula (3).

The following constitution :—



has, as a result of this work, been assigned to brazilin by Perkin and Robinson (Chem. Soc. Trans. 1908, 93, 496), and is in complete harmony with the facts above enumerated.

Oxidation of trimethylbrazilin with chromic acid

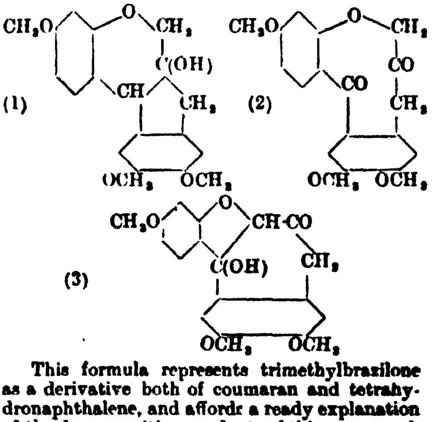
When trimethylbrazilin is oxidised with chromic acid it is converted into *trimethylbrazilone* (Gilbody and Perkin, *v. infra*)—

$$(CH_3O)_3C_{16}H_{11}O_2 + 2O = (CH_3O)_3C_{16}H_9O_3 + H_2O$$

and this apparently simple reaction has proved to be of an extremely puzzling character.

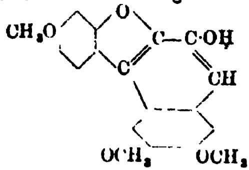
When trimethylbrazilone is oxidised with permanganate, it gives *m-hemipinic acid, 2-carboxy-5-methoxyphenoxyacetic acid, brazilic acid, dimethoxycarboxybenzoylformic acid, dimethoxycarboxybenzylformic acid, methoxycarboxyphenoxylactic acid,* and *brazilinic acid.*

In an earlier paper, Gilbody and Perkin (Chem. Soc. Trans 1902, 81, 1040) suggested for trimethylbrazilone a constitution based upon their first formula for brazilin (*see* above), but it was subsequently shown (*ibid* 1908, 93, 498) that the reaction proceeds as follows · By the oxidation of trimethylbrazilin (1) with chromic acid a disruption of the central linkage occurs, with the formation of an unstable diketone (2), and this subsequently undergoes aldol condensation, and trimethylbrazilone is produced (3)—



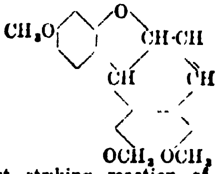
This formula represents trimethylbrazilone as a derivative both of coumaran and tetrahydronaphthalene, and affords a ready explanation of the decomposition products of this compound.

An important point in favour of this constitution is afforded by the behaviour of trimethylbrazilone with alkalis, or acetic anhydride and other dehydrating agents, for it is thus converted with loss of one molecule of water into *anhydrotrimethylbrazilone* $(CH_3O)_3C_{16}H_7O_2$. There can be little doubt that the formation of this substance is due to the elimination of water from the aldol grouping in trimethylbrazilone, and that it possesses the following formula:



Anhydrotrimethylbrazilone is thus a derivative of *β-naphthol*, and it possesses many of the properties of this substance. It is soluble in dilute alkali, and this solution gives with diazobenzene chloride a red azo- dyestuff. Diazonaphthalene chloride behaves similarly, and the dye thus produced dissolves in sulphuric acid with a blue colour.

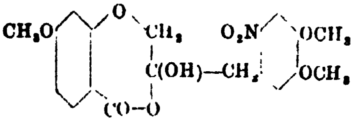
When trimethylbrazilone is boiled in acetic acid solution with phenylhydrazine, *deoxytrimethylbrazilone* $C_{16}H_9O_2(CH_3O)_3$ is obtained, and this is probably a dihydronaphthalene derivative of the formula



The most striking reaction of trimethylbrazilone is its behaviour with nitric acid, when it yields a compound possessing the composition of a *nitrohydroxydihydrotrimethylbrazilone*

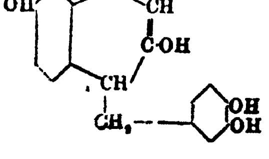
$$C_{16}H_9O_2(CH_3O)_3+HNO_3 = C_{16}H_{10}O_6N(CH_3O)_3$$

This substance dissolves in alkali with a purple colour, but on standing the colour rapidly fades, *o-nitrohomoveratrol* separates, and the solution contains *p-methoxysalicylic acid.* Oxidation with permanganate gives *2-carboxy-5-methoxyphenoxyacetic acid*, and these decompositions point clearly to the formula



as representing the constitution of this nitro-compound. (*See also* Perkin and Robinson, *ibid.* 1909, 95, 381.)

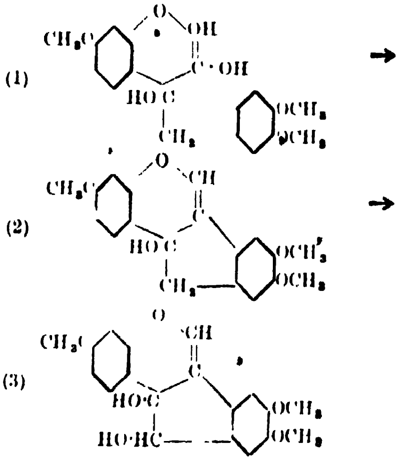
Feuerstein and v. Kostanecki (Ber. 32, 1024) assigned at first the following constitution to brazilin:—



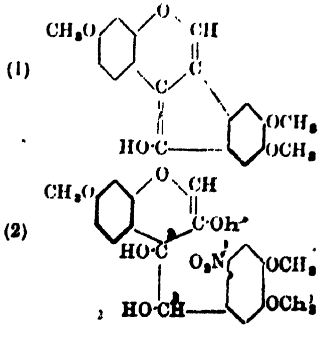
which was based upon the production from it of dihydroxypheno-γ-pyrone (Schall and Dralle) by alkaline oxidation, and of protocatechuic acid by fusion with alkali (Herzig).

It was, however, pointed out by Perkin that this formula does not account for the presence of *m*-hemipinic acid among the oxidation products of trimethylbrazilin, and Herzig and Pollak (Monatsh. 1901, 22, 207) advanced a similar criticism. On the other hand, it was suggested at the time by v. Kostanecki and Lampe (Ber. 1902, 35, 1667) that *m*-hemipinic acid was not to be regarded as an oxidation product of trimethylbrazilin itself, but that it arose from the formation, during the oxidation, of a phenanthrene or indene- derivative, which by the further action of permanganate gives this acid. Such an indene-condensation is illustrated by the following scheme, which, according to these authors, probably occurred during the formation of trimethylbrazilone from trimethylbrazilin.

The first product of the oxidation with chromic acid will possess the formula (1), and this is converted by the following stages into trimethylbrazilone (3).—

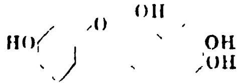


This constitution accounts in a simple manner for the formation of the anhydrotrimethylbrazilone (1), and the nitrohydroxydihydrotrimethylbrazilone (2), of Perkin, which can be represented as follows:—

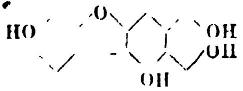


When anhydrotrimethylbrazilone is digested with hydriodic acid, anhydrobrazilone $C_{16}H_{10}O_5 + H_2O$ is produced, but when trimethylbrazilone itself is treated in a similar manner, the result is of a peculiar nature. The compound $C_{16}H_6O(OH)_4$ so obtained does not consist of brazilone, but possesses the formula (1) or (2), and on distillation with zinc dust gives *brazan* (3) (Kostanecki and Lloyd, Ber. 1903, 36, 2193).

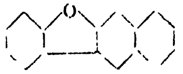
1.



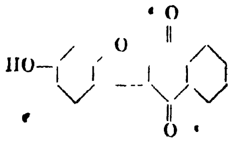
2.



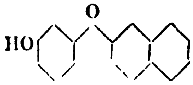
3.



In 1899 Liebermann (Ber. 32, 924) obtained anhydro-*a*-naphthoquinone resorcin by the condensation of 2·3-dichlor-*a*-naphthoquinone with resorcin

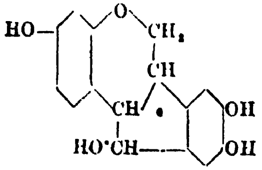


and this, according to v. Kostanecki and Lampe (Ber. 1908, 41, 2373), is 3-hydroxybrazanquinone By reduction with hydriodic acid, this gives hydroxybrazan



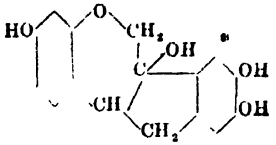
and from this latter or from the quinone itself, brazan, identical with that obtained from trimethylbrazilone, is produced by distillation with zinc-dust. Brazan crystallises in leaflets, and melts at 202°.

v. Kostanecki and Lampe (Ber. 1902, 35, 1674) considered it probable that, after all, trimethylbrazilin does contain, as found by Perkin, a nucleus which on oxidation yields hemipinic acid, and appear to have adopted the following as their final formula for brazilin :—

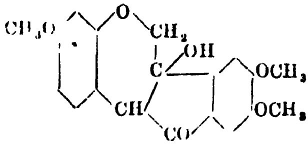


This constitution, it is evident, will still harmonise with the formulæ of trimethylbrazilone and anhydrotrimethylbrazilone given above by these authors.

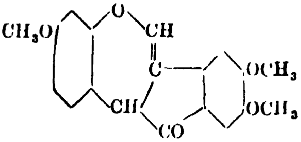
Herzig and Pollak (Ber. 1906, 39, 267) suggested the following constitution for brazilin, trimethylbrazilone, and anhydrotrimethylbrazilone :—



Brazilin.

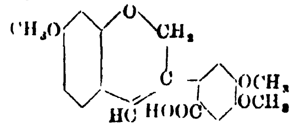


Trimethylbrazilone.

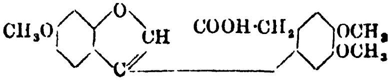


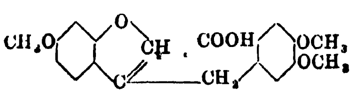
Anhydrotrimethylbrazilone

Herzig, moreover, observed (Ber. 1904, 37, 631) that trimethylbrazilone undergoes isomeric change when it is dissolved in sulphuric acid, and yields *γ-trimethylbrazilone* $C_{16}H_9O_3(OCH_3)_3$, m.p. 170°–173°, to which the formula

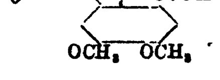


was assigned (Herzig and Pollak, Monatsh. 1906, 27, 743). Perkin and Robinson (*l.c.*) find that on oxidation with permanganate this compound gives large quantities of *2-carboxy-4 5-dimethoxyphenylacetic acid* $(CH_3O)_2{\cdot}C_6H_2{\cdot}(COOH){\cdot}CH_2{\cdot}COOH$, and that there can be little doubt that its true constitution is represented by one of the following formulæ :—





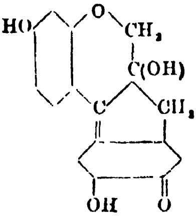
Finally, in 1906 Herzig and Pollak (Monatsh. 27, 743) considered it necessary to modify their first formula for brazilin, and have arrived at the conclusion that that finally proposed by v. Kostanecki and Lampe correctly represents this colouring principle. The more recent work of Perkin and Robinson detailed above shows, however, that such a constitution cannot be correct, because it does not account for the production of brazilinic acid by the oxidation of trimethylbrazilin



and there is every reason to consider that the formula suggested by the latter authors is the correct representation of the constitution (*cf.* also Perkin and Robinson, Chem. Soc. Trans. 1909, 95, 381) of brazilin.

Brazilein yields a triacetyl derivative $C_{16}H_9O_5(C_2H_3O)_3$, yellow leaflets, m.p. 203°-207° (Schall and Dralle, Ber. 23, 1434), and a trimethyl ether $C_{16}H_9(OCH_3)_3O_2$, which crystallises in two modifications, melting at 160° and 178° respectively (Engels and Perkin, Chem. Soc. Proc. 1906, 22, 132). Brazileïn trimethyl ether combines with formic acid, yielding a formic acid derivative which crystallises in garnet-coloured prisms, and is decomposed into its components by treatment with alcohol.

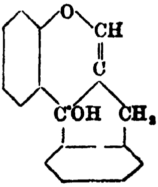
The constitution assigned to brazilein by Perkin is as follows :—



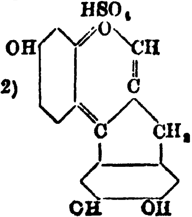
When brazilein is dissolved in sulphuric acid and the solution is diluted with acetic acid, minute orange-red prisms of *isobrazilein sulphate* $C_{16}H_{11}O_4{\cdot}SO_4H$ separate (Hummel and A. G Perkin, Chem. Soc. Trans. 1882, 41, 367), and this, on treatment with alcohol, gives the basic sulphate $C_{16}H_{12}O_5(C_{16}H_{11}O_4{\cdot}SO_4H)_2$, which crystallises in red needles. Hydrochloric and hydrobromic acids at 100° give *isobrazileinchlorhydrin* $C_{16}H_{11}O_4{\cdot}Cl$, and *isobrazileinbromhydrin* $C_{16}H_{11}O_4Br$, and both compounds consist of orange-coloured prisms, which are somewhat readily soluble in water, forming a solution which contains free haloid acid. These interesting substances dye mordanted fabrics colours which are entirely different from those yielded by brazilein, and the shades which are produced, especially on calico, somewhat resemble those given by alizarin. From these haloid salts by digestion with silver oxide a substance is produced known as *isobrazilein*, which has the formula $C_{16}H_{12}O_5$, but is totally distinct from brazilein.

According to Engels, Perkin, and Robinson (Chem. Soc. Trans. 1908, 93, 1140), whose paper must be consulted for the detailed account of brazilein and its derivatives, these *iso*brazilein salts are derived from *4·3-indenobenzopyranol* (1), and the sulphate which is *trihydroxy-4·3-indenobenzopyranolanhydrohydrogen sulphate* (2), may be represented thus :

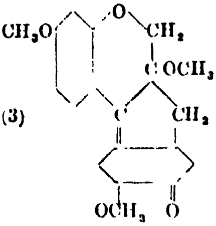
(1)

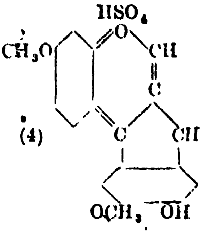


(2)



It was found, for instance, that when brazilein trimethyl ether (3) is treated with sulphuric acid, it is converted with loss of methyl alcohol into the dimethyl ether of *iso*brazilein sulphate (4)

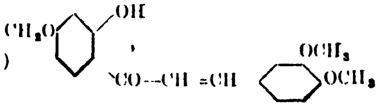




These authors assign an orthoquinonoid structure to this and similar oxonium salts.

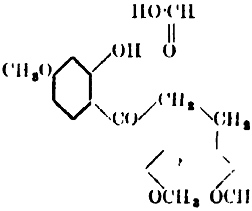
More recently Crabtree, Robinson, and Turner (Chem. Soc. Trans. 1918, 113, 859), employing butein trimethyl ether, have succeeded by very simple methods in synthesising isobrazilein hydrochloride. By reducing butein trimethyl ether (1) :—

(1)

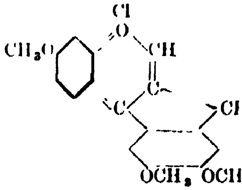


the dihydro (benzylacetophenone) compound (2) is obtained. This by digestion with an excess of absolute formic acid in presence of zinc chloride is transformed into the hydrochloride of isobrazilein trimethyl ether (3) :—

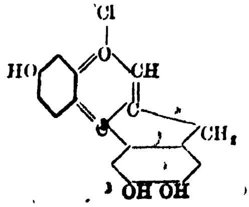
(2)



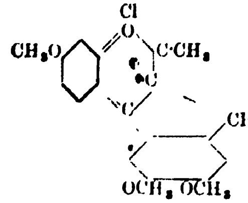
(3)



With fuming hydrochloric acid at 120°-150° demethylation occurs and isobrazilein hydrochloride is produced :—



By the substitution of acetic acid for formic acid in this reaction the corresponding methyl isobrazilein derivative can be obtained :—



The synthesis in this manner of a colouring matter so closely allied to brazilin itself by the employment of butein, a yellow dye which exists in the flowers of the *Butea frondosa* (Perkin, Chem. Soc. Trans. 1904, 85, 1459), is of exceptional interest.

The *commercial preparations* of Brazilwood known as Brazilwood extract and Brazilwood liquor, are prepared by boiling the ground fresh wood with water, and evaporating the decoction thus obtained to various degrees of consistency without access of air, or as rapidly and at as low a temperature as possible, *e.g.* in vacuum pans.

Dyeing Properties.—Before dyeing, the logs as imported are rasped to a coarse powder, and this is then usually moistened with water and allowed to ferment for some weeks. This operation is performed in order to increase the colouring power of the wood, and there can be little doubt that a considerable quantity of the brazilin present is thereby oxidised to the colouring matter brazilein. It has been considered by some that the fresh wood contains in reality a glucoside of brazilin, which, under the influence of fermentation, is hydrolysed, but no evidence has been forthcoming in support of this suggestion.

Although still used in calico-printing and in wool-dyeing, Brazilwood and its allies have lost their importance, chiefly because of the fugitive character of the colours they yield. In calico-printing, sappan liquor is employed for producing steam-reds and pinks, the mordant used being aluminium acetate or stannic oxalate, separately or combined, together with some oxidising agent, *e.g.* potassium chlorate or a copper salt. It also enters into the composition of steam-chocolates and certain steam colours in conjunction with other dyewood extracts. These woods have also been much used in the past along with garancine in dyeing the reds, chocolates, and other colours of cheap prints.

In wool-dyeing these woods have been applied for the purpose of dyeing reds and various shades of claret and brown, the wool being previously mordanted with alum and cream of tartar or oxalic acid, or with potassium dichromate, in which case other dyewoods, *e.g.* logwood and old fustic, are applied in addition. The colours produced by this method are now only used to a limited extent.

In cotton-dyeing, peachwood-red was formerly obtained by first preparing the cotton with tannin matter, then mordanting with a stannic salt, and finally dyeing with peachwood, sappanwood, &c. Browns were obtained by the use of logwood in addition, with or without a final passage through a ferric salt solution (nitrate of iron). These colours are now replaced by others obtained from coal tar. A. G. P.

BRAZILEIN and **BRAZILIN** *v.* BRAZILWOOD.

BRAZILIAN ANIME *v.* OLEO-RESINS.

BREAD may be defined as the dough made by the mixture of the flour of grain with water, charged in some way with gas so as to distend it, and afterwards baked. The resulting loaf has a delicate spongy structure which causes it to be the most readily and easily digested of all wheat foods. The simplest and most primitive form of bread making consisted merely in mixing flour with water and baking the dough, and it survives still in the Passover cakes of the Jews and in the 'damper' of the Australian settler. The charging with carbonic gas is commonly effected by fermentation with leaven or yeast; alternative methods involve the use of baking powders (*q.v.*) or the direct injection of the gas. In addition to producing gas, fermentation has a profound effect on the constituents of flour, and improves the flavour and digestibility of the loaf.

The mechanical result of aëration is the creation of innumerable vesicles or cells within the dough, which are subsequently distended by heat, the whole mass being encased in the baking within the crust of dextrin formed by the action of heat upon the starch. The making of bread from wheaten flour is only possible because the latter contains gluten. Gluten is a mixture of proteins which becomes viscid when mixed with water, and, when blown up with gas, has sufficient coherence to remain in the form of a honeycomb instead of collapsing and allowing the gas to escape.

Leavening (Lat. *levo*, to rise) has been practised from time immemorial in the East; from the Egyptians it passed to the Greeks and thence to the Romans, whose conquests and colonies extended the art. It consisted in the first instance probably in a natural fermentation of the dough by leaving it to become sour; but to hasten the process it became usual to add to new dough a portion of old fermented paste or 'leaven.' More recently, yeasts were substituted for the piece of leaven. These were of various origin, that from the distillery being the most suitable. To-day, 'pressed' or German yeast, which consists of yeast grown in a special way, purified by repeated washing and compressed into cakes, is the most generally used. This keeps well, is uniform in quality, and enables the baker to exercise a close control over the regularity of the process.

Dough consists roughly by weight of two-thirds flour and one-third water, the quality of the water being a matter of some importance. The softer the water the quicker is the fermentation, and since the quality of the bread depends on fermentation being allowed to proceed to exactly the right point, it cannot be carried out under precisely the same conditions with hard as with soft water.

Chemistry of bread making.—The chief constituents of flour, so far as bread making is concerned, are (1) the carbohydrates, (2) the proteins. The former include sugars and starch, the proteins consist of a small proportion of soluble protein and a large proportion of insoluble gluten.

The gas formed during panary fermentation is produced by the action of the yeast organism on dextrose. Flour contains about 1 p.c. of sucrose and a little raffinose: before fermentation, both these sugars are converted into dextrose by the enzyme *invertase* present in yeast. This amount of sugar would not suffice to give the necessary amount of gas, but it is supplemented by the maltose produced from the starch of the flour, maltose being itself converted into fermentable dextrose by another enzyme *maltase* contained in yeast.

The formation of maltose is effected by the agency of a diastatic enzyme present in flour; it begins directly the flour is wetted and continues throughout fermentation until the loaf is baked. Yeast contains no diastatic enzyme, but it is possible that its action on the proteins of flour facilitates the production of diastase.

Gas escapes from the dough throughout the process of making a loaf, and the supply available must be sufficient to distend the loaf and maintain it fully distended until it is fixed in the oven. Flours which have relatively little diastatic enzyme will produce insufficient gas, and this fact explains perhaps the beneficial results sometimes obtained on adding malt extract, which is rich in diastase, to dough. This question is in reality somewhat more complicated in that diastase consists of two enzymes—a liquefying enzyme which renders the starch soluble, and a hydrolysing enzyme which converts it into maltose. It is the former rather than the latter enzyme which is sometimes lacking in flour.

Gluten is the characteristic and the most important constituent of flour (v. GLUTEN). It is the agent which principally determines how much water a dough will take; what length of time it requires to be fermented; what will be the size of the loaves, and their colour, flavour, and general appearance. The baker requires quality rather than quantity: the relation between chemical constitution and quality is not yet fully understood (*see* British Association Report on Wheat, Winnipeg, 1909). During fermentation, gluten becomes softer and at first more elastic, subsequently it softens still further, loses elasticity, and begins to break down. Baker's yeast always contains lactic acid organisms, and the conditions in a long sponge are favourable for the formation of this acid, which has a marked solvent and disintegrating action on gluten. Accordingly, in a long sponge, the gluten is considerably disintegrated. The baker's art consists in taking the sponge when sufficiently mellow. If under-fermented, a foxy crust is obtained; if over-ripe, the gluten becomes too much disintegrated and the loaf is less bulky, inclined to crumble, and in extreme cases becomes sour.

Common salt is very generally added to bread. This is done firstly to give the necessary flavour, as owing largely to the action of salt in stimulating the palate, minute quantities of other substances can be recognised in its presence. Secondly, salt has a toughening and binding effect on gluten, though it has a solvent effect on some of the proteins of flour. In view of the modern theory that the properties of gluten are due to small quantities of associated salts, the effect of the added sodium chloride must be taken also into account. Salt also checks diastatic action and fermentation to some extent. Use is made of this property by the baker in dealing with sponges which are over-ripe: a little more salt than usual is used in making the dough, and the subsequent fermentation is retarded and the disintegrated gluten somewhat toughened.

To make a large, well-aërated, shapely loaf of good colour and flavour, it is necessary to use a large proportion of flour from strong wheats. Such a flour usually contains more nitrogenous compounds than a weak flour. Commercially, a demand has arisen for strong flours, which accordingly realise a higher price than weak flours. The strongest flours come from parts of the United States and Western Canada, also from Hungary. English wheats give, as a rule, weak flours, which by themselves are unsuited for modern bread making.

It is the object of the large millers to produce a brand of flour suited for bread making which is a blend of several wheats, and to maintain this brand of flour of uniform quality throughout the year. The preparation of sample loaves, made under carefully standardised scientific conditions, still remains the most satisfactory test of quality, and many flour mills maintain a laboratory for this purpose.

According to Humphries, the starch of flours made from wheat grown in hot, dry climates is very stable and resists disintegration. Such flours require special treatment, the addition of malt extract being a very common process. This addition generally causes an improvement in flavour, due, it is supposed, to the production of dextrinous products, which further have the effect of making the bread more moist.

There is a loss of weight during panary fermentation, due to the conversion of carbohydrates into alcohol and carbon dioxide. Jago estimates this loss at 1·3 p.c.; other authorities give somewhat higher values. Experiments made at Pittsburg indicate that over two-thirds of the total fat present in flour is lost during baking.

The manufacture of bread. To-day, in large towns, bread is usually made in bakeries on a manufacturing scale, and machinery is employed for the mixing of the dough, weighing and moulding of the loaves, whilst the baking is carried out in large draw-plate ovens.

There are various systems of bread making depending on whether the dough is made right off in one operation, or whether a portion of the flour, the yeast and the water, are first made up into a loose paste—the sponge—and the rest of the flour added some hours later. A third system involves the preparation of a ferment most commonly consisting of potatoes, boiled and mashed with water to which a little raw flour is added. The yeast is introduced into this and fermentation carried out so as to favour growth and reproduction and get the yeast in a particularly active state. Flour is added to make a sponge, and this, some hours later, made into dough. The longest system of fermentation is that practised in Scotland. An eighth or tenth of the flour is made into a fairly tight dough with a little yeast and allowed to lie 14 to 18 hours, during which time the gluten becomes almost entirely soluble, and the dough acquires a distinctly vinous smell and taste. It is then broken up with flour and the remainder of the liquor to a thin sponge, which lies about 1½ hours till it shows signs of turning and is then made up into a rather soft dough. The long systems formerly in use, were partly the result of custom and partly due to the slow working yeasts used. To-day, particularly in large bakeries, the tendency is in the direction of the straight dough, though the sponge-and-dough method is very largely practised. It has been claimed that the longer processes require less yeast, make bulkier bread, and bread of better flavour.

When the dough is ready it is scaled off and kneaded into shape. This presses out nearly all the gas and toughens the gluten; if it is not thoroughly done the loaf is likely to contain holes. The loaves are next put aside in a warm place to prove, during which the gluten relaxes and the yeast expands the dough evenly. Too much proof must be avoided, as on putting the bread in the oven the excessive expansion is frequently followed by the collapse and flattening of the loaves. The loaves are then baked at 450°-500°F., a 2-lb. loaf requiring about 40–50 minutes. During baking, the gases are at first expanded and the dough swells, the yeast is killed, some of the starch cells burst, the heat sets the gluten and the starch, and finally the crust is converted into dextrin and in part caramelised.

It is the baker's object to get the maximum number of loaves from a sack of flour. Accordingly, that flour is selected which has the greatest power to take up and retain moisture. Such flours are often termed strong. A sack (280 lbs.) of good flour yields about 96 quartern loaves.

Vienna bread is a term applied to rolls and light fancy bread baked in an atmosphere entirely charged with steam, to obtain which a special oven construction is adopted. The starch of the flour is burst by heat and changed into dextrin by the aid of moisture, so that a rich golden-brown highly glazed crust is obtained.

Leavened bread.—In France and elsewhere on the Continent, bread is made from leaven, but in the more important towns this mode of bread making has been given up for the Viennese and English processes. The practice in the preparation of the leaven consisted in a series of stages ('levain de chef, levain de première, levain de seconde, levain de tout point'), by which, starting with a piece of dough put away from a previous baking and adding at intervals more and more flour and water, the required quantity is leavened. From this is taken a half, which when baked yields a dark, sour bread; the remainder, being again mixed with a quantity of flour and some yeast, produces a whiter and less sour dough, a portion of which is baked and the residue once more added to fresh flour. This subdivision is repeated three times, the bread improving at each stage. A characteristic example of leavened bread is seen in the rye bread (Schwarzbrod) of Germany.

Next to wheat, rye is the chief bread-making grain throughout the world, and in particular it is largely used in Northern Europe. Rye bread is moister, closer, and darker in colour than ordinary household bread. There are several qualities, differing in the proportion of bran contained, the so-called 'pumpernickel' being an extreme example. Fine rye bread is as digestible as wheaten bread, but in the case of pumpernickel a very large proportion is unabsorbed (Romberg, Archiv. f. Hygiene, 1897, 28, 244).

Baking Powders.—Carbon dioxide may also be generated within dough by the action of baking powders, which are usually mixtures of sodium carbonate and some acid or acid salt, and evolve gas when moistened or heated. Owing possibly to the difficulties of distributing fresh yeast, baking powders were formerly widely employed in America. They are not used much in this country for white bread. They are usually classified according to the acid constituent, as tartrate, phosphate, or alum powders (v. BAKING POWDERS). The so-called self-raising flour contains baking powder already mixed with it.

Aërated bread is made by injecting carbon dioxide into dough by mechanical means. The process was originated by Dr. Dauglish in 1859, and at one time enjoyed considerable popularity, but it has not met with universal favour on account of the raw and insipid taste of the bread, due to the absence of the products which yeast produces during fermentation. The carbon dioxide is produced separately and forced into water under pressure: this water is mixed with the flour in a specially constructed vessel, in which the pressure is maintained. On opening the vessel, the dough rises and can be immediately baked. The advantages claimed for the system are uniformity of result, and the avoidance of the losses in weight which occur during fermentation. A later development consisted in mixing a little wort, made from malt and flour and fermented till sour, with the water to be aërated, so as to improve the flavour. The process is eminently suited for the manufacture of whole-meal bread, as the preparation of a batch of dough can be effected in thirty minutes.

Composition of Bread.—The general composition of bread is very variable. About two-thirds of the volume is made up of gas. By weight it contains 40–50 p.c. of water and 6·5 p.c. of protein, the balance being mainly carbohydrate. Hutchison gives the following mean figures for a number of breads analysed by him:—

	Water	Protein	Fat	Carbohydrates	Cellulose	Ash
White . .	40	6·5	1·0	51·2	0·3	1·0
Whole meal .	45	6·3	1·2	44·8	1·5	1·2

On keeping, a loaf gradually loses moisture to the extent of 8 p.c. in 48 hours, 14 p.c. in 72 hours (Goodfellow) or 14 p.c. in 1 week (v. Bibra). At the same time, the bread becomes stale, but this change is not attributed to loss of moisture, as much of the freshness is restored on heating, during which considerably more water is lost. It is suggested that staleness is due to a gradual combination of water with the starch or gluten which is readily broken up by heat; or, alternatively, that it is due to the shrinkage of the fibres which form the walls of its visible pores.

Katz (Zeitsch. physiol. Chem. 1915) has shown that, whereas the softening of the bread crust is due to the absorption of moisture, the crumb will become stale even when no loss of moisture takes place.

The experiments indicate that when bread crumb is kept at ordinary temperatures and loss of moisture prevented, the starch becomes harder and the amount of water-soluble polysaccharides diminishes, the latter being suggested as the cause of the sweeter taste of new bread as compared with stale.

The gluten appears to absorb moisture from the starch granules as staling proceeds, the latter shrinking, with the result that the granules are readily separable from the gluten, thus causing the bread to become crumbly.

The shrinkage of the granules can be seen with the microscope, narrow air spaces being observed between the granules and the gluten.

The adulteration of bread with alum, zinc, and copper sulphates, lime, &c., is now entirely a thing of the past. These were added to prevent the injurious effects of an excess of diastase on the starch during panary fermentation when inferior flour was employed. The cheapening of flour and the critical demands of the public for a well-risen white loaf, as well as improvements in the miller's technique, have necessitated the use of the best flours in bread.

The question of colour, meaning brightness of appearance in crumb and crust, is an important one; at the moment, the demand is for a white loaf. Colour is largely a question of optics; a weak but very white flour may make poor dingy-looking loaves, whilst a darker, stronger flour will make loaves which are better aerated and hence appear much whiter.

A modern development is the artificial bleaching of flour, usually with nitrous fumes produced by some electrical process. There is no proof that bread made with bleached flour is deleterious to health, but its use has been forbidden in America under the Pure Food Laws. It is a matter of controversy whether bleaching by nitrogen peroxide is due to oxidation or to nitration. Bleaching does not change a low-grade flour into a higher one, and bleached flour should therefore be declared as such.

The souring of bread is one of the baker's problems. It is the result of a combination of bacterial fermentations, the bacteria being introduced by the yeast, by the flour, or, as should not occur, by the use of dirty vessels. The flavour of fermented bread improves gradually as the process proceeds until a maximum is reached, after which, if fermentation is continued, it begins to deteriorate. At this stage the alcoholic ferment is exhausted and the acid fermentation begins to predominate. The sourness is mainly due to lactic and acetic acids, the odour to acetic and sometimes butyric acids (J. Soc. Chem. Ind. 1916). A cause of mustiness in bread has been traced to the presence of *Rhizopus nigricans* and *Aspergillus* in the flour from which the bread was made.

Extracts made from such flours when mixed with good flour caused mustiness or sourness in the resulting bread.

Such bread-diseases as ropiness (*cf.* E. J. Watkins, Ropiness in Flour and Bread, J. Soc. Chem. Ind. 1906, 350) are due to specific bacteria. According to Kayser and Delaval, ropiness is due to bacteria of the genus *Mesentericus*, originating in flour. The spores form rods 3–6 μ long and 0·4–0·6 μ thick, sometimes united in pairs and very resistant to chemical and physical reagents. The development on bread is very rapid with abundant spore formation. The bread becomes yellowish-brown, soft, and viscous and acquires an objectionable smell. The addition of lactic acid to the dough with from 30 to 45 minutes baking, depending on the weight of the loaf, prevents the germination of spores.

In a modern bakehouse, bacterial diseases should not occur; they may often be traced to the use of unsound flour.

Whole-meal Breads.—The majority of the patent breads belong to the 'brown' variety, and contain more of the wheat grain than the white flour. In some, the finely ground bran is introduced, in others the germ, whilst a third class claim to contain the complete wheat grain. Bran is very rich in diastatic enzyme, here termed cerealin, and its introduction causes a very rapid conversion of the starch into dextrin and sugar. This causes the dough to become soft and clammy and to bake brown: in addition, it becomes very prone to souring. The use of sodium bicarbonate and hydrochloric acid for aërating whole-meal bread is common. When the fermentation process is used, the bran is not introduced until the dough stage. Whole-meal bread has a great tendency to become sodden; it has to be baked for a considerable time, and consequently often has a thick crust. Germ has a very injurious effect on flour, owing to its diastatic character, and the tendency to become rancid. Every effort is therefore made to remove it as completely as possible. When subjected to the action of superheated steam, the germ is cooked, the diastatic properties are destroyed, and it acquires a pleasant malt-like, nutty flavour and aroma. This process was patented by R. Smith of Macclesfield, and a mixture of one part of treated germ and three parts of white flour constitutes Hovis flour, from which Hovis bread is made.

The relative nutritive values of white and whole-meal bread is a highly controversial subject. It is claimed that whole-meal bread is richer in protein and so more valuable, but this is far from being generally true. A second contention is the larger amount of mineral matter, especially phosphoric acid, in the brown bread. This is certainly true, but experience has shown that the mineral matter is not all absorbed from white bread, whilst in whole-meal bread the quantity absorbed is so much less that it is probable the blood obtains much the same amount from both (Hutchison). Whole-meal bread is defectively absorbed, owing to the cellulose which it contains preventing the gastric juices from gaining access to the neighbouring nutritive ingredients, and for the same reason it interferes somewhat with the absorption of other foods. When the unsatisfactory nature of the whole-meal bread itself and the precautions necessary in its manufacture are taken into consideration, its universal use in times of plenty is not to be advocated. With bread containing added germ the case is different, the bran is absent and the food value, both as regards protein and phosphate, is larger than of white bread.

The use of flour containing the untreated original germ of the wheat berry for bread is, none the less, disadvantageous, since the flour easily becomes rancid and the germ enzymes commence to act on the gluten from the moment the flour is made, causing the loaf to be of poor colour and to be less finely vesiculated and digestible. These factors more than outweigh the advantages of the very small additional amounts of protein, oil, and phosphate introduced and the slightly sweeter flavour of germ bread. The germ contains 10–12 p.c. of oil, which, it is stated, can be used for the production of margarine. Under war conditions in Germany arrangements were made to collect the germ from the mills and extract this oil. The residue of the germ yields a valuable protein food. The germ also contains such vitamines as are present in the wheat-grain. If the vitamines which are considered as essential to the maintenance of health, are to be obtained from none of the other foods eaten in the dietary, then wholemeal bread will have obvious advantages over that made from white flour. However, in actual practice this is not the case.

The desire for more phosphates can be met by the addition of phosphoric acid to the flour, as is indeed being done at the present moment during the milling process in order to improve the quality of flour (*cf.* Humphries, Eng. Pat. 13135 and 17279 of 1908; Chitty and Jago, Eng. Pat. 22434 of 1909; Levin, Eng. Pat. 3073 of 1910).

Under the stress of war conditions both milling and baking practices were altered, and every effort was made to render the maximum possible proportion of the wheat grain available for human food. Millers were only allowed to manufacture straight run flour, and the percentage to be extracted from wheats of various origin was laid down in numerous orders under the Defence of the Realm Act. This amounted to 81 p.c. for English and hard Manitoba wheats, and 83 p.c. for Indian and Australian varieties. In addition, not more than 25 p.c. and not less than 10 p.c. flour from other cereals was to be mixed with the wheaten flour. Bread was to be at least 12 hours old before it was sold.

E. F. A.

BREAD FRUIT. The fruit of *Artocarpus incisa* (Linn.). The tree grows freely in tropical islands, and yields fruit continuously for 9 months in the year. The fruit is nearly spherical, and sometimes weighs 5 or 6 lbs. It is usually gathered while yet unripe, *i.e.* before its starch has changed into sugar; sometimes the unripe fruit is peeled, wrapped in leaves and cooked whole, when a product resembling ordinary bread is obtained; or the unripe fruit is dried, powdered, and sifted, yielding a flour which has the following composition:—

Water	Protein	Fat	Starch	Fibre	Ash
14·3	1·0	0·2	83·8	0·2	0·4

(Balland, J. Pharm. Chim. 1903, 17, [10] 476).

The leaves and wood of *Artocarpus incisa* are devoid of colouring matter (A. G. Perkin, Chem. Soc. Trans. 1898, 73, 1019). A closely related tree (*Artocarpus integrifolia*) bears a still larger fruit, 'jak fruit,' weighing about 25 lbs., of which about 26 p.c. is flesh, the remainder being rind 66 p.c., and seed 8 p.c. The flesh, when ripe, contains about 5 p.c. of sugar, mainly cane sugar (Prinsen, Geerligs, Chem. Zeit. 1897, 21, [72] 719).

H. I.

BREAN *v.* Oleo-resins.

BREEZES. (*Braise*, Fr.) The dust of coke or charcoal. The coke burner applies this term to the small residual coke obtained in coke burning. The sifted ashes removed from houses is called 'breeze,' and sold under that name to brickmakers and others. An arrangement for burning breeze is described in J. Soc. Chem. Ind. 5, 425.

BREÏDIN, BREÏN *v.* Oleo-resins.

BREMEN BLUE and **BREMEN GREEN.** Pigments containing a basic copper carbonate with alumina and calcium carbonate.

BREWING. Beer is made from water, malt, and hops. Raw, prepared grain, or sugar is often substituted for a portion of the malt, and some other vegetable bitters occasionally for a portion of the hops.

Water used in brewing must be free from sewage pollution, poisonous metals, or substances which may affect the flavour of the beer, such as iron.

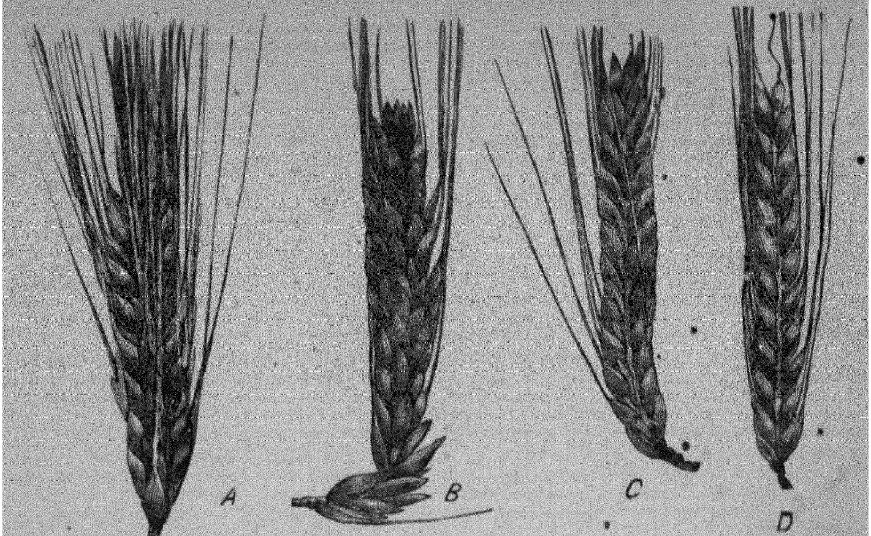
The composition of the water used in mashing has an important effect on the final product. Indeed, it may be considered that the reputation of the best-known brewing districts was initially due to their natural water supplies. The following table gives the amounts of the more important constituents of some of these waters. The figures represent parts per 100,000:—

	Burton	Dublin	London	Munich	Pilsen
CaO .	20–40	14	2–10	10–20	4–10
MgO .	5–15	1	1–2	3–4	2–4
SO_3 .	40–80	1–4	1–20	2–4	2–14
CO_2 .	15	10	4–35	10	3–5
Cl . .	4	2	2–10	6	1–4
Na_2O and K_2O .	6	1	4–20	—	2
Nitrates .	2–10	—	—	—	—

The Burton waters, by means of which are produced the finest pale and strong ales, are characterised by calcium sulphate with smaller quantities of carbonate, and magnesium sulphate and carbonate. Small quantities of chlorides and nitrates are usually present, even in waters which are free from sewage pollution. The amount of calcium sulphate varies considerably in the different wells, owing to the uneven distribution of the gypsum in the formations through which the water percolates.

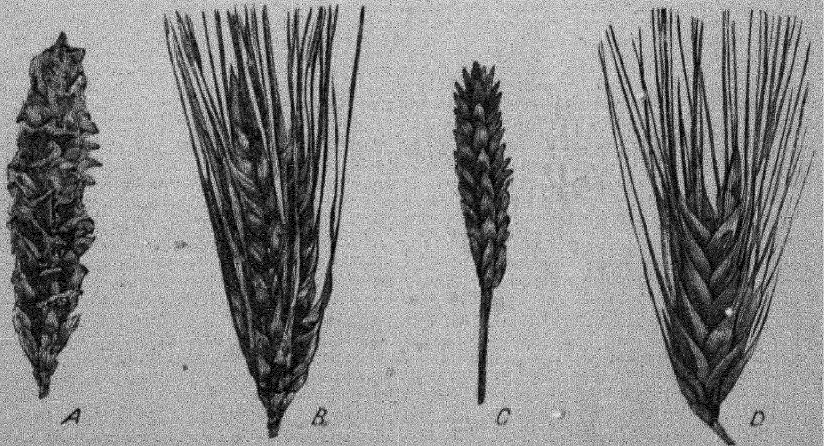
The Dublin water used in brewing the well-known stout has its chief constituent, calcium carbonate, removed by boiling before use, so that as used in the mash tun it is a very pure water.

The London waters are used for beer and stout brewing, but although the beers are not much known outside the district, London porter has more than a local reputation. They are chiefly characterised by calcium and sodium carbonate; sulphates and chlorides are also usually present. Some show a high amount of sodium chloride, and are, no doubt, contaminated by sea water, and if more than 100 parts NaCl per 100,000 are present are unsuitable for brewing.



TYPICAL SPIKES OF THE FOUR SPECIES OF CULTIVATED BARLEY.

A, Hordeum vulgare; B, Hordeum intermedium; C, Hordeum distichum; D, Hordeum deficiens.



SPIKES OF FOUR FORMS OF BARLEY, SHOWING SEVERAL COMMON CHARACTERS.

A is hooded; B and D are awned; C is awnless; A and B are naked; C and D are hulled; A, B, and C have narrow outer glumes, and D wide outer glumes.

FIG. 1.—VARIETIES OF BARLEY.

The Munich waters are very similar to the Dublin waters, and the dark full-flavoured lager is their product.

The Pilsen waters are extremely pure, and in the small amount of salts the carbonates do not dominate the sulphates, as in the Dublin, London, and Munich waters. The lager beer produced is a pale and delicate beer.

Waters containing sodium chloride up to 50 parts per 100,000 are considered suitable for brewing mild ales.

Where the natural water does not conform to one of these types, it is usual to make some attempt at imitating it by the addition of one or more salts. Thus, if pale ale is to be brewed, calcium sulphate or chloride is added; if mild ale, a smaller proportion of calcium salts and a little sodium chloride. For brewing stouts, the water is softened by the addition of suitable salts. In general, calcium and magnesium carbonates are removed by boiling or by heating under pressure with agitation. Such treatment, although resulting in a better beer, is said not to equal that obtained by the untreated natural waters.

Much has been written in order to explain the effect of the dissolved salts. Waters containing calcium sulphate produce pale, delicate beers which clarify well; calcium chloride appears to have similar effects. Calcium salts remove much phosphoric acid. Malt always contains more of this than the yeast requires, and it is possible that a removal of a portion may be beneficial, although it is conceivable that under some conditions, such as the use of a large proportion of some malt substitutes, too much might be removed. Magnesium salts do not give such satisfactory results; the beers have a reddish shade, and do not clarify so well. Sodium chloride produces a sweet flavoured beer. Calcium and magnesium carbonates give dark, harsh flavoured beers, which do not clarify easily, and these effects are accentuated if sodium carbonate is present.

On the whole, the evidence indicates that although the nature of the dissolved salts has some effect, yet the chief results are due to the change which the salts produce on the hydrogen ion concentration when the malt is mashed with the water.

The effect of acidity on enzyme action is well known, and the bad effects of alkaline waters are largely due to their restrictive effect on enzyme action. Schjerning (C. R. de. trav. du Lab. de Carlsberg, 1913, 312) measured the hydrogen ion concentration of worts made with waters containing various salts. He found calcium sulphate and chloride and magnesium sulphate and chloride, when about 100 parts per 100,000 are present, all raised this from P^h 6·1 to 5·7. That sodium chloride and sodium sulphate had no effect, and that calcium and magnesium carbonates lowered it. He also found that P^h 5·5 was the most favourable for enzyme action on the carbohydrates, and 5·3 for the proteid transformation, and that slight changes between this and 6·1, the normal P^h of malt worts prepared with distilled water, have a marked effect on these actions. Sherman and Thomas (J. Amer. Chem. Soc. 1915, 625) find a P^h 4·2 to 4·6 for the maximum diastatic action. The effects of these salts on enzyme action have been confirmed by other authors. H. T. Brown (J. Inst. Brewing, 1909, 216) and Weiss (C. R. du Lab. de Carlsberg, 1903, 216) found that calcium salts increased the amount of soluble nitrogen compounds, and many others have observed the effect on starch transformation.

Malt contains primary and secondary phosphates, and it is easy to construct an equation showing how calcium salts may increase the acidity, thus :—

$$4K_2HPO_4+3CaSO_4 =2KH_2PO_4+3K_2SO_4+Ca_3(PO_4)_2$$

Other equations may be written, showing the formation of dicalcium phosphate, but as this is also insoluble, the result will not be affected. It may be otherwise with magnesium salts, as dimagnesium phosphate is soluble, and this may explain the less satisfactory effect of magnesium salts. On the other hand, Schjerning found them to have the same effect on the hydrogen ion concentration as calcium salts.

The preference of brewers for hard water for brewing beers thus seems explicable; but the equally well-established fact that soft water must be used for stout does not appear so evident. The lager beer brewers also find hard waters unsuitable. Some Continental authorities have gone the length of stating that the most suitable brewing water for all purposes is water free from dissolved salts, but the faith of the pale ale brewer in his sulphated water remains. *See* also O. Miskowsky, Zeit. f. d. ges. Brau. 1911, 49 and 97; Windisch and Goldacker (Jahresber des. Ver. u. Lehranstalt f. Brauerei, Berlin, 1916; Readman, J. Soc. Chem. Ind. 1894, 367; Lott, Trans. I. Br. 1897, 344; Matthews, Trans. I. Br. 1893, 109, and 175).

Malt is made from barley, occasionally from wheat or oats. Barley used for malting is mainly of four different varieties:— Fig. 1.

A. *Hordeum vulgare* (*hexastichum*), found in commerce as Chilean barley, sometimes Syrian.

B. *Hordeum intermedium*, found in commerce as North African and Smyrna barley. Bere.

C. *Hordeum distichon*, found in commerce as Goldthorpe, Chevalier, &c.

D. *Hordeum deficiens*, Bulletin 622, Bureau of Plant Industry, Washington, U.S.A.

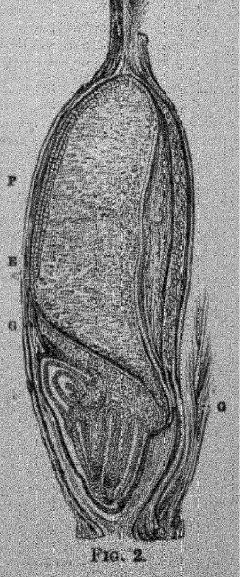


FIG. 2.

The barley corn consists of three chief parts, the coverings (the paleæ (P), the endosperm (E), and the embryo (G) (Fig. 2).

The coverings contain the greater portion f the cellulose and cellular matter, and a larger roportion of ash than the remainder of the orn; the endosperm contains the starch and ome reserve proteid.

The six-rowed barleys, the first two on the bove list, are smaller than the two-rowed arleys, roughly in the proportion of 3 : 4; he proportion of endosperm to the remainder f the corn is smaller, and consequently they ontain less starch. The chevalier barleys conain a less weight of skin (paleæ) than the oldthorpe.

The following table summarises the most rustworthy data obtained from the analyses f barley. Whilst the relative amounts of the onstituents differ, the same substances are resent in all ripe barleys used in malting, hether of different varieties, or grown under ifferent climatic conditions. Barley may be onsidered as normally containing 14 p.c. of oisture.

Average Composition of Dry Barley.

Starch	50–60 p.c.
Gums	9–10 ,,
Nitrogen compounds .	8–14 ,,
Sugar	2 ,,
Fat	2–3 ,,
Cellulose and fibre . .	15–30 ,,
Ash	2½–3½ ,,

The gums are hydrolysable to glucose, rabinose, and xylose (Lindet, Compt. rend 903, 73; O'Sullivan, Chem. Soc. Trans. 1882, ; Brown, Trans. Guiness Lab. 1906, 312).

Nitrogen compounds. 45 p.c. are insoluble n water and alcohol; 35 p.c. insoluble in water, ut soluble in 75 p.c. alcohol (hordeine); and 0 p.c. soluble in water (leucosin, edestin, &c.) Osborne, Amer. Chem. Soc. 1895, 539).

Sugars consist chiefly of cane sugar with a ittle raffinose and glucose (O'Sullivan, Chem. oc. Trans. 1886, 58).

Fat contains 78 p.c. neutral fat, 14 p.c. ree fatty acids, 4 p.c. lecithin, and 6 p.c. cholesterol (Stellwaag, Zeits. f. d. ges. Brau, 1886, 75).

Cellulose and fibre. About one-third is true ellulose.

Ash consists chiefly of silica and potassium hosphate; probably in the barley the phoshorus is not present as phosphate (Windisch, . C. 1906, 1573). A lipoid or diamino phosphaide has been identified. Barley also contains nzymes, including a diastase of translocation hich does not act on starch paste, but saccharises soluble starch (Kjeldahl, C. R. Lab. Carlserg, 1879, 129; Ford and Guthrie, J. Inst. rewing, 1908, 61).

Malting consists in the partial germination f the grain, by first steeping it in water, then llowing it to grow to a definite amount, and hen stopping the process by drying by heat.

The object in malting is to so modify the ell walls of the endosperm, and produce enzymes hat in the mash tun the starch may be readily issolved; to do this with the least loss by espiration or rootlet; without transforming oo much of the insoluble proteids into soluble ompounds; and avoiding the production of ndesirable decomposition compounds by moulds r bacteria.

It is evident that the first essential is a suitable barley. Such a barley must be mature in the widest sense of the word. If it is, then all the grains will, under the proper conditions, germinate evenly. It must be uniform in size and in composition, both chemically and morphologically. It must be free from damaged corns or foreign grain. Other things being equal, barleys with a high nitrogen content are not so satisfactory.

Elaborate schemes have been drawn up in Germany for the valuation of barley, based on a system of marking of points, but they are too cumbersome for ordinary practice. Experience enables a fair judgment to be made of the malting value of a sample. Unless a barley has been harvested under the best climatic conditions, it is found that its uniformity of germination is improved by drying on a kiln, and this is a common practice. Also that storage for a few months after harvesting is for the same reason advisable.

The malting process is commenced by steeping the grain in water. The steeping cistern is usually of brick or iron, and provided with a perforated bottom for drawing off the water.

It is usual to use a moderately hard water, such as would form a good domestic supply, but as some authorities advocate the addition of lime-water, it would appear that a slightly alkaline water is quite suitable.

Two or three days are necessary at a temperature of 10°–13° C. (50°–55° F.); the thicker-skinned varieties taking the longer time. About 50 p.c. of water is absorbed, and the grain becomes quite soft to the finger-nail.

One of the inner coatings of the barley grain is semi-permeable, and will not allow any of the soluble constituents to pass from the interior, nor admit anything but pure water from such waters as are likely to be employed for steeping (A. J. Brown, Proc. Roy. Soc. 1909, 81). A considerable amount of matter is extracted from the surface and outer skin of the grain, and, of course, from the interior of damaged corns. As numerous bacteria, &c., are always adherent to the surface of the barley, the water soon becomes putrid, and it is therefore customary to change the steep water several times.

The drawing off and renewal of the water aërates the steeping barley, and this is found to be beneficial.

Too long a steeping impairs the vitality of the corn, and too short does not allow sufficient water to be absorbed to carry on the germination sufficiently.

It is probable that germination commences during steeping, but the amount of change is small.

After steeping, the grain is thrown out of the cistern on to the growing floors. These are made of cement or tiles. Chitting soon begins, leading to the production of rootlets, and the plumule begins to grow. Owing to the adherence of the paleæ, the plumule grows up the side of the corn under these, and does not emerge until it reaches the distal end of the grain. The rootlets emerge from the proximal end of the grain. These outward appearances of germination are accompanied by profound change in the interior of the grain.

Germination is an enzymic process of demolition, followed by a building up. The embryo sécretes enzymes, which break down into a soluble form the reserve matters of the endosperm, and utilise them for its growth. So at any stage before germination is complete there will be a whole series of compounds present in the grain from complex to simple, and again from simple to complex.

One enzyme, *cytase*, attacks the walls of the starch cells; this action is most important, as on its completeness depends the tenderness of the malt. The walls of the starch cells of various barleys differ materially in their tendency to ready dissolution. Generally those barleys most prized for malting are those in which the cell walls give way most easily. These cell walls must be broken down before the starch is available; the products of their transformation form an important food for the first growth of the young plant. This dissolution not only precedes starch dissolution, but proceeds more rapidly, and this fact renders it possible to attack the greater parts of the cell walls before the starch is to any great extent dissolved. The diagram (Fig. 3) shows the process (Brown and Morris, Chem. Soc. Trans. 1890, 469). A at 3 days, B at 6 days, C at 10 days.

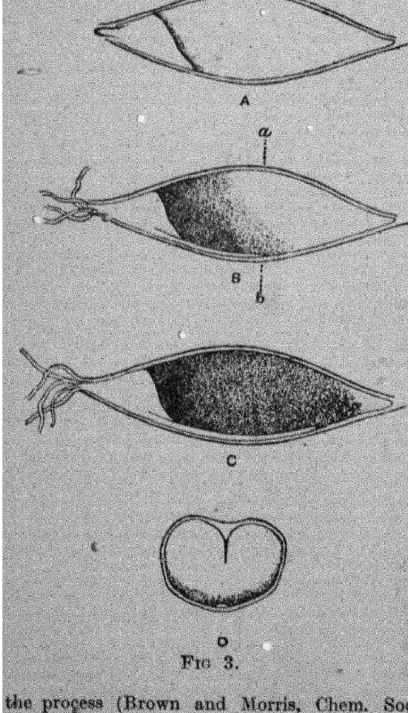

Fig 3.

Amylase attacks the starch and transforms it into sugars, part of which are still found in the finished malt, part utilised by the embryo and part oxidised by respiration to carbon dioxide and water. Proteolytic enzymes attack the reserve protoplasm (Weiss, C. C. 1904, 385); there are probably also fat splitting enzymes, &c.

These changes are affected by temperature, amount of moisture, aëration, and the business of the maltster is to control them. This he does by turning the malt, spreading it in thick or thin layers, sprinkling it with water, and regulating the temperature of the malthouse as best he may. If the temperature be allowed to rise above 12°–13° (55° F.), increased enzyme action leads to larger rootlet production and respiration losses. Increased temperature, accompanied by increased moisture, leads to increase in both proteid and starch degradation products in the finished malt (Brown, J. I. Br. 1909, 190). If too much water be given the plumule (acrospire) grows too fast. Both excess and deficiency of water reduce oxidation and rootlet growth. If the carbon dioxide of respiration is too much dispersed by excessive turning and the grain is too much aired, there is excessive respiration loss. Too little oxygen impairs the necessary germinative changes (Schjerning, C. R. Lab. Carlsberg, 1910, 169; Brown, J. Inst. Brewing, 1907, 394; and 1909, 170). The grain having grown several bushy rootlets, and the acrospire from 2/3 to 3/4 up the grain, it should have arrived at the proper state of endosperm modification; that is, the cell walls should be broken down. 10°–13° (50°–55°F.) is considered the most satisfactory growing temperature (Day, C. J. 1891, 664; Blaber, Brewers J. 1907, 359; Weiss, C. C. 1904, 373). The time on the floor necessary for this is from 10 to 12 days at the usual malting temperature (50°–55°F.), the thin six-rowed varieties take longer. Some Continental malsters floor the malt for a shorter time, but they are satisfied with a less modified malt.

In order to save the considerable amount of labour and space necessary in a floor malting, and to obtain more command over the temperature, several other germination methods have been devised; these go by the general name of pneumatic malting. The steeped barley is placed in rotating drums which are supplied with cooled saturated air, the amount of which may be regulated at will. The difficulty is, that in cooling the malt by a current of air excessive respiration takes place, and this often at the later stage of germination, when a check on respiration is most necessary. A method of overcoming this is to conduct the final stage of germination in the drum or in a box in which the carbon dioxide is allowed to accumulate.

The grain is now ready for the next process that of drying.

The kiln consists of a tall building adjacent to the growing floor. On the ground floor is one or more fire baskets for burning coke or anthracite coal, or a furnace for heating air in case the drying is to be done without bringing the products of combustion in contact with the malt. The former is the British plan, the latter the Continental Above the fire baskets or furnace, is a floor or two floors of perforated tiles or wire mesh, on which the grain to be dried is loaded, and above is a roof with a cowl or other suitable ventilating appliance with adjustable openings. The air inlets on the ground floor are also capable of regulation.

If the kiln has two floors, the drying is begun on the top floor and finished on the bottom floor.

The malt being loaded in the kiln, the temperature is slowly raised so that about 65°–66° (150° F.) is reached in three days, when the temperature is further raised to 93°–94° (200° F.) more or less, dependent on the kind of malt that is being dried.

Owing to the slow rise of temperature, germination continues during the earlier stages of drying; but as the temperature increases the vitality of the corn is destroyed, the enzymes being reduced or altered. The amount of diastase in the dry malt is 1/3 to 1/4 of that in the green malt. In the last period empyreumatic products are produced by the caramelisation of the carbohydrates and proteids, and the well-known biscuity flavour appears. In order to produce this, the temperature and moisture must have a certain correlation. Too much water at a high temperature would produce a cooked product, and too little, not sufficient caramelisation.

If the products of combustion are allowed to come in contact with the malt, care must be taken that the fuel used is free from arsenic. Coal and coke nearly always contain some, so that that variety must be selected which does not contain more than 1/20 grain arsenic per pound.

When the malt is dry, it is removed from the kiln and passed through a machine which first detaches the rootlets by beaters, and then separates them from the malt by screens. When cool, the malt is stored in air-tight bins until required for use in the brewery. If exposed to damp air, it absorbs moisture and deteriorates.

The rootlets or 'culms' form a valuable cattle food, a large part being digestible. Their composition is :—

Fat	1–2	p.c.
Proteids	24–28	„
Carbohydrates	42–48	„
Cellulose and fibre	11–15	„
Ash	6–7	„

100 parts dry Chevalier barley yield on the average 89 parts malt; 4 p.c. is lost in rootlets, and 7 p.c. in respiration (E. S. Beaven, J. Inst. Brewing, 1902, 587).

The changes which take place when barley is converted into malt are complex. In a normally malted barley about 60–70 p.c. of the nitrogen compounds are in some way altered, and about 35–40 p.c. have passed from the endosperm to the embryo. Some of the nitrogenous compounds are removed with the rootlet, so that malt always contains less than the barley from which it is made. On the whole, a large proportion of the insoluble albuminoid of barley is still insoluble in the malt; the hordein is partly converted into a similar body, *bynin*, and partly into soluble nitrogenous compounds of lower molecular weight.

The soluble bodies are further degraded. About 40 p.c. of the nitrogenous bodies are permanently soluble on mashing. The nitrogen in the non-coagulable nitrogenous matters of malt soluble in cold water is distributed as follows: (H. T. Brown, J. Inst. Brewig, 1907, 413):

Ammonic nitrogen	3·5	p.c.
Albumose nitrogen	20	„
Peptone nitrogen	31	„
Amide and amine nitrogen [1]	8·5	„
Organic bases nitrogen (betaine, choline)	4	„
Unaccounted for	33	„
	100	

When mashed, the soluble nitrogen substances will be increased about 50 p.c. Schjerning (C. R. Lab. Carlsberg, 1910, 387) states that 20 p.c. of the total nitrogen of the malt should be tryptic decomposition products (ammonia, amine-amid), and that 5 or 6 p.c. of the total nitrogen amount occurs in the wort as albumin (leucosin). About one-third of the total nitrogen of the malt is soluble on mashing.

From 16 to 18 p.c. of the starch has been transformed into sugars the greatest portion (9–15 p.c.) is found in the malt, a portion has been utilised by the growning embryo, another portion is removed by the rootlet, and some has been lost by respiration.

Malt is always more acid than barley, and it has been suggested that as it usually contains less fat than barley, a portion of this is due to saponification and corresponding liberation of fatty acid. The increased acidity has also been attributed to the work of acid-forming bacteria during the flooring and early stages of the drying.

Malt contains fats containing free fatty acids and unsaponifiable matter; also a lipoid (diaminophosphatide) (Lüers, Zeitsch. ges. Brau. 1915, 97, 125).

Malt, like barley, contains amylans or gums, but we know nothing of the change produced in these by malting.

The cellulose and fibre are very slightly, if at all, affected by the malting process.

There is a little less ash in malt than in barley, as the steep water dissolves about one-tenth of it; the constituents are, however, unaltered.

One of the most important facts for the brewer is the proportion of the malt soluble in the mash tun. This includes all the water-soluble compounds of the malt and those transformed into soluble compounds by enzymes at the mashing temperature. The chief of these is starch, but some of the insoluble nitrogenous substances are also rendered soluble.

The 'extract' varies from 75 p.c. or more for the best two-rowed varieties, such as English, Hungarian, &c., to 70–73 p.c. for Californian and Smyrna, and is as low as 65 p.c. for some of the very thin six-rowed North African varieties.

There is probably more than one amylase, perhaps two; one liquifies, and one saccharifies; but there may be more. It is said that amylase may be extracted by a 50 p.c. aqueous solution of glycerine or a 3 p.c. aqueous solution of pyridene, and that such extracts will retain their activity for years. Maltase is also present (Marino and Fiorentino, Gazz. chim. ital. 1906,

---

[1] Chiefly asparagine, a little leucine and tyrosine and a trace of allantoin.

395; Davis and Ling, Chem. Soc. Trans. 1904, 16).

A proteolytic and two peptolytic enzymes are present, the former with an optimum temperature of 56°–58° C., and the latter 25°–37° C., the first is destroyed and the others greatly weakened at 50° C.

Also peroxidase and catalases which exist in barley increase during germination and decrease by kilning (Van Laer, J. Inst. Brewing, 1906, 313; Schjerning, C. R. Lab. Carlsberg, 1910, 200).

Malt, as it leaves the kiln, is free from moisture, but on exposure it quickly absorbs a small percentage. Care must be taken that this does not exceed 3 4 p.c., or the malt becomes slack and deteriorates. Unknown (possibly proteolytic) changes take place which render it unfit for brewing.

As already stated, a portion of the malt is often replaced by substitutes In 1915 British brewers used 76 p.c. malt, 1 p.c. unmalted grain, 6 p.c. maize, rice, and other preparations, 16 p.c. sugars. American brewers used large amounts of raw grain or maize grits. German brewers in pre war days used no malt substitutes, but some used partially malted barley, which more nearly resembled barley than malt. Although no doubt unmalted grain, maize, rice, and their preparations are used on the score of economy, the same cannot be said of the sugar; the use of this is considered to yield a beer that clarifies quicker, but the chief reason is, that a fuller (sweeter) beer is obtained. This is what the public demands.

Maize, rice, and their preparations are used either as grits, consisting of the broken up endosperm free from the germ and coverings, or as the same material flaked, i.e. a form in which the starch has been partly gelatinised by moisture and heat

The sugars in common use are raw cane sugar (not raw beet sugar, which contains nauseous impurities), refined cane sugar, invert sugar prepared by inverting with weak acid raw cane sugar and purifying the product, and glucose prepared by the action of acid on starch (*q.v.*).

Hops give to beer its well-known flavour, and act as a preservative. They also fulfil other important functions in the course of brewing. A characteristic peculiarity of the bitterness of hops is that it is transient, after the beer is swallowed the bitterness at once passes away.

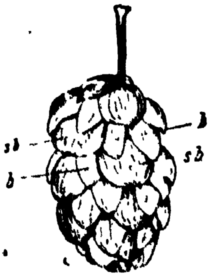

FIG. 4.

(*From Percival's Agricultural Botany, Duckworth & Co.*)

The ripe female flower is the part used in brewing. This consists of a cone of bracts (*b*). At the base of the bracts are the seeds and lupulin glands. Owing to the absence of male plants in the Continental gardens the hops are seedless. English and American hops are seeded owing to the presence of a few male plants in the gardens. There are good reasons for both these practices, dependent on the variety of hops grown. In an experiment made on English hops it was found that seeded hops contained 15 p.c. lupulin compared with 17 p.c. in the same variety seedless, but as the yield was much larger in the first case, 147 lbs. lupulin per acre were obtained in the one case against 92 lbs in the other.

The brewing value of the hop depends mainly on the lupulin The amount varies very greatly, from a few p.c. up to as much as 20 p.c. of the weight of the hop. It contains essential oil, wax, resins, and one or more alkaloids, &c

The essential oil forms 0·2–0·8 p.c. of the hops. It is easily soluble in alcohol and ether, but only in 600 parts of water. Its principle constituents are an aliphatic hydrocarbon *myrcene* $C_{10}H_{16}$, b.p. 166°–168°, and a sesquiterpene *humulene*, b.p. 263–266°, these form 80–90 p.c. of the oil. There are also oenanthylic, caprylic, and pelargonic ethers of myrcenol ($C_{10}H_{17}OH$) (Chapman, Chem. Soc. Trans. 1895, 783; 1903, 505; and Rabak, J. Inst. Brewing, 1915, 75).

Most of the oil is volatilised when hops are boiled with the wort, but as hops are also added to the finished beer, the oil from these latter will remain

The resin is said to consist of two crystallisable slightly acid bitter substances soluble in petroleum spirit, named the α- and β-resins, and a resin (γ-resin) insoluble in petroleum spirit, but soluble in alcohol and not precipitated by lead acetate.

All three are soluble in ethyl-ether and methyl alcohol

The α-acid $C_{20}H_{30}O_5$, m.p. 56° C., precipitable by alcoholic lead acetate, may be oxidised to valeric acid, the β acid not precipitated by this reagent is $C_{25}H_{36}O_4$, m.p. 92°–93° C., on oxidation yields a yellow resin; the γ-acid is stated by some authorities to be tasteless and valueless in brewing, and by others to have a slight bitter flavour and to be capable of coagulating some albuminoids from worts.

Authorities differ as to which of the first two are the more valuable in brewing; the β- acid is usually present in largest amount. Both of these are easily changed by heat or storage into insoluble and presumably less valuable resins The α- and β- or soft resins may be estimated in hops by extraction with petroleum spirit, which also extracts the wax; this may be removed by extracting with methyl ether, in which the wax is insoluble, and weighing the amount extracted; or titrating this with $N/_{20}$KOH, using phenolphthalein and taking 1 c.c. of normal potash as equal to 0·40 gram resin. There is considerable discrepancy concerning these resins in the literature of the subject.

About 2·5 p.c. of tannin is present in hops; whether this is of value as an albuminoid precipitant is uncertain. Hops also contain 0·5–1 p.c. nitrogen compounds soluble in hot water (Chapman, Chem. Soc. Trans. 1914, 1895 and 879). Small quantities of alkaloids are present in hops, and choline has been identified; also carbohydrates, fibre, ash, and moisture. An oil can be extracted from the seeds. Hops contain diastase.

Power, Tutten, and Rogerson (Chem. Soc.

Trans. 1913, 1291) examined the alcoholic extract which was insoluble in water and amounted to 14·1 p.c. of the hops examined. These were New Kent, containing 10·5 p.c. water, 2·4 p.c. tannin, 7·9 p.c. ash. They isolated from it :—

Ceryl alcohol $C_{27}H_{56}O$, hentricontane $C_{31}H_{64}$. A phytosterol $C_{27}H_{46}O$, A phytosterol glucoside $C_{33}H_{56}O_6$. A mixture of volatile fatty acids, consisting of formic, acetic, butyric, valeric, and a hexenoic $C_6H_{10}O_2$, b.p. 204°-208°, and identified as δ-*iso*propylacrylic acid and a little nonoic acid $C_9H_{18}O_2$; saturated and unsaturated non-volatile acids, including palmitic, stearic, and cerotic acids, and an acid $C_{20}H_{40}O_2$, m.p. 62·5°-63°, apparently an isomeride of arachidic acid, cluytonic acid $C_{21}H_{42}O_3$, m.p. 69°; humulol $C_{17}H_{18}O_4$, m.p. 196°, with a bitter taste; and xanthohumol $C_{13}H_{14}O_3$, m.p. 172°, tasteless.

It thus appears that the bitterness of hops is not due to any single substance, but is to be attributed to a number of products, most of which are amorphous. One well-defined bitter substance, *humulol*, has, however, been isolated.

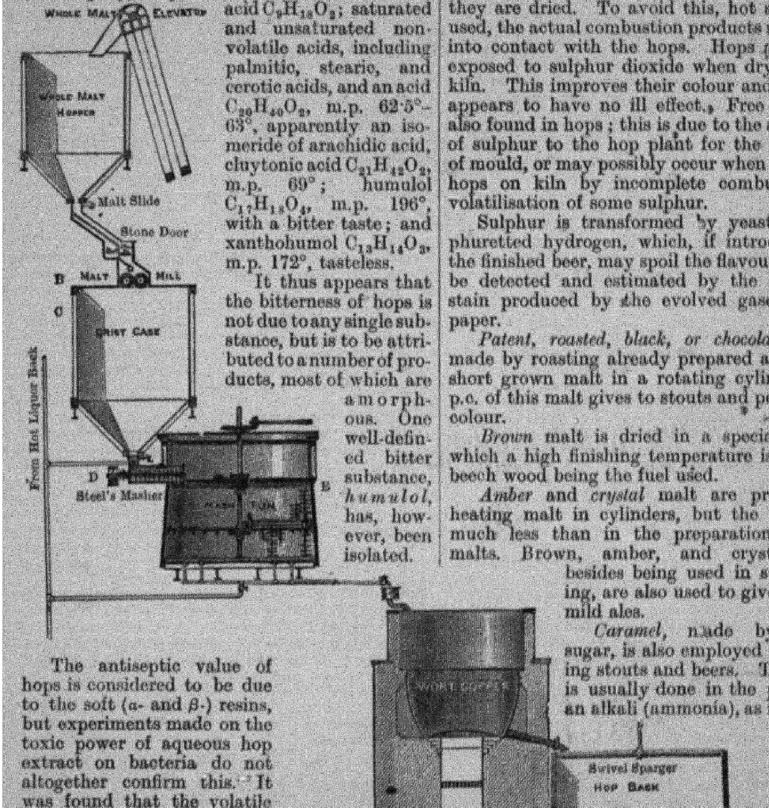

FIG. 5.

The antiseptic value of hops is considered to be due to the soft (α- and β-) resins, but experiments made on the toxic power of aqueous hop extract on bacteria do not altogether confirm this. It was found that the volatile constituents have no antiseptic power, that five-sixths of the antiseptic power was extracted by one hour's boiling with water, but that under these conditions not much of the soft resins was extracted, and the portion extracted seemed to be changed to the hard or insoluble resin. The antiseptic substance was present in true solution, and compared with other antiseptics was weight for weight more toxic to beer bacteria than salicylic acid or potassium metabisulphite (Brown, J. Inst. Brewing, 1910, 641; and 1913, 261).

It thus appears that the nature of the preservative substance of hops is still to be determined, and that the value of the results obtained from estimations of the so-called hard and soft resins is doubtful. In practice empirical methods are employed for valuing hops. These are based on the 'feel' and 'aroma' of the hops when rubbed between the hands. This, in experienced hands, enables a judgment to be made of flavouring and preservative values. It seems likely that the judgment so arrived at on the preservative power is often erroneous; but in the present state of the chemistry of the hop no more trustworthy means is available.

Hops are sometimes contaminated by arsenic derived from the fuel used in the kilns in which they are dried. To avoid this, hot air is often used, the actual combustion products not coming into contact with the hops. Hops are usually exposed to sulphur dioxide when drying in the kiln. This improves their colour and otherwise appears to have no ill effect. Free sulphur is also found in hops; this is due to the application of sulphur to the hop plant for the prevention of mould, or may possibly occur when sulphuring hops on kiln by incomplete combustion and volatilisation of some sulphur.

Sulphur is transformed by yeast into sulphuretted hydrogen, which, if introduced into the finished beer, may spoil the flavour. It may be detected and estimated by the amount of stain produced by the evolved gases on lead paper.

Patent, roasted, black, or chocolate malt is made by roasting already prepared and usually short grown malt in a rotating cylinder. Ten p.c. of this malt gives to stouts and porters their colour.

Brown malt is dried in a special kiln, on which a high finishing temperature is obtained, beech wood being the fuel used.

Amber and *crystal* malt are prepared by heating malt in cylinders, but the roasting is much less than in the preparation of black malts. Brown, amber, and crystal malts, besides being used in stout brewing, are also used to give colour to mild ales.

Caramel, made by heating sugar, is also employed for colouring stouts and beers. The heating is usually done in the presence of an alkali (ammonia), as in this way intenser colours are produced. For chemistry of caramel, *see* Cunningham and Dorée (Chem. Soc. Trans. 1917, 589-608). *V.* CARAMEL.

The first stage of actual BREWING is the grinding of the malt. If the malt were completely modified, that is, if the cell walls of the starch cells were completely disintegrated, this would be a comparatively easy matter, and the simple method of just crushing the grain between two plain iron rollers would be all that is necessary. Although malt never is perfectly modified, yet much that is made is sufficiently so for this method to be employed in many breweries. Still even with the best malts, when crushed by this method, it is possible to detect starch in the residue remaining in the mash tun after extraction is completed. This is due to the fact, as has already been described, that dissolution of the cell wall proceeds from the proximal to the distal end of the grain; and that as even the finest barleys do not germinate absolutely evenly, to avoid excessive loss from overgrown corns, the process must be stopped in many corns before its completion, so that there must be a number of corns containing a smaller or greater 'hard end.'

In order to reduce these 'hard ends' to a condition in which they will dissolve in the mash tun, they must be finely ground. If the whole corn were finely ground, the extraction would be so slow, as to make the process unworkable. Mills have therefore been devised in which the roughly crushed malt is separated by sieves and air currents into various portions, and the grits and hard ends finely ground and re-mixed with the remainder of the crushed malt Fig. 6 is a modern malt mill.

The grinding is usually preceded by treatment in cleaning machinery, in which the malt is brushed, beaten, exposed to a current of air, and sieved. Thus stones, surface dirt, straw, weevily (empty) corns, and other foreign bodies are removed.

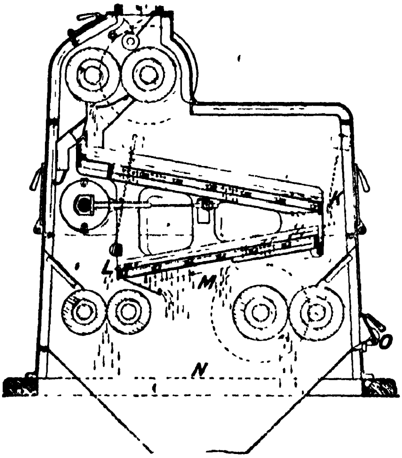

Fig. 6.

The ground malt is collected in receivers (malt hoppers or grist cases) until the amount required for the brew is complete. These receivers command the mash tun, the vessel in which the malt and water are mixed.

Fig. 5 is a diagrammatic representation of the mashing side of a brewery.

Mash tuns (Fig. 7) consist of wood or iron vessels fitted with false bottoms of perforated metal plates. Pipes are connected with the bottom of the tub for drawing off the extract (wort). In the upper portion, or above the tun, are inlets for the malt, hot and cold water; and an underlet for hot water is usually inserted in the bottom of the tun. The tun is generally provided with mixing gear ('rakes'). A sparger for sprinkling hot water on the surface of the mash is required, so that the grains may be thoroughly extracted.

At the proper time, water at a pre-determined temperature and the ground malt are mixed. This is done either by placing in the mash tun sufficient hot water and admitting the malt with constant stirring, or the malt and hot water are admitted together through a special mixing machine, a 'steel' masher being the one in common use (Fig. 8). The mash may now be treated by the 'infusion' or the 'decoction' system.

The infusion system is employed in the production of British beers. The mash (temperature about 65°–66° (150°F.)) is simply allowed to stand for a couple of hours, and the infusion then drawn off, the insoluble residue (brewers grains) is exhausted by sparging with hot water.

The decoction system is employed for the production of 'lager' beers. The malt is usually mixed with water to give a comparatively low temperature mash, 38°–49° (100°–120° F.) (sometimes cold water is used), and allowed to stand at this temperature for a couple of hours; no starch degradation takes place, but it is a favourable temperature for proteid transformations. About one-third of the thick mash from the bottom of the tun is run into a copper (mash-copper) and then boiled for half an hour, after which it is returned to the mash tuns; this raises the temperature of the whole about 30° F. After another interval, a further portion is withdrawn and boiled and returned to the mash tun, and this again repeated if required. The mash is then treated as by the infusion system.

Instead of being extracted in mash tuns, the mash may be pumped into a filter press, and in this way the wort separated from the insoluble residue. Special presses have been designed for the purpose. Larger extracts are obtained, as it is possible to deal with finer ground malt.

When the mixture (mash) is first made, there is a rise of temperature of 2°–3° F. due to hydration or adsorption; the drier the malt, the more heat is evolved. Starch transformation causes a rise of 0·5° F. Important enzymic changes take place in the mash. The chief of these is the saccharification of the starch. There are also important proteolytic changes and other less important enzymatic actions. These changes are influenced by the temperature, fineness of grinding, amount of dilution, duration of the process, and composition of the mashing water, &c. The temperature has a great influence on the character of the starch transformation (*see* Starch). Brewery mashes are usually carried out between 63° and 68° (145° and 155° F.), and about four-fifths of the starch is converted into maltose; 65°–66° (150° F.) is the optimum temperature for quantity.

Proteid transformation is most active at a lower temperature, 45°–55° (113°–131° F.), but the action continues up to about 77° (170° F.). From 5 to 12 p.c. of nitrogen compounds are rendered soluble at 65° (150° F.), and if the decoction low temperature is employed, about 3-4 p.c. additional, but the change is chiefly in the production of more lower-grade bodies.

The fineness of grinding, as has already been pointed out, will affect the amount of extract, but the composition of the wort is not otherwise affected.

The extract increases with the amount of dilution up to 6 water to 1 malt, after which it decreases. This is due to an increase in the quantity of starch saccharified, as the amount of proteid transformation decreases with the dilution. All the enzyme actions reach their maximum amount within the first hour, or, at most, two hours.

The effect of alterations of the mashing water has already been described; the more sparging water is used for extracting, the greater is the amount of nitrogen compound extracted. For this reason brewers do not press the extraction too far.

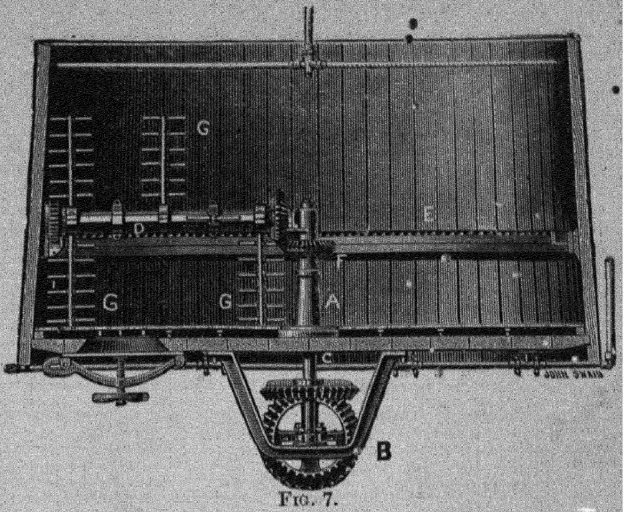

FIG. 7.

When raw grain or grits are used as substitute for a portion of the malt, the starch of these must be first gelatinised by boiling, and this when mixed with the mash is saccharified by malt diastase. It is stated, however, that if the material is finely ground, the starch can be saccharified in the mash tun by the malt diastase without previous boiling. Flaked grits will saccharify in the mash without previous boiling.

Sugars are usually added to the wort in the copper.

The draff or 'grains' remaining in the mash tun after extraction is completed, forms a valuable cattle food. It may be used fresh, and then contains about 70 p.c. water; in this state it does not keep well. If dried, it keeps indefinitely.

The composition of the dried product is :—

Carbohydrate .	41
Proteid . . .	22
Fat	7
Fibre . . .	16
Ash	4
Water . . .	10
	100

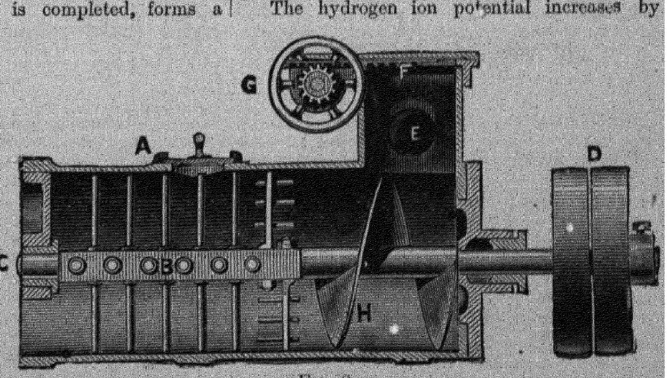

FIG. 8.

The mash tun wort as it flows from the mash tun is collected in a wort receiver or underback, and thence is conducted into the coppers where it is boiled with hops.

These vessels, as their name indicates, are made of copper (although iron vessels are also said to be used for this purpose) and heated by fire or steam. The amount of hops used varies with the quality of the beer to be brewed. Ordinary mild ales require about 1 lb. per barrel, bitter beers from two to three times this quantity, and export and strong ales still more. The average amount used in the United Kingdom in 1914–15 was 1¾ lbs. per barrel. Lager beer brewers use about ¾ lb. hops per barrel.

Boiling with hops destroys the enzymes of the wort, increases the acidity, precipitates coagulable albuminoids, hydrolyses some constituents, increases the wort constituents by the addition of the soluble portions of the hops, sterilises the wort, and darkens the colour, probably due to aëration causing oxidation.

The hydrogen ion potential increases by boiling with 1 lb. hops per barrel from 6 to 5·5, and to 5 if 2½ lbs. per barrel are added.

Proteid coagulation reaches its maximum after 4 hours boiling, about 5 p.c. of the total nitrogen is thus precipitated; the greater the amount of hops the greater the amount of coagulation, but as the hops contribute nitrogenous compounds, the total amount of nitrogenous bodies in the wort is not much affected.

After boiling, the contents of the coppers are emptied into the hop back, a vessel furnished with a false bottom of perforated plates by means of which the hops are strained from the wort. The layer of hops acts as a filter, and removes the albuminoids and other matter precipitated by boiling. The hops remaining are either extracted with hot water or pressed dry in a hydraulic press, the spargings or pressings, as the case may be, being added to the remainder of the boiled wort. The spent hops were formerly used as a manure, but now (1918), owing to the scarcity and high price of feeding stuff, are used as cattle food, either fresh from the brewery or usually dried and ground and incorporated with other materials. The dried hops contain 22 p.c. proteins and 35 p.c. assimilable carbohydrates (Baker and Hulton, J. Inst. Brewing, 1917, 455). The wort should run off from the hop-back quite 'bright.' It is now allowed to cool. Formerly only large shallow vessels were used, but now these vessels are of varying depth, or are sometimes dispensed with; in any case the wort remains in them only for a short time. The cooling is completed by allowing the wort to flow over refrigerators, vessels in which a current of cold water flows in tubes in the reverse direction to the wort which flows outside the tubes. The cooling stage is of considerable importance, both chemically and biologically.

The wort, during cooling, throws down a deposit, partly due to the separation of calcium oxalate, some of which forms a scale on the cooling vessel, and partly to a separation of minute particles called gluten particles, and which appear to be a compound of proteid and hop tannin (Brown, J. Inst. Brewing, 1913, 84). This substance contains about 10 p.c. nitrogen, it is easily soluble in alkalis, and is reprecipitated by a trace of acid. It not only separates during cooling, but continues to deposit more or less during all subsequent stages of brewing and storage. Although its total amount is small, never reaching more than 1 p.c. of the nitrogen compounds, yet owing to its liability to form opalescent suspensions, it is of considerable importance. Agitation whilst cooling from 49° (120° F.) to 27° (80° F.) is found to cause flocculation of these particles.

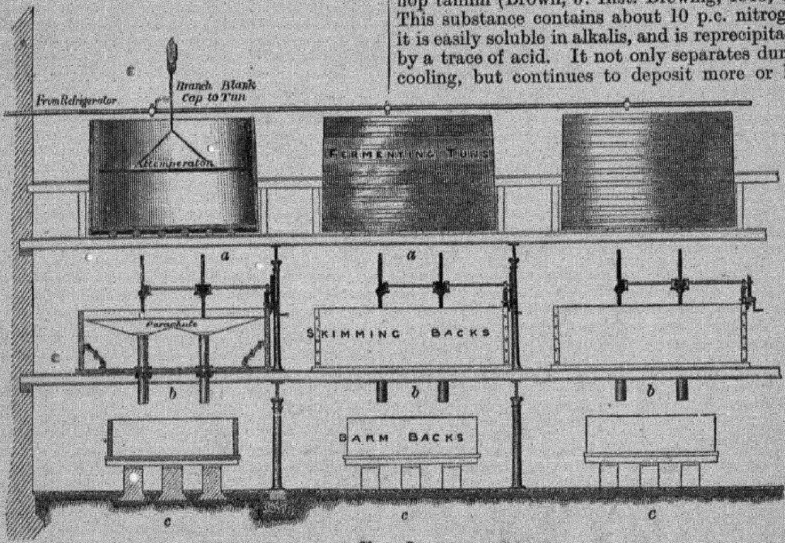

FIG. 9.

During the cooling process, the wort absorbs oxygen from the air. From experiments it appears that from 5 to 7 c.c. oxygen may be absorbed per litre of wort, the latter figure indicating full saturation.

The wort also usually becomes infected during cooling. Until the temperature falls below 55° C. (130° F.) there can be no infection; so for this reason coolers are sometimes dispensed with, and the worts run direct from hop back to refrigerator and thus rapidly cooled. This is effectual in reducing infection, but it has been found sometimes to lead to clarification trouble, which appears to be due to the separation of the above-mentioned gluten bodies in such a minute state that they will not deposit. In general some kind of cooler is used, either a shallow or deep vessel.

Infection on the cooler and refrigerator must be initially due to air infection, and proposals have been made to supply the rooms in which these are placed with sterilised air. In practice it is found, in all but exceptional cases, that the amount of air infection is very small compared with the amount of vessel infection. If the coolers are made of metal there should be little difficulty in keeping these sterilised, as the hot wort every time it covers them should do this; if they are wood it is found that, however well made, sterilisation is impossible. Owing to its porous nature organisms live in the pores just below the surface, and the non-conducting nature of the wood prevents any but the immediate surface layers rising to the sterilising temperature.

The refrigerators, with the necessary pipe connections, are metal, and it appears at first that there should be no difficulty in keeping these sterile, but owing to crevices at joints, &c., in practice complete sterility is impossible to attain.

With care, a harmful amount of infection can be avoided, and air sterilisation, although it may be looked on as a counsel of perfection, rendered unnecessary. If, however, precautions are not taken, the cooled wort may be very grossly infected.

The wort runs from the refrigerator at a temperature of 15°–16° (60° F.) or thereabouts, according to the time of the year and kind of beer, into the fermenting vessels. For lager beer, however, the wort is cooled to 5°–7° (40°–45° F.).

The fermentation vessels are made of wood, metal, stone, slate, concrete, &c. Metal may be considered the ideal material, as its surface is impervious, and it is easily sterilised. They are usually either circular or rectangular with flat bottoms; circular vessels have no corners in which dirt can accumulate, but rectangular vessels make more use of the often limited space.

As soon as the collection begins the wort is 'pitched,' *i.e.* is seeded with a yeast derived from a previous brewing. The number of yeast cells added is very much greater than the number of organisms with which the wort is normally infected. The amount, however, must be so regulated, according to the nature of the wort, that a considerable increase (5–10 times) is possible. The yeast '*Saccharomyces cerivisiæ*,' used by brewers, is a 'culture' yeast, that is, one which has been selected or possibly evolved in civilised communities as specially suitable for brewing.

There are two main varieties, 'high' or 'top' fermentation yeast, and 'low' or 'bottom' fermentation yeast.

The first is used at a higher temperature than the second; the brewery fermentations are consequently more rapid; the yeast rises to the top towards the end of the fermentation, whereas, under the conditions in which the latter is used, it falls to the bottom at the end of the fermentation. Lager beer is brewed on the low fermentation system; all other beers and stouts on the high fermentation system.

As worts usually become infected by other yeasts (wild yeasts) and bacteria during the cooling and subsequent processes, the yeast crop obtained at the termination of fermentation will contain foreign organisms. As this is used for seeding the succeeding worts, it is easily possible in time for the seed yeast to become seriously infected, even if the initial wort infection is kept down by suitable precautions. As will be seen later, these foreign organisms may lead to serious defects in the final product.

In order to surmount this difficulty, Hansen, in 1883, introduced his pure yeast system into bottom fermentation breweries He separated single yeast cells from the brewery yeast, and from each of these grew sufficient to make a trial brewing. The culture giving the most satisfactory result was selected and used in the brewery. A pure pitching yeast was thus obtained. This has been adopted with great success in lager beer brewing, but breweries working on the top fermentation system have not found the pure yeast thus prepared altogether satisfactory. Many reasons have been given for this. Although there seems to be no doubt that in some breweries, notably in Denmark and America, top fermentations are carried out successfully with a pure yeast; yet in many other breweries in which it has been tried, it has been abandoned. It is fairly well agreed that the explanation of its non-success is that a mixture of yeast is necessary in this case, although there is much diversity of opinion as to what this mixture should be (Claussen, J. Inst. Brewing, 1904, 308; Van Laer, *ibid.* 1894, 55; Siau, *ibid.* 1906, 118; Schionning, C. R. Lab. Carlsberg, 1908, 138; Morris, 1900, 333). Yeast may be freed from bacteria by treatment with solution of definite acidity (about 0·1 p.c. H_2SO_4) (Brown, J. Inst. Brewing, 1916, 328).

Fermentation by growing yeast cells is a complicated process, in which numerous chemical reactions take part. Although our knowledge of these is far from complete, yet many important factors have been determined. It is considered that only the hexose sugars are fermentable, the *di*-saccharides being first transformed into their constituent hexoses by enzymes, cane sugar by invertase, maltose by maltase. The rate of fermentation of glucose and levulose is independent of the concentration, except in very strong or very weak solutions; it is proportional to the amount of yeast.

The amount of yeast present in the fermenting wort at any time depends on many factors. If a small yeast seeding be introduced into wort, the yeast grows unrestrictedly until the concentration is sufficient to cause considerable chemical changes in the wort; the yeast growth is then slowed.

During the period of unrestricted growth the number of yeast cells increases logarithmally with the time; that is, over equal intervals of time (generation time) the number of cells double themselves. Brewers' yeast growing unrestrictedly at 20° C. has a generation time of three hours. Temperature has a great influence; between the limits at which yeast grows freely, 5° C. increase causes the rate of growth to be doubled. Carbon dioxide retards the rate; saturation with this gas halves the rate of growth. Alcohol over 2 p.c. retards the rate of growth, the amount depending on the temperature as well as the concentration. Air (oxygen) is necessary for yeast growth. Brewery wort naturally contains dissolved air, and oxygen combined with some wort constituent can also be used by the yeast. Half-fermented wort, saturated with carbon dioxide and prevented from absorbing oxygen by a covering of this gas, is deficient in oxygen necessary for yeast growth. The amount required is small. H. T. Brown estimates that 1·7 c.c. oxygen is necessary for the growth of 10^{10} yeast cells (about 2½ grams pressed yeast). Yeast growth also depends on the chemical composition of the wort. There must be present a carbohydrate, suitable nitrogenous substances such as are produced during the germination of the barley for the purposes of the growing embryo, and phosphates, potassium, calcium, and magnesium salts (A. J. Brown, Chem. Soc. Trans. 1905, 1395; H. T. Brown, J. Inst. Brewing, 1909, 169; and Annals of Botany, 1914, 197; Stern, Chem. Soc. Trans. 1899, 201; and 1901, 943; Slator, *ibid.* 1906, 128; 1908, 217; Biochem. J. 1913, 197; J. O'Sullivan, Chem. Soc. Trans. 1892, 593, and 926).

The changes which take place during the

fermentation of a brewery wort are briefly as follows: An average seeding (pitching) of 10 million cells per cubic cent. will increase up to about 100 million per c.c. There is a period of quiescence before growth starts. It then proceeds steadily, but retarding influences soon come into action and continually slow down the rate. The chief of these is the effect of carbon dioxide and the gradual failure of the oxygen supply. There is plenty of yeast food present, and the amount of alcohol is not sufficient to have any great influence. Rapid fermentation is now taking place, with evolution of large quantities of carbon dioxide which prevents air getting into the fermenting solution. It is at this stage of the fermentation that brewers who employ two fermentation vessels (*see* below) usually 'drop' or 'tun,' that is, transfer the fermenting worts from the one vessel to the other. This causes the removal of some carbon dioxide, and allows some air to be absorbed by the worts, there is a slight renewal of yeast growth; but the chief amount of yeast increase has now taken place. The rate of fermentation is now mainly dependent on the number of yeast cells and the temperature.

The influence of temperature is great; the following table gives the grams dextrose fermented per second by 10^{14} yeast cells (Burton yeast):-

Temperature	40° C. .	5·05 grams.
,,	35° C. .	4·05 ,,
,,	30° C. .	3·00 ,,
,,	25° C. .	2·08 ,,
,,	20° C. .	1·30 ,,
,,	15° C. .	0·68 ,,
,,	10° C. .	0·345 ,,
,,	5° C. .	0·140 ,,

The temperature continuously rises owing to the heat evolved by fermentation: the heat of fermentation of glucose is 22K. (Bouffard, Compt. rend. 1895, 357; A. J. Brown, J. Inst. Brewing, 1901, 93), and the brewer has to control this by suitable cooling appliances.

Glucose, fructose, and cane sugar are fermented faster than maltose; maltase is not so abundant in the yeast as invertase. Small amounts of glucose present in half-fermented wort may very likely have come from the maltose; there are also present in malt worts transformation products of starch of higher molecular weight than maltose, and there is some evidence that some of these are fermented.

The mechanism of alcoholic fermentation is still to be discovered, although some facts have been determined. Buchner and his co-workers (1893–98) proved that an enzyme capable of fermenting glucose could be separated from the living yeast cell by great pressure. Harden and Young (Proc. Roy. Soc. 1908, 299; 1909, 336; 1910, 321) have investigated this reaction and established the equation,

$$2C_6H_{12}O_6+2PO_4HR_2$$
$$=2CO_2+2C_2H_6O+2H_2O+C_6H_{10}O_4(PO_4R_2)_2$$

The hexose phosphate may be isolated and its salts prepared; when hydrolysed by acid it decomposes into phosphoric acid and fructose; it is slowly hydrolysed by an enzyme present in yeast juice and the resulting sugar fermented. By filtering the juice through gelatine supported by a porous filter cell, Harden and Young were able to separate the juice into two portions, either of which was itself incapable of fermenting glucose, but which regained this property when reunited. The filtrate containing the co-enzyme can be boiled without losing its activity, but the residue is thermolabile. Harden (Biochem. J. 1917, 1104) found that a mixture of potassium or ammonium phosphate with acetaldehyde or potassium pyruvate can function completely as the co-enzyme. Instead of yeast juice obtained from the living cell by pressure; these reactions can be carried out by Lebedeff's dried yeast (Compt. rend. 1911, 49), or zymin (Albert, Buchner, and Rapp, Ber. 1902, 2376).

How far this important work bears on brewery fermentation it is difficult to say. Fermentation by living yeast is not influenced by the addition of phosphates, and one-half of the sugar is not fermented rapidly and one-half slowly. It seems probable that there are intermediate products between the sugar, and alcohol, and carbon dioxide, and although much work has been done, the theories so far advanced do not carry conviction.

The chief products of alcoholic fermentation are alcohol and carbon dioxide, the amount of alcohol produced according to the simple equation of Gay-Lussac is 51·1 p.c. from a mono-saccharide, and 54·1 p.c. from a di saccharide. The sugars of malt worts consist of about 83 p.c. maltose and 17 p.c. of sugars pre-existent in the malt which are mainly cane sugar, glucose and fructose. H. T. Brown (J. Inst. Brewing, 1914, 693) found there was produced at the commencement of the fermentation 56 p.c. of alcohol (0–1·5 p.c. alcohol) falling to 52·6 p.c. (1·5–3·0 p.c. alcohol) and 51·5 p.c. (3 p.c. alcohol onwards).

Besides alcohol and carbon dioxide there are produced by the fermentation, glycerol, succinic acid (Ehrlich, Bied. Zentr. 1908, 197), and higher alcohols (Ehrlich, Ber. 1907, 1027; Ashdown and Hewitt, Chem. Soc. Trans. 1910, 1636).

A considerable reduction of the nitrogen content of the wort takes place during fermentation. This varies from 20 to 40 p.c. of the total wort nitrogen, according to working conditions. By adding more sugar and again fermenting it is possible to remove nearly 60 p.c., but a further fermentation will only remove a few per cent. more (H. T. Brown, J. Inst. Brewing, 1907, 423).

The hydrogen-ion potential increases during fermentation from 5 to 4 (Luers, Zeits. Ges. Brau. 1914, 79).

The amount of acid produced during fermentation is dependent on the acidity of the wort; within limits, the more alkaline the wort the more acidity is produced; thus the yeast tends to produce a certain favourable concentration of acid (Windisch and Koolman, Woch. Brau. 1914, 225; Moufgang, Brass. et Malt, 1913, 177 and 297; 1914, 72).

If the wort were left undisturbed in the fermentation vessel, the first cauliflower-like foam which forms in a few hours, would give place about two hours later to a larger rocky and glistening foam, and this in two or three days in turn to a yeasty head. Throughout the greater portion of the fermentation, the yeast, which has a higher specific gravity than the wort, is kept in suspension by the rising bubbles of carbon dioxide, but towards the end it flocculates and entangles the rising bubbles of

CO_2, the spongy mass thus formed rises to the surface, forming the yeasty head. If, however, not quickly removed, the gas is lost and the yeast falls to the bottom of the liquid. If yeast be not removed as soon as it rises, but be allowed to fall through the fermented wort (or beer as it now is), it communicates to this a yeasty flavour and spoils it. In bottom fermentation the yeast also flocculates towards the end of the fermentation, which owing to the low temperature proceeds much slower, and the yeast falls to the bottom of the vessel.

The top fermentation brewer, therefore, adopts some system of 'cleansing,' that is, some mode of removal of the yeast as soon as it rises to the surface. There are two typical systems in use, *i.e.* 'the skimming system,' in which the fermentation throughout proceeds in large vessels, and the yeast as it rises is skimmed off; and the 'cleansing system,' in which the latter portion of the fermentation is conducted in casks, and the yeast allowed to work out of the bung hole, the cask being kept sufficiently full by toppings of bright beer. There are many modifications of these two systems.

The skimming system is the one chiefly employed in the United Kingdom, but instead of skimming off the yeast by hand, an apparatus termed a yeast parachute is fixed in the fermenting vessel; this has a funnel shape with the narrow end in communication with a pipe passing through the bottom of the vessel (Figs. 9 and 10).

The height of the aperture is controlled by suitable gearing, so that the yeast as it rises flows over the edge through the pipe into a vessel below. In very large vessels this is assisted by the movement of the board. Attemperators, or coils through which cold water can be circulated, are usually fitted so that the temperature of the fermenting wort may be controlled.

It is usual to commence the fermentation in a plain vessel and 'drop' the wort when about half fermented into the skimming vessel. The effect of this has been described above.

An elaboration of the simple cleansing in casks, is the Burton Union System. This is so totally different from the skimming system that all others may be said to be intermediate, and it is not proposed to describe them.

The beer to be worked or 'cleansed' by the Burton System, is collected and pitched (seeded) in vessels of about 50 barrels capacity, and the fermentation allowed to proceed until the attenuation of the fermenting wort is about two-thirds of the original gravity, and the temperature has risen to 18°–21° (65°–70° F.). The wort is then 'tunned,' that is, transferred to the unions.

A set of Burton Unions (Fig. 11) consists of two rows of casks, each cask holding about 150 gallons, mounted horizontally on trunnions on aframe work. Above the casks is fixed a long shallow trough (the yeast trough), not quite one-half the width of the double row of casks, and at one end of the union set is a smaller cross trough, the bottom of which is a few inches lower than the yeast trough, but high enough to command the casks. Each cask is furnished with a swan neck which fits into a socket in the highest portion of the cask, and projects just over the edge of the yeast trough, and with a tap at the lowest portion of the cask, the nozzle of which projects a couple of inches into the cask. The tap has a screw thread, so that the inlet can be lowered or the tap entirely removed, leaving the cask opening free. The casks are also provided with attemperators through which cold water may be passed for controlling the temperature of fermentation. The yeast trough is also provided with attemperators which are counterpoised in order that they may be easily lifted up.

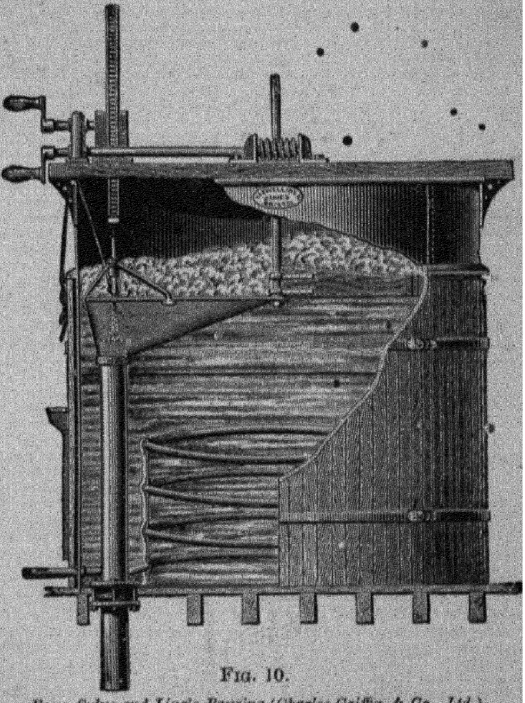

FIG. 10.

From Sykes and Ling's Brewing (Charles Griffin & Co., Ltd.).

At one end the yeast trough communicates with the cross trough or feeder by outlets at various levels, any one or all of which may be closed as required. The feeder communicates with the casks by a long side pipe, the feeder inlet of this having a screw cup which may be raised or lowered, in order to prevent sediment from the feeder getting into the cask, or the cup may be removed entirely. This pipe is furnished with a main tap to control the flow into the cask (the feed), and each cask with a separate tap, so that any one may be disconnected. There are also outlets from the yeast trough and feeder for removing yeast (barm).

The casks, top trough, and feeder are filled with the fermenting wort, but none of the vessels is full of liquid, as there is a considerable amount of foam. The fermenting wort in the cask is under the pressure of the head of liquor in the feeder, and consequently so long as carbon dioxide is being produced in quantity, a foam is forced up the swan neck into the yeast trough. This settles to some extent, and furnishes more head of liquor in the feeder, and so the circulation continues. With a wort of fairly high gravity the whole bulk of the brewing would circulate several times. When the fermentation nears the end, the character of the foam changes, owing to the rise of the yeast. It becomes yeasty, and in the yeast trough separates, a part of the yeast settling to the bottom, and a part forming a thick skin on the surface; in between these two layers is a stratum of fairly bright beer. This bright beer only is allowed to return through the feeder, where a little more settling takes place, into the casks, so that ultimately the casks become filled with more or less bright beer, and the greater part of the yeast remains in the yeast trough. The beer is allowed another day or so in the cask to settle, and it is then run from the bottom tap by a trough into a vessel below (the racking vessel), the tap projecting into the cask sufficiently to hold back the sediment (grounds).

The fermentation is so controlled that at the racking stage there always remains some fermentable sugar; and as whatever mode of yeast removal is adopted, it is impossible to remove all, some remains in suspension. In this state the beer is racked, *i.e.* transferred from the brewery vessels to the carriage casks. It is convenient and usual to employ an intermediate vessel (racking vessel). This is provided with taps, usually of special design, so that the casks are filled without loss due to overflow.

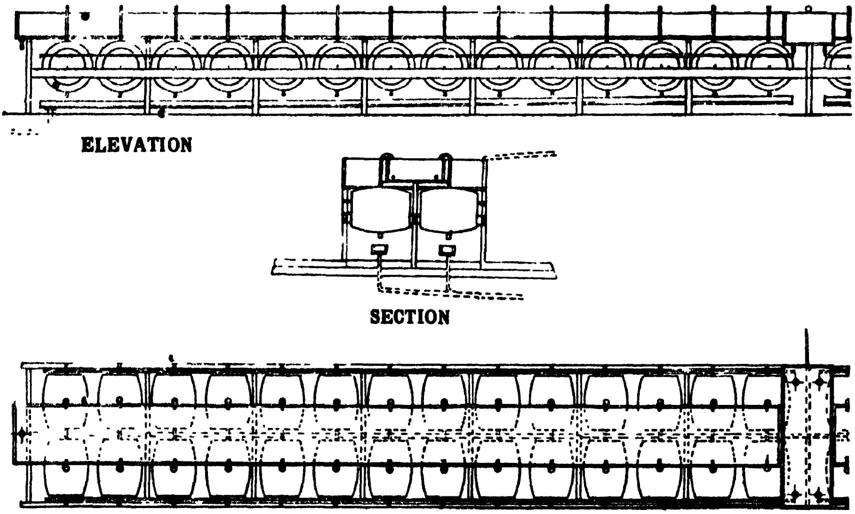

Fig. 11.

Lager beer is not racked into the carriage casks immediately at the conclusion of the brewery fermentation, but kept in cold stores for 2–4 months in lager casks (large vessels holding 100–3000 gallons). During storage a slow after-fermentation takes place, and during the last period the carbon dioxide is allowed to accumulate up to a pressure of 2–4 lbs. per square inch. The beer clarifies, and is racked into casks or bottles for immediate consumption. Stout is also often stored in vats between the end of the brewery fermentation and racking stage.

Several additions are commonly made to the beer when racked direct from the brewery vessels. Hops are usually added, from 2 oz. per barrel up to 1 lb. per barrel for strong or stock ales. Hops of fine flavour are chosen for this purpose, as the hop oil which is lost when boiled in the copper is here retained and adds to the beer aroma. Preservative substances of the hop dissolve in the beer, and the bracts, &c., mechanically assist clarification. Hops contain diastase, which, acting on some carbohydrate constituents of the beer, may produce fermentable sugar, and thus give life or 'condition' to the beer (Brown and Morris, J. Inst. Brewing, 1893, 94).

Sugar solutions are often added at racking, or shortly afterwards. This makes 'condition' certain.

An antiseptic, usually a sulphite, is commonly added. Beer naturally contains some SO_2, this is introduced during the kilning of the malt and drying of the hops; as much as 25 milligrams per litre have been found, but most beers contain only a few milligrams per litre (Bonn, Ann. des Falsifications, 1909, 44); it is also an ancient custom to sterilise the interior of the vessels with sulphur dioxide. When sulphurous acid (or sulphites) is added to beer, a portion is soon oxidised, the remainder combines with the sugars or other aldehydic or ketonic compounds, and in this state is much less toxic than the free acid. Wiley (U.S.A. Dept. of Agriculture, 1907) and Kerp (Arb. aus der Kaiserliche Gesundheitsampte, 1904, 21, 153–284; 1907, 26, 231) have made exhaustive investigations on its toxic action. The moderate use of this antiseptic is generally permitted.

The Beer Materials Committee, 1899, reported that it would be unwise to prohibit preservatives in beer. An International Food Congress, Paris, 1909, recommended that it be allowed up to 85 milligrams per litre. Such an amount has but a slight retarding effect on yeast growth and fermentation, and less is sufficient to prevent the growth of some common beer bacteria, such as *saccharobacillus Pastorianus*, which in the absence of sulphite may do much damage.

An important by-product of the fermentation is the yeast or barm; not so long ago this was a waste product difficult to get rid of, and only used as a manure. Now it is a valuable food, and otherwise useful.

The barm, as separated from the beer, is a thick creamy mass, and is usually pressed in a filter press, the bright beer being returned to the brewery vessels. The filter cake is a cream-coloured powdery mass containing about 75 p.c. water. If allowed to stand, it autolyses and liquefies in a few days by the action of the digestive enzymes it contains; the most satisfactory way to preserve it, is to dry it on steam-heated rollers. The pressed yeast is heated, when it liquefies, and then flows in a thin film on to the hot revolving roller, a current of hot air drives away the steam, and in about three-fourths revolution the film is dry and is scraped off by a fixed knife. Such dried yeast is an excellent food for cattle, but possesses a rather bitter flavour; this may be to some extent removed by washing the pressed yeast before drying with ammonium or sodium carbonate. It contains 5–10 p.c. water, 50–60 p.c. albumenoids, 25–35 p.c. carbohydrates, up to 4 p.c. fat, and about 10 p.c. ash, of which about one-half is phosphoric acid. By some refinements in the preparation a product is obtained resembling meat extract, and largely used in the preparation of dried soups (Petit, Brass. et Malt, 1917, 257). It has been shown to contain water soluble accessory growth-promoting substance; this is not present in meat extracts (Drummond, Biochem. J. 1917, 255).

From brewers' yeast is prepared nucleic acid (Clarke and Schryver, Biochem. J. 1917, 319); this, on hydrolysis, yields phosphoric acid, adenine, guanine, uracil, cytosine, and *d*-ribose. Yeast nucleic acid or its sodium salt is injected subcutaneously with the object of increasing the number of leucocytes. Silver preparations (nucleosil and nargol) are used in inflammatory diseases, and iron salts (fer ascolic and nucleogen) in cases of anæmia. Thyminic acid (solurol) is also prepared from yeast and used for rheumatism and gout.

Brewers' yeast has been used from time immemorial for bread-making. Within recent years its use has been largely supplanted by 'bakers' yeast,' a different variety of *Saccharomyces*, which works at a higher temperature and does not undergo autolysis so quickly. This yeast, although not suitable for brewers use, is employed by distillers. Brewery yeast is, however, improved for bakers' use by passing through a fermentation in a not-hopped (distillers)' wort (Baker, J. Soc. Chem. Ind. 1917, 836). Yeast contains glycogen, as much as 40 p.c. has been found; when used in fermentation estimations yeast must be freed from glycogen by exposing it in thin layers to the air, otherwise there will be a considerable correction to be applied for the auto-fermentation of the glycogen (Henneberg, W. f. Brau. 1902, 781; and Zeit. Spiritusind, 1916, 242). It may be easily prepared from yeast (Harden and Young, Chem. Soc. Trans. 1912, 1928), and at the same time another carbohydrate, the yeast gum of Salkowski (Ber. 1904, 497 and 925) is obtained. This latter yields mannose on hydrolysis. Yeast contains about 2 p.c. lecithine (*di*-palmitoncholine-lecithine). Yeast has a strong reducing power, it reduces sulphur and also sulphites under certain conditions to sulphuretted hydrogen, and under starvation conditions can even reduce sulphates (Stern, Chem. Soc. Trans. 1899, 201; and J. Inst. Brewing, 1899, 399).

The beer racked into the carriage casks is 'shived down.' The residual sugar and yeast react, and the carbon dioxide produced by fermentation super-saturates the beer, and it is now ready for sale. If left undisturbed for a few weeks the beer will normally fall bright. This is not quick enough for ordinary purposes, so it is usual to add 'fining.' Fining is prepared from isinglass, the swimming bladder of various fishes, *i.e.* Acipenser (sturgeon) giving Beluga leaf, Siberian purse, and other Russian isinglass; Polynemidæ giving Bombay, East Indian, and Penang isinglass; Siluridæ (catfishes) giving Brazil lump; and some well-known food fishes as cod, whiting, haddock, and hake giving inferior kinds of isinglass (Bridge, J. Inst. Brewing, 1905, 508). Sole skin is also used. To prepare fining, isinglass is soaked in water acidified with acetic, tartaric, or sulphurous acid, or a mixture of these; it swells up, and more water is added from time to time, until the isinglass is thoroughly 'cut' and a viscous liquid is obtained, from which the undissolved skin is removed by wire sieves. About 3 lbs. of isinglass makes a barrel of fining. From 1 pint to 1 quart added to a barrel causes a coagulation in which both fining and the suspended matter of the beer take part and which soon settles out, leaving the beer bright. If the cask is vented and carbon dioxide is coming off freely, the coagulum is entangled by the rising bubbles of gas and expelled through the vent hole. Fining will not remove actively fermenting yeast or bacteria. It is known that beer colloids carry an electric charge and move to the cathode (Emslander and Freundlich, Zeitsch. physikal. Chem. 1904, 317), and a simple explanation of the action of fining appears to be that the fining colloid carries an opposite charge, and hence, when mixed, the two coagulate.

Isinglass dissolves in hot water, and a solution of gelatine is obtained, which however has no fining action on beer.

The cask of bright beer is now ready for consumption. Cask beer kept 'on tap' more than a few days deteriorates owing to the loss of carbon dioxide and aeration. Bottled beer is free from this risk of deterioration and has advantages of convenience; hence an increasing demand has arisen for it.

If bright beer be bottled, corked, and placed on one side for a few weeks, it will usually be found that a growth of yeast has taken place with fermentation and consequent production of condition in the beer. The yeast easily settles out, and there is usually also a deposit of glutin bodies. This yeast will, as a rule, not be the yeast which has produced the brewery fermentation, and which has also produced the 'condition' which follows immediately on racking, but a wild (secondary) yeast possessing quite different properties, and which has fortuitously obtained access to the beer. The matter fermented corresponds with the composition of a mixture of dextrin and maltose (Morris, J. Inst. Brewing, 1895, 125). This fermentation would, of course, also take place if the beer had remained in cask, and the beer would have become turbid from the growth of the wild yeast; but when growth and fermentation were completed, the yeast would have settled out, leaving the beer again bright, but with an altered flavour. Only beers brewed with good material and a sufficiency of hop remain stable for the length of time necessary for the secondary fermentation and subsequent clarification; inferior and lightly hopped beers fall a prey to bacteria.

The best brands of bottled ale thus produced possess a character and piquancy which is definite and much in demand. Owing to the difficulty of always ensuring the correct amount of fermentable matter and secondary yeasts, and the preparation of a beer of sufficient stability, other methods of preparing bottled ale have been devised.

The most successful is to rack the beer into strong casks or metal tanks and add sufficient sugar, which, when fermented, will produce a considerable pressure of carbon dioxide. This having taken place, the casks containing the beer under pressure are placed in a cold store (if the beer has been conditioned in tank, the beer is forced by air pressure into a similar tank in cold store) and kept at a temperature of 2° (29° F.) for a week or more. The beer, when cooled, should still be super-saturated with carbon dioxide. The cooling causes a precipitation, and in time the beer would fall bright. This would, however, take so long that it is usual to filter the beer through cellulose pulp made up in a filter press. The beer issues from this brilliant, and passes to the bottle-filling machine; in this the pressure is maintained so that no carbon dioxide is evolved, which would cause foaming, and render the regular filling of the bottles impossible. The full bottles are removed from the machine and quickly corked. The beer is ready for immediate consumption, and when raised to room temperature pours out with considerable sparkle, and in this way resembles what may be termed naturally conditioned beer. It has the advantage of being free from sediment, but as the beer is not sterile, this only continues for a few weeks, after which a sediment forms. A considerable loss of colloids takes place during chilling and filtering, and this renders the beer inferior in flavour to beer not thus treated.

It is not usual to pasteurise beer brewed in this country; it keeps sufficiently well for ordinary use, which varies from a few weeks to a few months; strong ale, which is often kept for a year or more, keeps quite well for this time owing to its high alcohol content and hop rate; and export ale will remain stable for years, being brewed from fine malt and large proportion of hops. With lager beer, however, the contrary is the case; if required for export this must be pasteurised, usually at a temperature of 55°–60° (130°–140° F.), and is often so treated for home consumption as it does not keep more than 3–6 weeks at ordinary temperatures.

The chief beer brewing countries are the United Kingdom, the United States of America, Germany, Austria, Belgium, and Denmark. In each country the methods, and consequently the products, differ. The United Kingdom brewers employ mainly the high fermentation system, although a little lager is also produced. The beers are mild, bitter, and stout (porter). The mild ale differs from the bitter in being brewed with less hop, 1 lb. against 2 lb. per barrel for a wort of sp.gr. 1050, and with a higher dried malt giving a sweeter and darker beer.

Stouts and porters are prepared with an intermediate quantity of hops and roasted malt to give the black colour and flavour.

Pale ale is a bitter beer prepared from a wort of sp.gr. 1060 and about 3 lbs. hops per barrel. Strong and export ales are highly hopped, the wort for the former is usually of a sp.gr. 1100, but occasionally beer from worts sp.gr. 1125 has been brewed.

The average original gravity was 1052 in 1914, since then, special war restrictions have reduced this to 1030 (1918).

The average amount of hop per barrel used in 1915 was 1¾ lbs.

The beer duty is levied on the specific gravity of the worts.

German and Austrian brewers employ almost exclusively the low fermentation system. Dark beers are brewed from well-grown high dried malts, and light beer from less grown low dried malts.

In pre-war days very little malt substitute was used in Germany. Berlin white beer is brewed from wheat and barley malt. The gravity of German beers did not materially differ from those of the beers of this country, although the average gravity is lower owing to the non-production of strong ales. The average gravity of Austrian beers is a little more than that of German beers. The war has caused a considerable reduction, beers being now brewed of an original gravity of 1012-1036. The beer duty is levied on the material.

United States brewers employed both high and low fermentation systems, that is, brewed 'ale' and 'beer,' as the products of these two systems were there called. The tendency was, however, for beer (lager) to be the chief product. Rice and maize preparations were used extensively as malt substitutes, and the malt was prepared from a barley of higher nitrogen content than the European brewers would care to use. The duty was levied on the beer produced.

Belgium brewed chiefly top-fermentation beer, but imported considerable quantities of all varieties from the United Kingdom and Germany. Lambic, Faro, and Mars are spontaneously fermented beers prepared from wheat and barley malt, and may take as long as three years to prepare. They have a high acidity. Lambic is prepared from a wort sp.gr. 1065, Mars 1030°, and Faro a mixture of the other two.

In France beer is chiefly brewed in the northern part and mostly by top-fermentation.

Holland brews chiefly top-fermentation beer of rather poor quality, but the brewing of lager is increasing.

Denmark has a highly developed brewing

industry. Both top and bottom fermentation beers of average gravity are produced. The duty is levied on the beer, but that containing less than 2·25 p.c. alcohol is duty free.

Sweden produces half its beer from a wort sp.gr. less than 1024, and this is free from duty; the other half being low fermentation beer of the usual lager type.

The following table gives the average percentage composition of the chief types of beers :—

	Original wort	Unfermented residue	Alcohol	Acidity as lactic acid	Ash	Nitrogen	Phosphoric acid
Pale ale . .	15·4	5·3	5·3	0·1	0·36	0·08–0·09	0·05–0·06
Strong ale . .	24·2	11·2	6·9	0·3	0·55	0·12	0·10

Analysis of Brewing Materials and Beers.—*Water* is analysed by methods in common use.

Malt analysis is largely empirical. Official methods have been laid down by the Institute of Brewing (Journal, 1906, 1; and 1910, 529), by Continental Brewing Stations (J. Inst. Brewing, 1903, 594; Zeitsch. ges. Brauw. 1914, 372 and 384). The determinations usually made are :—

Moisture.—As malt oxidises and otherwise decomposes when heated, a definite time and temperature is prescribed for drying.

Extract obtained on mashing. As this also varies with the conditions, the official method must be used to obtain comparable results. It is customary to express the result of extract determination as the specific gravity which would be obtained if 1 quarter (336 lbs.) of malt yielded one barrel (36 gallons) wort. The specific gravity is expressed in 'brewers pounds.' This method of expressing the specific gravity is arrived at by taking the weight of one barrel water (360 lbs.) as unity, and the 'pounds' gravity is the figure obtained by deducting 360 from the specific gravity thus expressed. That is, 1 lb. gravity $=\frac{361}{360}=1{\cdot}0028$; or 3·60 lbs. gravity $=\frac{363{\cdot}6}{360}=1{\cdot}010$. Degrees of specific gravity (*i.e.* the excess over 1000) can be converted into 'brewers pounds' by multiplying by 0·36. Continental brewers express the extract as percentage. To obtain the quantity of matter in solution from the specific gravity, the saccharometer of Balling is largely used; this is graduated according to the following empirical scale :—

Degrees Balling	=Sp. gr.	Degrees Balling	=Sp. gr.
1	1·0040	6	1·0240
2	1·0080	7	1·0281
3	1·0120	8	1·0322
4	1·0160	9	1·0363
5	1·0200	10	1·0404
11	1·0446	15	1·0614
12	1·0488	16	1·0657
13	1·0530	17	1·0700
14	1·0572	18	1·0744

The degrees Balling are supposed to indicate percentages of cane sugar; they certainly do not correspond with the percentage of matter dissolved in malt worts. The tables of Schulze-Ostermann (Zeit. f. d. ges. Brauw. 1878, 248; 1883, 16) are also used extensively and give percentages, and grams per 100 c.c., for malt worts. A set of tables drawn up by Elion (Zeitsch. angew. Chem. 1890, 291 and 321) can lay greater claim to accuracy, and also give an approximation to the percentage solids in beer residues. According to this table, if the excess specific gravity over 1000 be divided by the following factors, the result expresses the grams per 100 c.c. at 15° C. For 25 grams per 100 c.c. factor is 3·97; for 20 grams 3·98; for 15 grams 3·99; for 10 grams 4·00; for 5 grams 4·01; for 1 gram 4·018.

A simple calculation will show that the figures expressing brewers pounds extract, per quarter, per barrel, divided by one of the above factors multiplied by 0·336, will give percentage extract. The factor may usually be taken as 4, so that a malt yielding 90 lbs. extract, contains $\frac{90}{4\times0{\cdot}336}=67$ p.c. matter soluble on mashing.

Colour of the wort or beer is determined by Lovibond's tintometer. Continental analysts employ decinormal iodine solution as the standard for comparison.

Matter soluble in cold water is determined; this is considered to give an indication of the manner in which the germination was carried out.

Diastatic activity, measured by Lintner's method or the modification laid down by the

Institute of Brewing Committee, is a useful indication of the kilning.

Nitrogen is conveniently determined by the Kjeldahl process.

Ash.—The determination of ash by burning in a muffle usually gives low results, owing to the loss of acid radicals, as in sulphates or chlorides. Suitable precautions must be taken to prevent this.

Hops.—The chemical examination of hops has already been referred to.

Malt substitutes, such as maize, rice, and their preparations, and sugars are in general analysed by methods in common use. The extract of starchy material is determined by the addition of a sufficient quantity of malt to convert the starch, and on the same lines as that of malt. The extract yielded by the sugars is usually expressed as 'pounds' extract per 2 cwt. per barrel.

Worts and beer residues are examined for matter fermentable by yeast, the optical activity, and cupric reducing power determined; and these determinations may be interpreted in quantities of dextrin, maltose, and other matter with some approach to probability (Morris, J. Inst. Brewing, 1895, 125).

Beer.—The most important determinations are those of the alcohol and the unfermented residue, from which can be deduced the original gravity of the worts before fermentation. This analysis is treated of in great detail in the Report on Original Gravities by Thorpe and Brown (J. Inst. Brewing, 1914, 569), and on this is based the official table used for revenue purposes, and which is given here:—

Spirit indications	Corresponding degrees of gravity lost
1	4·25
2	8·50
3	12·90
4	17·30
5	21·85
6	26·40
7	31·00
8	35·65
9	40·30
10	45·00
11	49·85
12	54·85
13	59·95

A measured quantity of the beer (usually 100 c.c.) is taken, filtered, and washed into a distilling flask; a condenser is connected and the beer distilled to about four-fifths of its volume. The distillate and residue are each made up to the original volume and the specific gravities taken, usually with a 1000-grain specific-gravity bottle. The table gives the degrees of original specific gravity equivalent to the specific gravity of the distillate. The amount of alcohol contained in the distillate is found from published tables, of which an excellent one appears in the report above mentioned, and is also published separately.

The carbohydrates, nitrogen, ash, and colour of beer are estimated in the same manner as indicated above for malt worts.

Preservatives.—Methods for the estimation of preservatives in beer are given in Bulletin 65 of the United States Dept. of Agriculture, 1901, and circular 33 of the same, March, 1907. The most common is sulphurous acid; it cannot be estimated by direct titration with iodine, as the sulphurous acid is in a fairly stable state of combination; but an approximate titration may be made by first decomposing with alkali, then acidifying and titrating (Ripper, J. pr. Chem. (2), 46, 428). The most satisfactory method is to acidify with phosphoric acid, distil in a current of carbon dioxide, and receive the distillate in a solution of iodine, the sulphuric acid formed is weighed as barium sulphate.

Salicylic acid may be detected by extracting a concentrated and acidified beer residue with a mixture of petroleum spirit and ether. The ethereal solution is drawn off, and evaporated. The residue dissolved in water gives the well-known violet colour with dilute ferric chloride if salicylic acid is present. If saccharin is present, this would be extracted at the same time, and recognised by its intense sweetness. Boric acid, fluorides, benzoic acid are occasionally added. Complete details of beer analytical methods will be found in W. Windisch, Das. Chem. Lab. des Brauers, Berlin, 1907.

Characteristics and Defects of Beer.—Beer should have a pleasant flavour and aroma, be super-saturated with carbon dioxide, and when poured into a glass be bright with a persistent foamy head. Beer defects caused by the absence of these characteristics may be due to chemical or biological causes, or a combination of both. Bacteria are often a cause of defective beer, slight changes in acidity have a marked effect on the susceptibility of the beer, slight increases in acidity making it more, and slight increases in alkalinity less, stable.

Aerobic forms such as the ordinary acetic acid bacteria do not grow in beer charged with carbon dioxide. One of the most common causes of spoilt beer is *Sarcina* (*Pediococcus cerevisiæ*), this causes turbidity and acidity. Another bacteria causing a silky appearance and production of acidity is *saccharobacillus Pastorianus.* Ropiness is another defect caused by bacteria; there are several bacteria which can cause this, usually not much acidity is produced, nor is the beer necessarily turbid. The composition of the substance which gives the viscosity is $C_6H_{10}O_5$ (A. J. Brown, Chem. Soc. Trans. 1886, 432; Lafar, Technical Mycology, transl. by C. T. C. Salter, London, 1898, 1910).

Wild yeast or torula growing in beer will usually produce turbidity, and sometimes unpleasant flavour and smell. This, however, is by no means always the case, and if bacteria do not obtain access to the beer, when the yeast growth is completed, it settles out and leaves the beer bright with an altered, but possibly improved, flavour.

An unpleasant bitter flavour is produced by the culture yeast if the greater portion be not promptly removed at the termination of the primary fermentation. This is due to the cell contents passing into the beer.

If beer be infected with bacteria and wild yeasts, it does not always happen that these organisms grow and spoil the beer. Much work has been done to determine the conditions which influence this. H. T. Brown (J. Inst. Brewing, 1916, 344), in a review of our present knowledge, concludes that the composition of the beer has no influence on its liability to wild yeast growth; but that allowing for the bactericidal influence of hops, there is some relation between the total nitrogen content and its liability to bacterial disease. It is disappointing that the large amount of accumulated knowledge has not been of more assistance to the brewer in avoiding these troubles. We are led back to the work of Pasteur and his followers, to the pre-eminent importance of mycology to the brewer.

Beer turbidity is often caused by the so-called gluten bodies referred to above, separating out in such a minute form as not to settle. This is often the case with pasteurised beer. Wallerstein (U.S. Pat. 995820) suggests the addition of a proteolytic enzyme to degrade these bodies, and this has been found efficacious in some cases. This form of turbidity is closely connected with the chemistry of the colloids of beer. These bodies play an important part in the production of flavour and foam retention. They may be poisonous to yeast and also affect the stability of beer towards bacteria. Little is known of their properties, but a statement of the present stage of our knowledge will be found in the Report on Colloid Chemistry, Brit. Assoc. 1917. A. L. S.

BRIDELIA BARK or ASDUANA. The bark of *Bridelia montana* is a useful Indian astringent (Dymock, Pharm. J. [3] 7, 309).

BRILLIANT ARCHIL, -AZURINE, -BLACKS *v.* AZO- COLOURING MATTERS.

BRILLIANT CONGO, -CROCEÏN, -DOUBLE SCARLET, -GERANINE *v.* AZO- COLOURING MATTERS.

BRINDONIA INDICA *v.* GARCINIA INDICA.

BRIQUETTES *v.* FUEL; also PITCH.

BRITANNIA METAL. Is an alloy of variable composition, usually containing only tin and antimony, although brass and bismuth are sometimes added.

An alloy consisting of 9 parts of tin and 1 part of antimony is attacked slightly by solutions of common salt, potassium, ammonium, and magnesium chlorides, potassium sulphate, potassium nitrate, and sodium carbonate. Caustic soda has a more marked action (Dingl. poly. J. 221, 259).

This alloy is used in the manufacture of teapots, spoons, and dish-covers.

Articles made from it may be coloured by heating them for 15 to 30 minutes in a bath made by mixing 2 lbs. of water, 1½ oz. of cream of tartar, ½ oz. of tartar emetic, 2 oz. of hydrochloric acid, ½ lb. of pulverised zinc, and 1 oz. of powdered antimony. This gives them a brilliant lustre.

By heating in a bath composed of 1 part tartar emetic, 1 part cream of tartar, 3–4 of hydrochloric acid, and 3–4 of ground antimony, the following tints may be obtained: golden, copper-red, violet, and blue-grey.

A metallic ring can be given to articles made of Britannia metal by heating them in an oil-bath to 220° and then cautiously raising the temperature to below 3° above the fusing point of the alloy. Small articles must be kept at this temperature for from 15 to 30 minutes, large articles for one hour; the bath is then allowed to cool. The rapidity of the cooling seems to have no appreciable effect (D. Ind. Ztg. 1867, 507) (*v.* ANTIMONY).

BRITISH GUM *v.* DEXTRIN.

BROCHANTITE. A hydrated basic copper sulphate, $CuSO_4{\cdot}3Cu(OH)_2$, forming bright-green orthorhombic crystals, found in Cornwall, Urals, &c. It is largely present in some of the Chilean copper ores. L. J. S.

BRÖGGERITE. A crystallised variety of the mineral pitchblende (*q.v.*) or uraninite, found as small, isolated octahedra and cubo-octahedra in the felspar quarries near Moss in Norway. It contains about 80 p.c. uranium oxide, together with thorium, lead, &c. *Cleveite* is a very similar, or identical, mineral found in the felspar quarries near Arendal in Norway. L. J. S.

BROMAL. Tribromacetaldehyde CBr_3CHO. Prepared by passing bromine into a solution of paraldehyde in ethylacetate (Pinner, Annalen, 179, 68), or by passing bromine into absolute alcohol, fractionally distilling the product, and treating the fraction boiling at 165°–180° with water. The bromalhydrate thus formed is decomposed on distillation into bromal and water (Schäffer, Ber. 1871, 366; Löwig, Annalen, 3, 288). Bromal is an oily liquid boiling at 174° (760 mm.); sp gr. 3·34. Alkalis decompose it on heating into bromoform and a formate.

Bromalhydrate $CBr_3CH(OH)_2$. Crystallises from water in colourless monoclinic prisms containing one molecule of water of crystallisation, m p. 53·5°. It is less soluble than choralhydrate (Pope, Chem. Soc. Trans. 1899, 460).

Bromal alcoholates. Bromalethylalcoholate is a crystalline solid, m.p. 44°; readily soluble in alcohol, sparingly soluble in water (Schäffer, *l c.*). Étard (Compt. rend. 114, 753) has described the action of bromine on various alcohols with the formation of different bromal alcoholates.

The following condensation products of bromal have been prepared: *Bromalammonia* (Schiff and Tassinari, Ber. 1877, 1786); compound with *hexamethylenetetramine* (Lederer, Eng. Pat 17693; J. Soc. Chem. Ind. 1897, 1039); compounds with *formaldehyde* (Pinner, Ber. 1900, 1432); *bromaldiacetate* (Grabutti, Gazz. chim. ital. 1900, 30, ii. 191); *bromalglycolate* (Gabutti, Chem. Soc. Abst. 1902, i 261); and *bromalchloralcarbamide* (Kalle and Co., Chem. Soc. Abstr. 1902, i. 429).

BROMALBIN. A bromine derivative of protein.

BROMALIN. Trade name for a combination of hexamethylenetetramine with ethyl bromide used in the treatment of neurastheni and epilepsy (*v.* SYNTHETIC DRUGS.

BROMBENZENE *v.* PHENYL.

α-BROMCARMINE and β-BROMCARMIN *v.* COCHINEAL.

BROMEIGON. Trade name for an albumi preparation containing bromine.

BROMELIA. Trade name for β-naphthylethyl ether.

BROMETONE. Trade name for tribromo-*tert*-butyl alcohol $CBr_3{\cdot}C(CH_3)_2{\cdot}OH$. Used as a sedative and anæsthetic in sea-sickness, vomiting, chorea, &c.

BROMINE. Symb. Br. At. wt. 79·92. An element belonging to the class of the halogens, and the only element, other than mercury, which is liquid at ordinary temperature and pressure; discovered by Balard in 1826. Name from *βρῶμος*, a stench. Never found free; chiefly in combination with alkalis and alkaline earths. As AgBr, brom-argyrite or bromite, also as embolite in isomorphous mixtures with AgCl in Mexico, Chile, Honduras, in some Silesian zinc ores, and in Chile saltpetre. In sea water, in many marine plants and animals, and in many saline springs. Bromine, as bromindigo, has been found to be secreted by certain species of *Murex*, and is an essential constituent of the Tyrian purple of the ancients. Traces of it are occasionally to be met with in coal, and hence in gas liquors.

Bromine is contained in sea water in the ratio of 0·3 gram Br to 100 grams Cl. Water from the Dead Sea contains 3 grams of Br to 100 grams Cl. Some marine brines analysed by Hicks gave the following results in grams per litre:

Sp. gr.	Total solids	Cl.	Br.
1·141	17·00	124·6	1·3
1·194	24·01	176·9	1·7
1·193	22·04	171·8	1·6
1·221	26·42	202·9	2·2

1·202	25·60	189·2	0·7
1·223	26·98	205·8	1·7
1·062	8·38	55·6	0·3
1·066	8·82	58·5	0·4
1·075	9·99	65·7	0·5
1·069	9·27	61·5	0·3
1·057	7·49	50·5	0·4

At ordinary temperatures bromine is a dark brown-red liquid of most irritating smell, very volatile; vapour yellowish-red, and becoming less transparent when heated.

It boils at 63° and solidifies at 73° to a brown-red crystalline mass of semi-metallic lustre and conchoidal fracture. The solidifying point is considerably depressed by chlorine. The specific gravity of liquid bromine is 3·18828, 0°/4° (Thorpe); if free from chlorine 3·10227, 25°/4° (Andrews and Carlton). Coefficient of expansion 0·0011 between 25° and 30°. Specific heat of solid 0·08432 cal., of liquid 0·1071 cal., of gaseous bromine 0·0555 cal.

Latent heat of evaporation at b.p. 45·6 cal., critical temperature 302·2°. Vapour pressure:—

Bromine water when cooled deposits bromine hydrate in hyacinth-red octahedral crystals. Girau (Compt. rend. 1914, 159, 246) proposed, in the place of the composition $Br_2,10H_2O$ usually given (Löwig), $Br_2,8H_2O$ on the strength of thermo-chemical and analytical data.

The solubility of water in bromine is uncertain; according to Wildermann 100 mol. Br dissolve 0·4 mol. H_2O. Of technical importance is the solubility of bromine in the final mother liquors of bromine manufacture:

At	2	10	20	30	40	50	55°
	64·4	64·0	63·6	63·2	60·8	60·0	58·4

grams Br are soluble in 1 litre.

Bromine is very soluble in alcohol, ether, carbon disulphide, chloroform, carbon tetrachloride, hydrogen chloride, arsenic chloride, sulphuryl chloride, sulphur dioxide. Sulphuric acid dissolves traces only. It is miscible with liquid chlorine and appreciably soluble in compressed gases, particularly oxygen, which at 300 atm. holds 6 times the quantity with which it is saturated at ordinary atmospheric pressure.

Bromine is opaque to X-rays; the degree of opacity of bromine compounds is in direct proportion to their percentage of Br. Bromine acts violently on hydrogen, sulphur, phosphorus, arsenic, antimony, tin, aluminium, the heavy metals, and potassium; but it does not react with sodium or magnesium even on heating to 200°. It combines with unsaturated organic compounds and acts as a bleacher and disinfectant. Its vapour acts on the mucous membrane and occasions great irritation, and has been used, therefore, in gas warfare.

Extraction and Manufacture. — Bromine occurs in nature principally, and so far as its industrial preparation is concerned, exclusively in the shape of bromides, accompanying in small quantities the chlorides of sodium, calcium, and magnesium. Its quantity is never large enough to admit of its being prepared directly from the raw material, but where the latter is in the first instance worked for sodium chloride and other salts, the bromide accumulates in the mother liquors, and can be recovered from these. Thus Balard discovered bromine in the mother liquors obtained on making common salt from sea-water, and for many years it was prepared from the mother liquors of the saltworks at Kreuznach, Schönebeck, Neusalzwerk, and other places in Germany. It was also found in 1846, by Alter, in similar mother liquors in America, especially in those at Natrona and Tarentum, later on at Pittsburg, Syracuse, Pomeroy (Ohio), and in the Kanawha region in West Virginia (Mason City, Parkersville, &c.).

Manufacture was first begun in 1846 at Freeport, Pa. U.S. Pat. 12077 for the extraction of bromine from brine was taken out in 1854 by Amalie Stieren of Natrona, Pa. The American bromine industry is at present carried on at Saginaw, St. Charles, Bay City, Midland, and Mount Pleasant, Michigan; at Pomeroy, Ohio; Mason, Hertford, and Malden, West Virginia; in all these localities, except Malden, in connection with the salt industry.

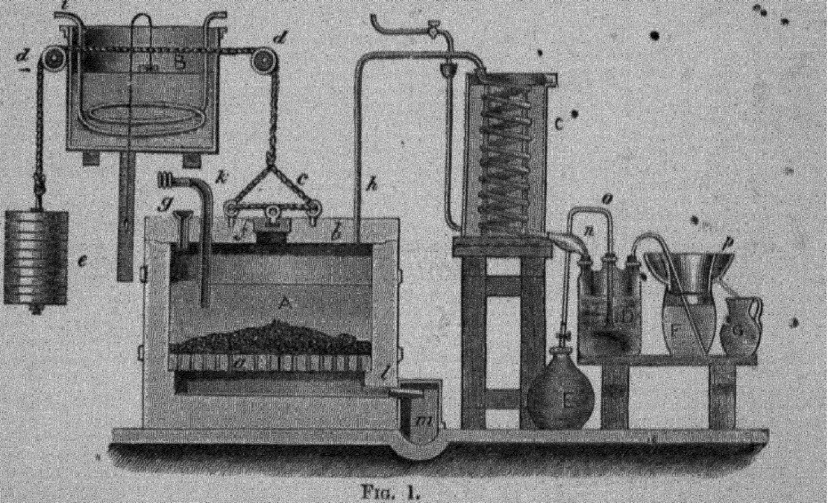

Fig. 1.

Until about 1860 the little bromine that was made was nearly all used for scientific purposes. Then, however, medicine and photography began to demand a greater supply of bromides, and later on the manufacture of coal-tar dyes raised an even more extended demand for bromine. It now became remunerative to recover it in the working up of kelp for iodine, but this yielded only little and impure bromine, and was not long continued. An idea was conceived of recovering it from the water of the Dead Sea, but the project, hardly practicable in itself, was abandoned when Frank had shown that an ample supply of bromine could be obtained from the mother liquors of the Stassfurt potash industry (v. Potassium chloride). He commenced his practical operations in 1865, when he manufactured about 750 kgs. of bromine; in 1867 the output had already increased to 7½ tons, and in 1885 the Stassfurt production of bromine was estimated at 260 tons per annum, the price having gone down from 50 or 60 (sometimes as much as 90) marks per kilogram to 0·75 mark. This lowering of the price was principally due to the fact that since 1868 America had come into the market with bromine made from the above-named saltworks; their liquors contained it in such quantity that they were able to sell much below Stassfurt prices.

The world's production before the war was practically controlled by the 'Associated American Producers,' and the 'German Bromine Convention,' in Stassfurt Leopoldshall.

The rise in price caused by the war gave a new incentive to the American bromine industry. However many of the new producers, after making considerable profits, have abandoned manufacture, and the industry in the vicinity of

Saginaw, Mich., for instance, is now in the hands of a few firms who buy the mother liquors from the other salt producers.

Chemical Processes.—The raw material worked at Stassfurt, crude carnallite (*v.* POTASSIUM CHLORIDE), contains bromine to the extent of from 0·15 to 0·25 p.c. in the shape of *brom-carnallite* $MgBr_2{\cdot}KBr,6H_2O$, isomorphous with carnallite. In the manufacture of potassium chloride, the magnesium bromide accumulates together with magnesium chloride in the mother liquors, which contain usually about 14 grams KCl, 50 grams $MgSO_4$, 348 grams $MgCl_2$, 12 grams NaCl, 2-4·5 grams Br per litre, and have sp.gr. 1·31. As it is impossible to separate the magnesium bromide by fractional crystallisation, the bromine is always extracted chemically, being replaced by a current of chlorine, according to the equation:

$$MgBr_2 + Cl_2$$
$$MgCl_2 + Br_2$$

The chlorine is either generated within the liquors by means of hydrochloric acid and manganese ore, or it is prepared outside and passed into the solutions, cheap compressed chlorine in steel cylinders being nowadays available for that purpose.

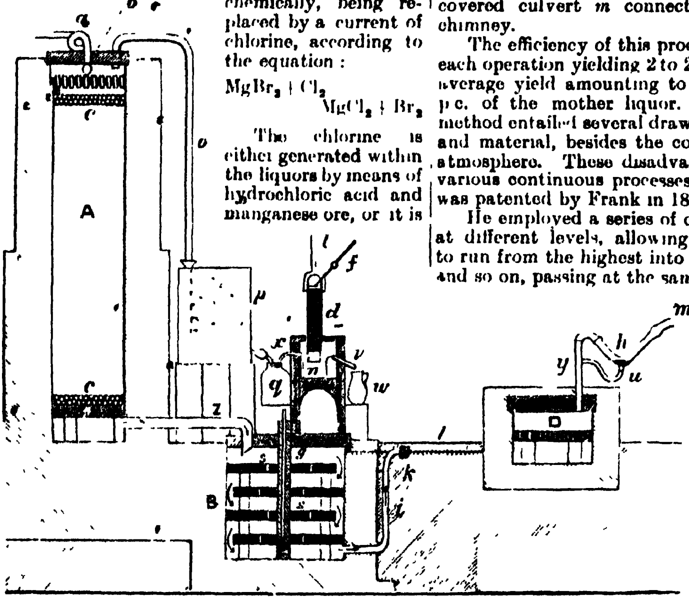

FIG. 2.

In the early days of the bromine industry, the extraction was always done by intermittent working. One of the first apparatus employed was devised by Frank, and is shown in Fig. 1. It consisted of a square vessel or still, A, made of sandstone or slate properly jointed together, of about 3 cubic metres capacity, which was charged with a definite quantity of mother liquor previously heated to 60° in tank B by steam coil *i*; about 200 kgs. of manganese ore, sufficient for several operations, were spread on the false bottom *a*. After closing the man-hole *f*, the required quantity of sulphuric acid of sp.gr. 1·7 was run in through pipe *g*, which was subsequently stopped up with clay, and live steam was passed into the liquor through pipe *k*. The chlorine evolved on boiling acted upon the magnesium bromide present and liberated bromine. This came over pure at first, but above 75° a mixture of bromine, chlorine, and water vapour passed through the lead pipe *h* and the stoneware condensing coil C into the glass bottle D, holding about 8 litres. The distillation was carried on until the pale colour of the vapours in the glass adapter *n* showed that no more bromine was coming over. The condensate separated into a lower layer of bromine and an upper layer of bromine and chlorine water which could be siphoned off through *o* into vessel E, and was added to a subsequent charge. Uncondensed vapours passed into vessel F filled with iron turnings and water, and fitted with a collar, *p*, to allow for frothing, with a run-off into jar G. Each operation, lasting an hour to an hour and a half, was terminated by knocking out plug *l*, and running off the liquor through the covered culvert *m* connected to the factory chimney.

The efficiency of this process was very small, each operation yielding 2 to 2·5 kgs. bromine, the average yield amounting to not more than 0·1 p.c. of the mother liquor. The intermittent method entailed several drawbacks—loss of time and material, besides the contamination of the atmosphere. These disadvantages gave rise to various continuous processes, the first of which was patented by Frank in 1878.

He employed a series of decomposing vessels at different levels, allowing the heated liquor to run from the highest into the next lower one, and so on, passing at the same time chlorine gas generated outside and steam into the lowest vessel, and in counter-current to the higher ones. He thus obtained a steady stream of bromine on the one hand, and a solution of magnesium chloride practically freed from bromine and uncontaminated with manganese salts, on the other. After a time, chlorine was passed into the second lowest vessel, and steam only into the lowest, to free its contents from chlorine before running off. However, the high pressure required to force the chlorine gas through several successive layers of the liquor presented great difficulties in the design and working of this plant. These were overcome by the application of the scrubber principle in the apparatus, patented in 1882 by the Leopoldshall Chemical Works (D. R. P. 19780), and shown in Fig. 2.

The heated mother liquor flows through the water-sealed pipe *a* into column A constructed of stoneware or acid-resisting stone, where it is evenly distributed by pipe *b*. The column is fitted with stoneware balls, *c*, *c* resting on a grating which effects a good contact of the liquor with the chlorine gas ascending through pipe Z. This pipe is wide enough to serve also as outlet for the liquor which runs into the steaming vessel B, provided with a number of superimposed flagstone shelves compelling the liquor to flow in a zigzag course, and finally issues through pipe s. Steam is forced into this vessel by means of a stone pipe *g* and is distributed through perforations in its base. The contents of B, which is always full, are kept boiling, and the steam rises principally through holes in the flagstones, thereby freeing the liquor from chlorine and bromine. The vapours meet the current of fresh chlorine arriving through pipe *l* (shown in dotted lines), which is conveyed through pipe z into the tower A, decomposing the magnesium bromide. The bromine is taken off on top, and passed by pipe *o* through the stoneware condenser *p* into the receiver *q*. The uncondensed vapours are led through *x*, into receptacle *n*, and arrested in the smaller scrubber *d* suspended by rod *t*, and fitted with iron borings, kept moist by a stream of water from tube *f*. The iron bromide collected in *n* is siphoned off through *v* into jar *w*. The regularity of the current of chlorine arriving from *m* is controlled by the amount of water condensing in the bend of the glass tube *h*. If too much water has accumulated, it is blown through the rubber tube *u* into the chlorine washer D. By filling the bend of *h* with water, the current of gas may be interrupted.

Of late years chlorine electrolytically prepared and compressed in steel cylinders has been used, whereby the regularity of the current is under complete control.

The apparatus patented by Wünsche-Sauerbrey (Fig. 3) is based on the same principle as the foregoing. It is, however, technically more perfect and consequently much superior in efficiency.

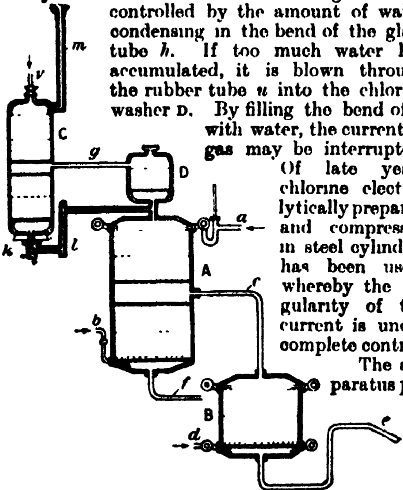

FIG. 3.

It consists of a decomposing vessel A, a steaming vessel B, a condenser C, and an auxiliary condenser D. The four units are built up of cast-iron elements of hexagonal cross-section, lined with stoneware plates and filled with a very large number, several thousands, of specially designed contact bodies (D. R. P. 158715) which rest on gratings of the same material. The four units are so arranged in height that a perfect counter-current is obtained, and in both the decomposer and condenser two centre gratings are provided, in order to keep a free space. The chlorine is passed into the decomposer at *b*, the liquor entering through *a* at a temperature of 65°; after treatment in this unit it runs into the steaming vessel through pipe *f*, where it is freed from chlorine and bromine vapours by means of live steam entering at *d* the vapours passing into the free space of the decomposer. The bromine leaves the decomposer at a temperature of about 95° and undergoes preliminary cooling in the auxiliary condenser D, but is completely condensed in the principal condenser by a stream of water, passing subsequently a bromine and water separator.

The features of this apparatus are the complete recovery of bromine and the thorough utilisation of steam. Although of moderate dimensions, the apparatus is capable, on account of the number and arrangement of contact bodies, to recover 250–270 kgs. bromine from 150 cub. m. liquor in 24 hours. It requires 0·6 kg. chlorine for every kg. of bromine made, and only 3 to 5 kgs. bromine are necessary in the form of iron bromide for the subsequent removal of chlorine from 100 kgs. crude bromine. The cost of production of 1 kg. bromine is 0·45 to 0·50 mark.

Whilst the value of Wünsche's apparatus depends on the most favourable distribution and utilisation of gas and liquor, Kubierschky has designed a plant (Ger. Pat. 194567) in which the counter-current proper is divided into a number of systematically arranged parallel currents, recognising the fact that bromine vapour will be heavier the purer it becomes. As the ratio of the density of water to that of bromine is 18 : 160, a simple upward current cannot possibly yield the best separation, as under currents will always be set up.

The apparatus consists of a single tower column, shown in Fig. 4.

It is lined with stoneware and divided into superimposed compartments, the division plates being liquor-sealed and allowing liquid to pass, but not gas. The compartments are provided with perforated plates *pp* or other contact bodies. Communication between the compartments is established by tubes *rr* so arranged that the vapour always enters from the lower compartment into the upper part of the next higher one, then descends over the plates along with the liquid, and enters the vapour pipe near the bottom, passing through this pipe again to the top of the next compartment, and so forth. The previously heated mother liquor enters at the top of the column, runs down in a direct course and is met by chlorine introduced in the lower part. Steam is passed into the bottom compartment, and follows the course described. The bromine, not subjected to under-currents, issues at *a* from the column and is condensed in an earthenware coil.

Although of extreme simplicity, this apparatus is much superior to all the others, especially in regard to yield, this amounting to from 90 to 95 p.c. of the bromine present in the crude liquors.

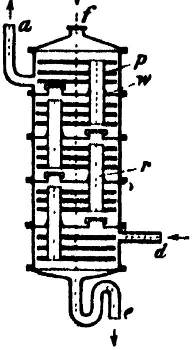

FIG. 4.

The mother liquors, obtained by spontaneous evaporation of sea-water to sp.gr. 1·274 at the salt works of Salin de Giroud, South of France are used for the production of bromide. They are further concentrated to specific gravity of

1·308 and allowed to crystallise during the winter. After removing the magnesium sulphate, bromine is extracted in the following spring by pumping the liquors into vessels of 20 cub. m. each, from which they descend in a regulated stream into stone rectifying columns through which a current of chlorine, from cylinders, and a current of steam ascends. The bromine, after passing through an inclined U-tube and a condensing coil, is separated from the water by gravity, the bromine-water being returned to the column. The crude bromine is rectified by passing steam through it, which carries away the chlorine and part of the bromine. Three units are employed, each of which deals with 50 to 60 cub. m. of mother liquor in 24 hours, and yields about 160 kilos of bromine Forty-four tons of bromine containing only about 1 p.c. of chlorine are thus obtained annually from 15,000 cub. m. of mother liquor. The liquors, after the extraction of bromine, are worked up for potassium chloride.

In America the manufacture is carried on in the majority of works in Ohio, West Virginia, and Michigan, by the intermittent process. The bittern from the main grainers of the salt works is further concentrated to a sp.gr. of about 1·38 (hot), and then passed to the bromine stills. Most of these are made from sandstone quarried at Buena Vista, near Portsmouth, Ohio, where the sandstone is practically free from iron oxide and is of close texture. The shape and construction differ in the various plants, and their working capacity ranges from 400 to 1200 gallons of liquid. Sodium chlorate and sulphuric acid of sp.gr. 1·84 are used in liberating the bromine from the bittern. The use of manganese dioxide and potassium chlorate has been discontinued. Steam is passed into the solution and, as the temperature rises, a reaction takes place approximately represented by the following equation :—

$$3MgBr_2+3H_2SO_4+NaClO_3 \\ =6Br+NaCl+3MgSO_4+3H_2O$$

The bromine set free passes from the still together with any excess of chlorine which is liberated. The bromine vapour is freed from chlorine after passing through washers filled with milk of lime forming calcium chloride and calcium hypochlorite. Some bromine is taken up by the lime, but is recovered later. The bulk of the bromine vapour is condensed in three lead coils arranged in series, each of which discharges the condensate into glass bottles, whilst any bromine passing the last bottle is caught in towers 6 feet to 8 feet high and 2 feet to 2 feet 6 inches wide, made of sewer pipe and filled with coke. The bromine caught beyond the first bottle is usually rather dilute and may be returned to the still. The lead pipes have lately been replaced by stoneware coils in several works. About 35 lbs. of bromine are obtained from 700 gallons of bittern.

The drawbacks of the intermittent process have led to the introduction of continuous processes. The Dow Chemical Company of Midland, Mich., has patented a number of modifications of these.

The chlorine used may be produced chemically or electrolytically within the reacting mass, or introduced from outside. In the place of steam for the removal of free bromine a current of air is used. The bromine is abstracted from the bromine-laden air by chemical re-agents such as iron turnings, lime, sodium bicarbonate, and others. These are worked up for pure bromine or bromine salts by subsidiary processes ; for instance, the ferric bromide solution may be converted into solid ferrous bromide by treatment with further iron.

Electrolytic Processes.—Of recent years, efforts have been made to effect the separation of bromine from the magnesium-bromide liquors by means of electrolysis. A number of processes have been devised by Wünsche, Höpfner, Nahnsen, Pemsel, Rinck, Dow, and Kossuth, but although in some cases plants have been working with more or less success, their introduction has not become general. All but the last-named process employ diaphragms, to avoid secondary reactions. Kossuth works without this, and achieves a great simplicity of plant and working, but at the expense of current required. The yield of electric energy is 40–50 p.c. in his case, and not more than about 70 p.c. in any other method. This low yield is largely due to the extremely small percentage of bromine in the liquors and the consequently large bulk to be dealt with, and to the formation of bromates and chlorates. The formation of solid magnesia is another drawback.

In nearly all the electrolytic methods proposed, the bromine remains dissolved in the solution and must be recovered by the processes described above.

Purification of Bromine.—Crude bromine, as obtained by most of the processes described, contains very small quantities of iodine, cyanogen, bromoform and carbon tetrabromide, lead bromide, and as principal impurity from 1 to 4 p.c. of chlorine as chloride of bromine. The oldest method of purification consisted in agitating the crude bromine with a solution of potassium or ferrous bromide. On account of the frequent breakages of the glass vessels employed, this method was replaced by that of redistillation. In some places glass retorts were used for this purpose, containing about 15 kgs. and heated in sand-baths. Only 3 or 4 charges could be worked in one vessel, and fracture of the retorts was a not unfrequent occurrence. In Stassfurt sandstones stills were and are still employed. These were square troughs with a stone cover, holding about 1 cubic metre. The distillation is carried out in the presence of ferrous or calcium bromide, these liquors being, when used up, added to the original mother liquors. Of late years advantage has been taken of the improved products of the stoneware industry, and stills of this material are largely used. To avoid the occasional cracking of these stills, Mitreiter employs vessels of boiler plate lined with a bromine-resisting material.

The still is charged with 200 litres ferrous bromide solution of 13° to 18°Bé, and about 600 litres crude bromine. The temperature is gently raised by direct steam up to the boiling-point. Double decomposition ensues between chlorine and ferrous bromide, and bromine distils over and is condensed in a stoneware coil, separated from water and then contains only from 0·05 to 0·10 p.c. chlorine.

Pure bromine may be made, according to Barstow, without the aid of steam or heat, by adding sulphuric acid to a mixture of 5 parts of bromide to 1 part of bromate in a cement-lined tub cooled by a lead coil, but kept above the crystallising point of the sodium sulphate formed. The free bromine formed according to the equation:—

$$5NaBr+NaBrO_3+3H_2SO_4 \\ =3Na_2SO_4+6Br+3H_2O$$

can be drawn off from the bottom of the condenser, the yield being 95 p.c. of liquid bromine, whilst the remainder is blown out from the solution with a current of air and recovered with alkali.

In another process, patented by Barstow (Fig. 5), a strong iron bromide solution is fed from tank 2 into the top of a tailings tower, 1, passes through a condensing coil, 3, thence through a re-action column, 4, in which it meets a rising stream of chlorine gas supplied from 5. The mixture of iron chloride and liquid bromine flows downward through the reaction column, and from it through a cooling worm, 7, to a container, 8, where it is separated by gravity. Any vapour formed by the heat produced in the reaction column, or carried away by air, which may be contained in the chlorine gas, is re-condensed in 3 or scrubbed out in tower 1. Any chlorine contained in the crude bromine is removed by agitation with an iron bromide solution, and the bromine retained by the iron chloride solution may be blown out with air and re-absorbed with a solution of ferrous bromide. No steam is used in the process, and the iron chloride can be produced as a commercial solution of sp.gr. 1·32.

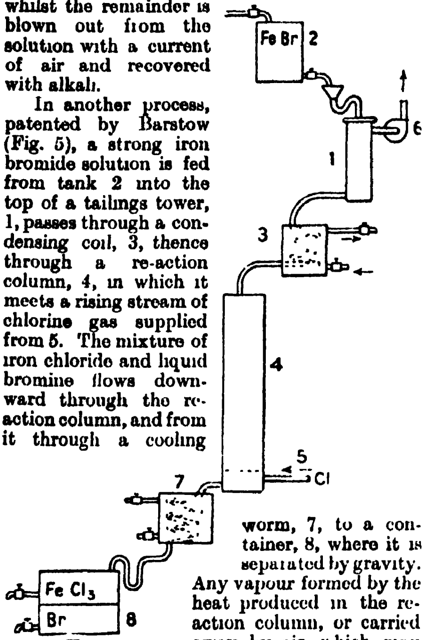

FIG. 5.

Recent processes attempt the purification by rectifying without the aid of chemical agents. Kubierschky (Ger. Pat. 174848) employs in connection with his separating apparatus a refining tower; the crude bromine flows downwards into a vessel charged with bromine and kept at boiling temperature. The chlorine rises in the tower, and the boiling bromine, freed from chlorine, is continually siphoned off and cooled.

The German Solvay Works (Ger. Pat. 205448) have found that in raising the temperature of crude bromine very slowly and keeping it just under its boiling-point, it is possible to free it entirely from its chlorine. The time factor is of great importance for the successful carrying out of their process.

On heating a charge to 59° for 36 to 40 hours, it is possible to remove practically all the chlorine with not much more bromine than corresponds to the composition of bromide of chlorine.

Bromine is sold in strong, white, stoppered bottles, holding 1 litre, and containing 2½ or 3 kilos. The glass stoppers must be well ground; they are secured by pouring some shellac on to the joint, covering them with clay putty, and tying wet parchment paper over all. From four to twelve such bottles are placed in a wooden box, the spaces between being tightly filled with kieselguhr or brown-coal ashes, depending upon whether the bromine is exported or sold for inland consumption.

The principal applications of bromine, whether in the free state or in the shape of bromides, are in photography, in medicine, in the manufacture of coal-tar dyes (especially eosine), and in scientific and analytical chemistry; in the latter it has to a great extent taken the place of chlorine, owing to the greater convenience of its manipulation. A similar substitution has been proposed for many technical purposes. It is used in the extraction of gold and the refining of platinum, and in connection with the manufacture of Prussian blue and potassium permanganate. It is also a disinfectant, and has found some application for this purpose, especially in the shape of *bromum solidificatum* patented by Frank (Ger. Pat. 21644). This is kieselguhr made plastic by means of molasses, &c., pressed into sticks of ½- and ¾-inch diameter, dried, burned to the extent that the sticks acquire a sufficient degree of hardness without losing their porosity, and saturated with liquid bromine in wide mouthed stoppered glass bottles. After the excess of bromine has been poured off, the sticks remain behind, containing about 75 p.c. of the weight of bromine, and are sold in the same bottles. This is a very convenient form of applying it, as a certain number of sticks represent a given weight, and no weighing out of liquid bromine is required.

Bromide of iron is made at Stassfurt and in America, and serves principally as raw material for the manufacture of potassium and sodium bromide. It is a compound of the formula Fe_3Br_8, containing 56-70 p.c. bromine, up to 0·5 chlorine, 18-19 p.c. iron, and 10-15 p.c. water and insoluble matter. The older method for its manufacture consists in passing bromine vapours free from chlorine over iron borings or turnings contained in a cast-iron or stoneware vessel, and kept moist by a stream of water. The solution obtained is passed through a filter cloth or sand filter to remove impurities, notably carbon, and evaporated in cast-iron pans, whereby enough bromine is added to obtain the compound Fe_3Br_8. The brown-red solution is concentrated to a pasty consistency and allowed to cool to a black crystalline mass.

The Associated Chemical Works of Leopoldshall have introduced a method whereby a charge of 1 ton of steel wire and turnings is treated in a closed stone trough with a mixture of bromine vapour and steam in the right proportion. The admission of bromine is so regulated that no bromine vapours are visible through a sight-glass provided on the outlet pipe which is connected to a little scrubber acting as a catch-box. As soon as brown vapours and the falling of the temperature from 170° to 100° indicate a lessening of the activity of the iron, the operation is terminated and the solution run off. Being sufficiently concentrated, the solution obtained in the process may be run direct into the transport barrels, where it is allowed to crystallise.

Bromine salt. In connection with the manufacture of bromine a substance commonly called 'bromine salt' is produced which finds application in the extraction of gold ores. It is practically the mixture $NaBrO_3 + 2NaBr$, and is made by saturating concentrated caustic soda solution with bromine. The solid salt obtained after draining off the mother liquor—which is evaporated—has the approximate composition $1NaBrO_3 + 5NaBr$. To this sodium bromate, electrolytically prepared from bromide, is added, and the mixture finely ground and packed in kegs.

Hydrobromic acid. HBr. *Bromhydric acid*; *Hydrogen bromide.* A colourless pungent gas of irritating smell; fumes strongly in the air. Condenses to a liquid at −73°. May be obtained synthetically by passing bromine and hydrogen through a hot tube or over heated platinum. Best prepared by action of phosphorus and bromine on water, $5Br + P + 4H_2O = H_3PO_4 + 5HBr$; or by the action of a concentrated solution of H_3PO_4 on KBr; or by dropping Br upon melted paraffin heated to 185°.

Gas very soluble in water; weight of normal litre 3·6142 grams; solution when saturated forms a colourless, strongly acid liquid of sp.gr. 1·78, and contains 82 p.c. HBr by weight, corresponding to the formula HBr,H_2O. If the concentrated acid be heated at ordinary pressures, the gas is evolved until the amount of HBr in the solution sinks to 47–48 p.c., when the liquid boils constantly at 126° under a pressure of 760 mm. This proportion of HBr corresponds to $HBr + 5H_2O$, but the liquid is not a true hydrate, since the composition is altered by varying the pressure; thus if the pressure be raised to 1·95 mm., the solution boils at 153° and contains 46·3 p.c. HBr.

The sp.gr. at 15° and p.c. composition of aqueous solutions of hydrobromic acid, is given in the following table (Wright, Chem. News, 23, 242):—

Sp. gr.	HBr p.c.	Sp. gr.	HBr p.c.
1·080	10·4	1·385	40·8
1·190	23·5	1·475	49·5
1·248	30·0	1·515	49·8

For pharmaceutical purposes a dilute solution of hybrobromic acid may be prepared by dissolving 84½ grains of potassium bromide in a fluid ounce of water and adding 9 grains of tartaric acid to the solution. After standing, acid potassium tartrate crystallises out and the solution contains about 10 p.c. of hydrobromic acid. Hydrobromic acid has been used in the treatment of ear complaints. R. L.

BROMINOL (*brominoleum*). Trade name for brominated sesame oil.

BROMIPIN, BROMOPIN. A combination of bromine with sesame oil employed in medicine (*v.* Synthetic Drugs).

BROMITE or **BROMYRITE.** Native silver bromide, found in Mexico and in Chile (*v.*

ω-**BROMOACETOPHENONE** *v.* Ketones.

BROMOCHINOL. Trade name for acid dibromosalicylate of quinine.

BROMOCOLL *v.* Synthetic Drugs.

BROMOFORM. *Tribrommethane* $CHBr_3$. This substance is occasionally met with in the liquid left after the rectification of bromine, in which it occurs associated with *chlorobromoform* $CHBr_2Cl$ (Dyson, Chem. Soc. Trans. 43, 46) and *carbon tetrabromide* CBr_4 (Hamilton, *ibid.* 39, 48).

Preparation.—It may be obtained by mixing 100 c.c. soda lye, 200 c.c. acetone, and 20 c.c. bromine. When the reaction has ceased, 10 c.c. acetone are added to remove the yellow colour of the hypobromite, the layer of bromoform which separates being tapped off and rectified. Yield 75 p.c. (Denigès, J. Pharm. Chim. 24, 243). It may also be prepared by the simultaneous action of bromine and caustic potash on alcohol, of bromine and lime on acetone (Beniger, Amer. J. Pharm. 63, 80); of calcium hypochlorite and potassium bromide on acetone (Fromm, Pharm. Zeit. 39, 164), and by the action of alkalis on bromal. It has been made electrolytically from potassium bromide and alcohol (Fabrik vom Schering, D. R. P. 29771); from potassium bromide and acetone (Coughlin, Amer. Chem. J. 27, 63; and Müller and Loebe, Zeit. Elektrochem. 10, 409), and from calcium bromide, alcohol, and water (Trechcinoki, Chem. Zentr. 1907, i. 13).

Properties.—It is, when pure, a colourless liquid, solidifying at 2·5° and boiling with slight decomposition at 146° under 751 mm. (Wolff and Schwabe, Annalen, 291, 241), at 151°/760 mm. (Thorpe, Chem. Soc. Trans. 37, 1880, 201. Sp.gr. 2·902, 15°/15° (Perkin, Chem. Soc. Trans. 45, 533); 2·8119, 8·5°/8·5° (Thorpe, *loc. cit.*). It is decomposed by potash into potassium bromide, hydrogen bromide, and carbon monoxide, and may be estimated by means of this decomposition (Desgrez, Compt. rend. 125, 780, and Annalen 23, 76; and Richaud, J. Pharm. Chim. 1899, 232). Under the influence of light and air it decomposes, the decomposition products depending on the time of exposure and the amount of available oxygen (Schoorl and Van den Berg, Chem. Zentr. 1906, i. 441). It has been used to a slight extent as an anæsthetic, and in the treatment of diphtheria. Bromoform in water, to which a little alcohol has been added, has been successfully used in cases of whooping-cough complicated with pneumonia (Stepp and Goldschmidt, J. Soc. Chem. Ind. 1890, 213).

BROMOGLIDINE, BROMOGLUTEN, BROMOPROTEIN. Preparations of wheat gluten or vegetable albumin containing bromine used as substitute for alkaline bromides.

BROMOL, BROMOLEIN, BROMOTAN *v.* Synthetic Drugs.

BROMURAL. Trade name for *a-monobromisovalerylurea*. Employed as a hypnotic. Forms white needles, slightly bitter in taste; readily soluble in hot water, alcohol, and ether, sparingly soluble in cold water; m.p. 147°.

BRÖNNER'S ACID, 2-Naphthylamine-6-sulphonic acid *v.* Naphthalene.

BRONZE *v.* Tin.

BRONZE POWDERS. Bronze powders are composed of copper, zinc, tin, and antimony, melted together in the requisite proportions.

In the process of manufacture, the alloy is cast into rods ¼ inch in diameter and 3 feet long. These are rolled until about 2 inches wide, and then cut into lengths suitable for handling. The pieces are hammered out thin, and cleansed by immersion in dilute sulphuric acid. The dried material is then beaten out by steam-hammers until the limit of thickness is reached, when it is cut up by shears into small particles or 'clippings.' These are then pulverised in stamp mills, and the powder sifted, to separate the heavier and better quality powder from inferior material. The latter is mixed with quartz powder and sold very cheaply (J. Soc. Chem. Ind. 1893, 12, 475).

The expense of the above process lies mainly in the production of 'clippings,' which necessitates a great deal of handwork, and a number of methods have been patented for reducing the alloy to a finely divided state by mechanical means. According to one method, the molten alloy is rained into a sheet-iron chamber, in which a shaft carrying blades is rapidly rotated, so as to greatly agitate the air and thereby minutely subdivide the metal at the moment of solidification (Fr. Pat. 331371, 1903). In another, the molten metal flows in a thin film into a receptacle, where it meets a current of compressed air or else a jet of water, the object being to produce bronze foil or leaves (Eng. Pat. 9064, 1903). Methods have also been patented for casting the metal in thin films on the inner surface of a rotating hollow cylinder or in the annular space between two rotating cylinders (J. Soc. Chem. Ind. 1903, 22, 150; Fr. Pat. 335112, 1903).

After the powdered metal has been sifted, the coarser grades are polished in a closed steel cylinder, in which steel wire brushes rub against the walls. When it is necessary to reduce the powder to a finer state of division, it is rubbed with gum-arabic solution, washed and dried at the lowest possible temperature.

Zinc-dust is frequently coated with brass by simple immersion in a copper and zinc cyanide solution, the powder being kept agitated by means of brushes (J. Soc. Chem. Ind. 1894, 13, 893, 958); the product is treated finally in a polishing mill, and used as a bronze powder.

Bronze powders have also been described containing 5–10 p.c. of aluminium, and 0·05–0·1 p.c. of bismuth. The shade of colour is altered by varying the percentage of aluminium, and by heating in air (D. R. P. 44242, 1887).

Few analyses of bronze powders have been published (J. Soc. Chem. Ind. 1910, 29, 1062). 'Gold' and 'bronze' powders were found to contain 70–85 p.c. of copper, and 30–15 p.c. of zinc, together with small amounts of lead, tin, arsenic, iron, and aluminium; 'aluminium' powders consist of nearly pure aluminium; and 'silver' powders contain 77 p.c. of zinc and 21·5 p.c. of aluminium.

Bronze powders are coloured in various ways. One method consists in heating the powder in an open vessel with oil and vinegar, or with wax, paraffin, or oils containing sulphur. Buchner's process consists in shaking the powder in a closed vessel with hydrogen sulphide solution, allowing to stand 24 hours, drying and heating in an oil-bath until sufficiently coloured (J. Soc. Chem. Ind. 1896, 15, 283). Artificial dyestuffs are also used for colouring bronze powders.

The following are examples:—

Colour of powder	Metallic constituents	Total organic matter	Colouring matter
Pink . .	Copper . .	0 3 p.c.	Azine scarlet G
Blue . .	Tin and zinc .	3·8 ,,	Victoria blue 4R
Copper colour	Copper (little zinc)	5·5 ,,	Safranine
Violet. .	Tin (little copper)	3·8 ,,	Fast neutral violet B
Pale green .	Copper and zinc	4·3 ,,	Malachite green
Olive green .	Copper and zinc	5 9 ,,	Brilliant green

Bronze powders are used considerably for printing on textile fabrics. For this purpose they must be mixed with a 'fixer' which allows the powder to be readily applied to the material, whilst so fixing it that brushing will not remove it; the fixer must not, of course, interfere with the brilliancy of the powder. Two classes of 'fixers' are in use, egg or blood albumen, and various varnishes having caoutchouc as their base. In printing such goods, the main point to be observed is that the impression shall be sharp, and applied with sufficient force to prevent the particular fibres from again rising. (For further particulars, *v.* J. Soc. Chem. Ind. 1896, 15, 283; 1900, 19, 243; 1906, 25, 1040; and for various bronze powder substitutes, *v. ibid.* 1896, 15, 284.)

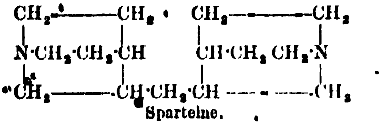
BROOKITE *v.* TITANIUM.

BROOM TOPS. *Scoparii cacumina* B.P. *Scoparius*, U.S. Pat. was deleted in 1916, but *Sparteinæ sulphas* is retained. (*Genêt à balais*, Fr.; *Besenginster*, Ger.). The tops of the common broom, *Cytisus scoparius*, Link = *Spartium scoparium*, L. (Bentl. a. Trim. 70), have been employed for their diuretic action since the Anglo Saxon period, and are noticed in nearly all the herbals and pharmacopœias (Planta genista). The main constituents are sparteine and scoparin

Sparteine $C_{15}H_{26}N_2$, a liquid alkaloid (Stenhouse, Annalen, 1851, 78, 15; Mills, *ibid.* 1863, 125, 71); subsequently shown to be identical with lupinidine from yellow lupin seeds (*L. luteus*) by Willstatter and Marx (Ber. 1904, 37, 2351). It may be obtained from broom tops by extraction with very dilute sulphuric acid, concentration of the extract and steam-distillation of the residue, after addition of alkali. The crude alkaloid may be purified by distillation in a current of hydrogen.

Properties. A colourless liquid, sp.gr. 1·034 at 0°, b.p. 188° under 18·5 mm., or 325° in a current of hydrogen under 754 mm. pressure (Moureu and Valeur, Compt. rend. 1903, 137, 194), 180·5° under 18 mm. (W. and M. *l.c.*). Slightly soluble in water, soluble in alcohol, ether, or chloroform; insoluble in light petroleum or benzene. The aqueous solution is alkaline and very bitter. $[\alpha]_D = -14\cdot6°$ in alcohol (Bamberger, Annalen, 1886, 235, 368), $-16\cdot42°$ (M. and V. *l.c.*) at 20°. Sparteine is a diacidic base, which forms difficulty crystallisable salts. The alkaloid and its salts are toxic.

Reactions and constitution. Sparteine behaves towards alkyl iodides as a ditertiary base, but contains no methyl linked to N (Herzig and Meyer, Monatsh. 1894, 15, 613; 1895, 16, 599; M. and V. *l.c.*). It furnishes no reduction products, and is unaffected by permanganate. Sparteine reacts with methyl iodide to form two monomethiodides, which are regarded as stereoisomerides. On 'exhaustive methylation' sparteine furnishes hemisparteilene $C_{15}H_{22}N$ and trimethylamine and finally sparteilene $C_{15}H_{20}$. On oxidation with chromic acid it yields spartyrine $C_{15}H_{24}N_2$, and eventually oxysparteine $C_{15}H_{24}ON_2$. With hydrogen peroxide dioxysparteine $C_{15}H_{26}O_2N_2$ results, presumably a di-ammonium oxide. From these and other data Moureu and Valeur (Compt. rend. 1905, 141, 261, 328) have assigned the following formula to sparteine—



Sparteine.

The principal papers relating to sparteine are as follows: Ahrens, Ber. 1887, 20, 2218; 1888, 21, 825; 1891, 24, 1095; 1892, 25, 3607; 1893, 26, 3035; 1897, 30, 195; Moureu and Valeur, Compt. rend. 1903, 137, 194; 1905, 140, 1601, 1645; 141, 49, 117, 261, 328; 1907, 145, 815, 929, 1184, 1343; 1908; 146, 79; 1911, 152, 386, 527; 1912, 154, 309; Bull. Soc. chim. 1909, [iv.] 5, 31, 37, 40; and résumé Ann. Chim. Phys. 1912 [viii.] 27, 245-391; Wackernagel and Wolffenstein, Ber 1904. 37, 3238; Willstätter and collaborators, *ibid.* 1904, 37, 2351; 1905, 38, 1772.

For the *salts*, *see* Bamberger (*l.c.*) and Corriez (Bull. Sci. Pharmacol. 1912, 19, 468, 527, 533, 602). The *sulphate* $C_{15}H_{26}N_2$, H_2SO_4, $5H_2O$ is official in the U.S.P., and forms hygroscopic crystals becoming anhydrous at 100° and melting at 153°. Crystals with 3 and with $8H_2O$ have also been described. The salt is soluble in about an equal weight of water, less so in alcohol. It has been recommended as a cardiac stimulant, but its action on the heart is doubtful. Sparteine is much less poisonous than coniine, which it resembles to some extent in action; it also resembles nicotine. For colour reactions of sparteine, *see* Reichard (Pharm. Zentr-H. 1905, 48, 385). The amount present in broom tops varies considerably with the season of the year. There is a well-defined maximum in March and minimum in August (Carr and Reynolds, Pharm. J. 1908 [iv.] 26, 542; Chevalier, Compt. rend. 1910, 150, 1068). The former authors found 0·07 to 1·06 p.c. in commercial specimens, and in specimens from the same locality 0·53 p.c. in March, 0·07 p.c. in August. Chevalier states that the alkaloid wanders into the fruit in the following season, mature seeds containing 1·1 p.c. Valeur (Compt. rend. 1917, 164, 818) has based a method for the estimation on the decrease of solubility in water of the free base with rise of temperature.

Scoparin $C_{20}H_{20}O_{10},5H_2O$, m.p. 202°–219° (according to the rate of heating), is a pale yellow powder separating from the aqueous decoction as a jelly and crystallising with difficulty from alcohol. The formula may be resolved into $C_6H_3{\cdot}OMe(4){\cdot}OH(3){\cdot}C_{13}H_8O_3(OH)_5$, the unresolved portion yielding phloroglucinol on potash fusion, and probably containing a pyrone ring (Goldschmiedt and von Hemmelmayr, Monatsh. 1893, 14, 212; 1894, 15, 360; A. G. Perkin, Chem. Soc. Trans. 1900, 77, 422). Scoparin dissolves slightly in water, readily in alkalis, *e.g.* in ammonia with a deep yellow-green colour. With ferric chloride it gives a violet-blue colour, rapidly becoming dark-brown; it reduces Fehling's solution. Heated with alcohol less soluble isoscoparin, m.p. 235°, is formed, which on solution in alkalis and re-precipitation is reconverted into scoparin. Scoparin is stated to be the cause of the diuretic action of broom tops. G. B.

BROPHENIN. Brom-*iso*-valerylamino acet-*p*-phenetidin.

BROSIMUM GALACTODENDRON (Don.). The latex of this urticaceous tree (cow-tree, milk-tree), growing in Venezuela, approximates to cow's milk in composition. It contains 35·2 p.c. of wax and saponifiable matters, which are used in the manufacture of candles (Boussingault, Pharm. J. [3] 9, 679).

BROUSSONETIA PAPYRIFERA (Vent.). *The Paper mulberry.* The fibrous bark is used in China and Japan for the manufacture of a kind of paper, and in Polynesia in the manufacture of Tapa cloth.

BROVALOL. The borneol ester of *a*-bromo isovalerianic acid $C_4H_8Br.CoOC_{10}H_{17}$.

BROWN, ACID, *v.* AZO-COLOURING MATTERS.

BROWN, ANILINE; BISMARCK BROWN, MANCHESTER BROWN, PHENYLENE BROWN, VESUVINE, LEATHER BROWN, CINNAMON BROWN, ENGLISH BROWN, or **GOLD BROWN;** *v.* AZO- COLOURING MATTERS.

BROWN, ANTWERP, *v.* PIGMENTS.

BROWN, ARCHIL, *v.* AZO- COLOURING MATTERS.

BROWN, BONE, *v.* PIGMENTS.

BROWN, CALEDONIAN, *v.* PIGMENTS.

BROWN, CAPHEK, *v.* PIGMENTS

BROWN, FAST, *v.* AZO- COLOURING MATTERS.

BROWN, FUSCANINE, *v.* AMINOPHENOL.

BROWN, GARNET. The potassium or ammonium salt of *iso*purpuric acid ($C_8H_4N_5O_6K$ or $C_8H_8N_6O_6$). Obtained by Hlasiwetz in 1859 by the action of potassium cyanide on picric acid (Annalen, 110, 289). Forms a dark-brown powder, readily soluble in hot water with red-dish-brown colour. Dyes wool and silk brown in an acid-bath. No longer is use (*v.* also ISOPURPURIC ACID).

BROWN, MADDER, *v.* PIGMENTS.

BROWN, NAPHTHYLAMINE, *v.* AZO- COLOURING MATTERS.

BROWN, PHENYL, *v.* PHENYL BROWN.

BROWN, PICRYL, *v.* PICRYL BROWN.

BROWN, PIGMENT, *v.* AZO- COLOURING MATTERS.

BROWN, PRUSSIAN, *v.* PIGMENTS.

BROWN, RESORCIN, *v.* AZO- COLOURING MATTERS.

BROWN, SOUDAN, *v.* AZO- COLOURING MATTERS.

BROWN, VANDYKE, *v.* PIGMENTS.

BROWN, VERONA, *v.* PIGMENTS.

BROWN BERRIES. The fruit of *Rubus fruticosus.*

BROWN COAL *v.* FUEL.

BROWN HÆMATITE *v.* IRON, ORES OF.

BROWN IRON ORE (*Limonite*) *v.* IRON, ORES OF.

BRUCINE *v.* NUX VOMICA.

BRUCITE. Native magnesium hydroxide, $Mg(OH)_2$, found as platy crystals with perfect micaceous cleavage, or as lamellar masses, in serpentine rocks, at Unst, one of the Shetland Isles, at Texas in Pennsylvania, &c. It sometimes contains a small amount of iron (ferrobrucite) or manganese (manganbrucite). A fibrous variety is called nemalite. L. J. S.

BRUNSWICK BLACK is prepared by fusing 2 lbs. of asphalt, and mixing thoroughly with 1 pint of hot boiled oil. When cool, 2 pints of turpentine are added to the mixture. An inferior but cheaper black may be made by boiling gently together for five hours 25 lbs. each of black pitch and gas tar asphaltum; 8 gallons of linseed oil, and 10 lbs. each of litharge and red lead are then mixed in, and the whole boiled. After cooling, the mixture is thinned by the addition of 20 gallons of turpentine (*v.* also BONE OIL).

BRUNSWICK GREEN. An oxychloride of copper, used as a pigment. Copper filings or turnings are moistened with a solution of salammoniac, and left in contact with the air; the oxychloride so formed is washed off with water, and dried at a gentle heat. The term is also applied to chrome green and to emerald green (*v.* COPPER and PIGMENTS).

BRUSHITE. A hydrated phosphate of lime, $HCaPO_4,2H_2O$, occurring in the guano of Aves Island and Sombrero in the Caribbean Sea.

BRUSSELS SPROUTS. A variety of the cabbage (*Brassica oleracea*), in which numerous small heads are developed along the stalk from the axils of the leaves, instead of one terminal head.

The edible portion contains, according to American analyses:

Water	Protein	Fat	Carbohydrates	Ash
88·2	4·7	1·1	4·3	1·7

(*see* CABBAGE). H. I.

BRYOIDIN *v.* OLEO-RESINS.

BRYONY ROOT. Bryony root has been used medicinally from a very remote period on account of its cathartic properties, and was formerly recognised by several of the national Pharmacopœias, but is now rarely employed. The plants yielding this root are *Bryonia alba*, Linné, and *Bryonia dioica*, Linné (Nat. Ord. Curcurbitaceæ), which are botanically closely allied. They are indigenous to the greater part of Europe, but the last-named species is the only one of the genus commonly found in this country, and, therefore, is frequently designated as English bryony. The roots of the two species are generally considered to possess the same properties, and they appear to be indiscriminately collected, although it has been asserted by Petresco (United States Dispensatory, 18th ed., p. 279) that they differ appreciably in their physiological action. The roots of *Bryonia dioica* contain an enzyme as a light-brown powder, which slowly hydrolyses the glucoside in the root, and also effects the hydrolysis of amygdalin and salicin. The alcoholic extract of the dried root yields a pale yellow essential oil of characteristic odour; a colourless crystalline neutral substance, $C_{20}H_{28}O_5$ (m.p. 220°–222°) $[\alpha]_D$ +58·6°; an amorphous glucoside of a brown colour and bitter taste, which on hydrolysis yields a brown resin, and a sugar forming *d*-phenylglucosazone (m.p. 208°–210°); an amorphous alkaloidal principle, brownish-yellow in colour, and of an intensely bitter taste. From the resin may be prepared (i) a phytosterol, $C_{27}H_{46}$ (m.p. 137°), optically inactive; (ii) a dihydric alcohol, *bryonol*, $C_{22}H_{34}O_2(OH)_2$ (m.p. 210°–212°), yielding a *diacetyl* derivative (m.p. 152°); (iii) a mixture of fatty acids, consisting of oleic, linolic, palmitic, and stearic acids. Bryonol appears to belong to a group of dihydric alcohols of the general formula $_nH_{n-8}O_4$, comprising: *ipuranol*

$$C_{21}H_{38}O_2(OH)_2$$

grindelol $C_{22}H_{36}O_2(OH)_2$, and *curcurbitol* $C_{24}H_{38}O_2(OH)_2$. The *bryonin* of previous investigators consisted of complex mixtures. The activity of bryony root cannot be attributed to a single definite principle, its purgative property resides chiefly in its resinous and alkaloidal constituents (Power and Moore, Chem. Soc. Trans. 1911, 99, 937).

BUBULIN (from *βοῦς*, ox). The name of a peculiar substance, said by Morin to exist in cow-dung, and to be precipitated by metallic salts, tincture of galls, and alum, and therefore to be active in the application of cow-dung to calico-printing.

BUCHU *v.* OILS, ESSENTIAL.

BUCHU or BUCCO. The leaves of three varieties of *Barosma* (ord. Rutaceæ), viz. *B. betulina* (Bartl et Wendl. f.), *B. crenulata* (Hook.), and *B. serratifolia* (Willd.), are known under this name. The leaves are used medicinally by the South African natives.

Their composition has been studied by Brandes (Arch. d. N. Apoth. Ver. 22, 229), Landerer (Buchner's Repert. 84, 63), Flückiger (Pharm. J. 3, 4, 689; [3] 11, 219), Wayne (*ibid.* 3, 6, 723). By extracting the leaves with light petroleum, Bialobrzeski (Chem. Zentr. 1896, ii. 551) obtained chlorophyll, a resin, and an ethereal oil containing chiefly diosphenol, together with a terpene $C_{10}H_{18}$, b.p. 174°–176°, and a ketone isomeric with menthone, and having the constitution $C_{10}H_{18}O$, b.p. 206°–209°; it yields an oxime and a tribrom derivative. After extraction with light petroleum, the leaves, on treatment with cold alcohol, yield 3 p.c. of a brownish-green bitter resin insoluble in benzene, and when the alcoholic extract is treated with sodium carbonate or by other methods diosmin is deposited, forming tasteless, odourless crystals, m.p. 244°.

Semmler and McKenzie (Ber. 1906, 1158) found that the round leaves of *Barosma betulina* yield about 2 p.c. of an oil which crystallises on standing at ordinary temperature; but the long leaves of *Barosma serratifolia* yield 1 p.c. of an oil which remains liquid under similar conditions.

According to Kondakoff and Bachtschiew (J. pr. Chem. 1901, 63, 49), the best oil of bucco or buchu leaves contains 10 p.c. of hydrocarbons, consisting of a variety of *d*-limonene and dipentene; 60 p.c. of a ketone $C_{10}H_{18}O$, $[\alpha]_D$, −16°6′, b.p. 208·5° – 209·5°, which, on reduction, yields a menthol not identical with the natural product; 20 p.c. of diosphenol; 5 p.c. of resin; and 5 p.c. of other constituents (Kondakoff, J. pr. Chem. 1896, 54, 433). After removing diosphenol from the oil of buchu leaves, Tschugaeff succeeded in obtaining xanthogenide derivatives of *d*-menthol from a fraction of the residue (J. Russ. Phys. Chem. Soc. 1910, 42, 714; Skovortsoff, *ibid.* i. 55). Diosphenol or buchu camphor (Bialobrzeski, *l.c.*; Kondakoff, *l.c.*; Semmler and McKenzie, *l.c.*; Semmler, Chem. Zeit. 1906, 30, 1208; Kondakoff, Chem. Zentr. 1905, ii. 1252; Chem. Zeit. 1908, 1090, 1100) is optically nactive, has m.p. 82°, b.p. 109°–110°/10 mm., 232°/755 mm. Its composition is probably $C_{10}H_{16}O_2$. It is a phenolic aldehyde, yielding an oxime, m.p. 156° (Semmler and McKenzie 125°). With hydrochloric acid it yields thymol and a little carvacrol. With hydriodic acid it yields a hydrocarbon $C_{10}H_{20}$, b.p. 165°–168°/762 mm.; whilst with sodium in alcoholic solution it forms (1) a menthol; (2) a crystalline glycol $C_{10}H_{18}(OH)_2$, m.p., 92°; and (3) an isomeric glycol, b.p. 141·5°–145°/13 mm. With alcoholic potash, a hydroxy acid of the terpene series, m.p. 94°, is obtained. This acid has been synthesised, and is identical with the natural product. The dibromide $C_{10}H_{14}O_2Br_2$ and other derivatives of diosphenol have also been obtained.

BUCKTHORN (*Rhamnus cathartica* [Linn.]). This plant is a native of England; it grows to a height of from 15 to 20 feet; its flowers are greenish coloured, and its berries four-seeded. The juice of these when in an unripe state has the colour of saffron; when ripe and mixed with alum, it forms the sap or bladder-green of the painters (*v.* PIGMENTS); and in a very ripe state the berries afford a purple colour. The bark also yields a fine yellow dye.

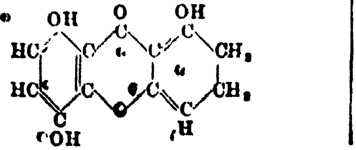
The berries of the *Rhamnus carthartica* (also known as Hungarian berries) have been examined by Tschirch and Polacco (Arch. Pharm. 1900, 238, 409), and evidently contain substances chemically distinct from those which are present in Persian berries.

Ether extracts from an aqueous extract of the berries *rhamnocitrin*, *rhamnolutin*, *rhamnochrysin*, and the residual watery liquid on boiling with dilute sulphuric acid gives, in addition to rhamnocitrin, *β-rhamnocitrin*. The berries already extracted with water contain *rhamnoemodin* and *rhamnonigrin*.

Rhamnocitrin $C_{13}H_{10}O_5$, yellow needles, melts at 221°–222°, and is soluble in alkaline solutions, with a yellow colour. Alcoholic lead acetate gives an organic coloured precipitate, and ferric chloride a green colouration. The solution in sulphuric acid possesses an intense green fluorescence.

Triacetylrhamnocitrin $C_{13}H_7O_5(C_2H_3O)_3$ forms colourless needles, melting at 199°–200°.

Rhamnocitrin appears to be a *dihydrotrihydroxyxanthone*, and probably possesses the following constitution:—



It dyes with iron mordant a green-brown, and with aluminium mordant a bright yellow colour.

Rhamnolutin $C_{15}H_{10}O_6$, small canary-yellow needles, melts above 260°, and gives with lead acetate an orange-red precipitate, with ferric chloride a green-black colouration. Its sulphuric acid solution possesses a strong green fluorescence. *Tetraacetylrhamnolutin* $C_{15}H_6O\ (C_2H_3O)_4$, colourless needles, melts at 182°–183°.

Rhamnolutin dyes aluminium- and iron-mordanted fabrics respectively canary-yellow and green-brown shades. It appears to be a *tetrahydroxyflavone*, isomeric with luteolin and fisetin.

β-Rhamnocitrin $C_{13}H_{10}O_5$ is sparingly soluble in alcohol and acetic acid, but is distinct from rhamnetin ($C_{12}H_{10}O_5$?), and does not contain methoxy- groups. It melts above 260°, and, generally speaking, its reactions are the same as those of rhamnocitrin itself, but, on the other hand, it possesses stronger dyeing property. *Diacetyl-β-rhamnocitrin* $C_{13}H_8O_5(C_2H_3O)_2$ forms colourless needles melting at 190°–191°.

β-Rhamnocitrin, according to Tschirch and Polacco, appears to resemble very closely the β-rhamnetrin of Schutzenberger (*see* PERSIAN BERRIES).

Rhamnoemodin $C_{15}H_{10}O_5$, m.p. 254°–255°, is similar to *frangula emodin* (*R. frangula*) which, according to Oesterle, melts at 250°.

Rhamnonigrin is converted by boiling with nitric acid into *chrysamminic acid*, and by digestion with boiling alcoholic potash into *emodin*.

The **alder buckthorn** (*Rhamnus frangula*) grows naturally, and is very abundant in woods and thickets, in some parts of Britain. The berries of this species are often substituted for those of the above; but they are easily detected, since they contain only two seeds. In a green state they dye wool green and yellow; when ripe, bluish-grey, blue, and green. The bark also dyes yellow, and, with preparation of iron, black (Lawson)

Rock buckthorn (*Rhamnus saxatilis*), yields berries which are used to dye morocco leather yellow. These, in common with the narrow-leaved buckthorn berries (*R. alaternus* [Linn.]) and those of the yellow-berried buckthorn (*R. infectorius* [Linn.]), are sold as Avignon berries. The wood of the *Rhamnus erythroxylon* (which is a native of Siberia, but grows freely in this climate), in a ground state yields the bright-red colour known to dyers under the name of *redwood*.

A. G. P.

BUCK WHEAT (*Fagopyrum esculentum* [Moench.]) is grown mainly for poultry and also for pig- and cow-feeding in Europe. Its flowers furnish excellent pasturage for bees. Kellner gives the analyses on opposite page.

Buckwheat, after soaking in water, furnishes excellent food for cattle and pigs, though not very suitable for young animals.

The globulin of buckwheat has the composition: C 51·69, H 6·90, N 17·44, S 1·16, and O 22·81. It contains about 13 p.c. arginine, 0·6 histidine, 7·9 lysine, and 1 p.c. cystein and a small amount of tryptophan (Johns and Chernoff, J. Biol. Chem. 1918, 34, 439).

The starch of buckwheat occurs in rounded angular grains of small size, showing a distinct hilum and a tendency to agglomerate.

	Water	Protein	Fat	Carbo-hydrates	Fibre	Ash
Seed	14·1	11·3	2·6	54·8	14·4	2·8

The flour is largely used in making buckwheat cakes, popular in America, but rarely met with in England. H. I.

BUCURUMANGA RESIN. A fossil resin, occurring in an auriferous alluvium near Bucurumanga, New Granada. It is light-yellow, transparent, somewhat heavier than water, becomes strongly electric by friction; is insoluble in alcohol; swells up in ether, becoming opaque; melts when heated; burns in the air without residue. It resembles amber in outward appearance, but does not give succinic acid on dry distillation. It contains 82·7 p.c. C, 10·8 p.c. H, and 6·50 p.c. O (Boussingault, Ann. Chim. Phys. [3] 6, 507) (*v.* RESINS).

BUFAGIN *v.* BUFOTALIN; and TOAD VENOM.

BUFFALO RUBIN *v.* AZO- COLOURING MATTERS.

BUFOTALIN, the poisonous principle of the toad, $C_{16}H_{24}O_4$, m.p. 148° (decomp.) $[\alpha]_D^{20}$ + 5·4°, is a crystalline neutral substance. Alkali converts it into the unsaturated *bufotalic acid*, proving bufotalin to be a lactone. The other two oxygen atoms are present as alcoholic hydroxyl groups. It dissolves in concentrated sulphuric acid with an orange red colouration which becomes deep red on standing, and shows a green fluorescence. Concentrated hydrogen chloride in the cold eliminates 2 mols of water, forming a pale-yellow crystalline compound *bufotalien* $C_{16}H_{20}O_2$, m.p. 210°. *Acetylbufotalien* separates in lustrous, yellow platelets grouped in rosettes, m p. 184° (decomp.).

Bufotalin is not identical with *bufagin* $C_{18}H_{24}O_4$, obtained from the parotoid gland of the tropical toad *Bufo Agua* by Abel and Macht (J. Pharmacol. and expt. Ther. 1912, 3, 319). This is also dextrorotatory (+11°), sparingly soluble in water, m.p. 217°–218°. (Wieland and Weil, Ber. 1913, 46, 3315).

The Chinese drug 'senso,' prepared from toad skins, appears to contain bufagin, associated with cholesterol, together with adrenaline and *bufotoxin*, a member of the picrotoxin group of poisons (Shimizu, J. Pharm. Expl. Ther. 1916, 8, 347). V. TOAD VENOM.

BUHRSTONE or **BURRSTONE.** A hard, tough rock consisting of chalcedonic silica with a cellular texture, especially suitable for use as millstones for grinding corn, paints, &c. It is white, grey, or creamy in colour. The best stones are from the Tertiary strata of the Paris basin, and have originated by the silicification of fresh-water limestones, the cellular spaces representing the casts of fossil shells and *Chara* seeds. L. J. S.

BUILDING STONE. The essential qualities of a building stone depend on its physical characters rather than on chemical composition. Nevertheless, the broad classification of building stones has a chemical basis, viz.:—

Sandstones and Grits, composed largely of silica in the form of quartz grains.

Limestones and Marbles, consisting of calcium carbonate, sometimes with magnesium carbonate.

Slates, consisting largely of secondary aluminium silicates.

Igneous Rocks (including granite, syenite, diorite, gabbro, porphyry, porphyrite, dolerite, diabase, rhyolite, andesite, basalt) composed of a dense crystalline aggregate of closely interlocking grains of hard silicate minerals, sometimes with quartz.

A few other miscellaneous rocks used as building stones include flint, serpentine, potstone, and laterite. Each of these kinds of rock is considered under its respective heading.

Although a large number of analyses of building stones are on record, these are of little direct value in estimating the quality of a stone. They are, however, useful in indicating whether a limestone is dolomitic (*i.e.* containing magnesia) or clayey in character, and in telling the nature of the cementing material in the case of sandstones. A simple test with acid is often useful in helping to recognise a limestone, otherwise there is usually not much difficulty in allotting different stones to their main classes. Colour and change of colour on weathering are usually connected with the amount and state of the iron present in the stone.

In the decay of building stones in buildings the processes involved are different not only in degree but also in kind from those which take place in the weathering of rocks *in situ*, as considered by geologists. Here chemical action is in general of less importance than that produced by mechanical means, especially by the action of frost and by extreme alternations of temperature, and by the organic action of lichens. The solvent action of pure rain-water is insignificant for all stones except alabaster. Carbonated water has a more pronounced solvent action on limestones and the calcareous cement of sandstones. In the case of silicate rocks[1] the action of carbonated water is extremely slight, unless the felspars have already been previously considerably altered by weathering *in situ*. In towns, however, the action of sulphurous, sulphuric (hydrochloric and nitric) acids brought down by rain-water is of more importance, particularly in the case of limestones. The calcium carbonate is converted into gypsum, and this crystallising with an increase in volume of slightly more than double causes a disruption of the surface layers of the stone. (On the weathering of Portland stone and magnesium limestone in the London atmosphere, *see* E. G. Clayton, Proc. Chem. Soc. 1901, xvii, p. 201; W. Pollard, Summ. of Progress, Geol. Survey United Kingdom, for 1901, 1902, p. 83). Here also the rate of decay is governed more by the state of aggregation of the calcium carbonate than by the chemical composition of the stone; a stone with a cement of mealy calcium carbonate going much more quickly. The sodium and magnesium salts of sea-water blown as spray on buildings often have a deleterious effect. Stones containing nodules of iron-pyrites should be rejected, since this mineral is readily decomposed, giving rise to unsightly stains and producing free sulphuric acid which causes further injury to the stone.

---

[1] Here the effect of alternations of temperature is of much more importance owing to the conjunction of minerals possessing different coefficients of expansion. In passing it may also be remarked that igneous rocks (and also jasper) are the only stones used for outside decoration which are capable of retaining a surface polish.

Preservatives against decay include painting the surface with oil-colours; or saturating the surface with a solution of sodium silicate, which may be followed by treatment with a solution of calcium chloride. The carved stonework (limestone) of the Houses of Parliament and the Abbey at Westminster was restored by Sir A. H. Church by the application of baryta water, the crumbly surface layer of gypsum being thereby converted into more resisting barium sulphate.

The different kinds of artificial stone manufactured for building purposes are classified roughly by Howe (*see* references below) as follows:—

1. Stones made of natural rock fragments held together by Portland or magnesium cement. *E.g.* 'Pentuan stone' and concrete.

2. Similar stones subjected to a subsequent hardening process by treating with sodium silicate. Here the action of the cement is modified and hydrated calcium silicates are formed which harden the stone. *E.g.* 'Victoria stone' made from the granite of Groby and Mount Sorrel, Leicestershire, 'Atlas stone,' and 'Hard York non-slip stone' made from sandstone.

3. Stones in which granulated rock or sand is cemented with calcium carbonate. *E.g.* Thom's patent reconstructed stone, many 'lime-sand' blocks, and pumice-, trass-, and pozzolana-lime stones.

4. Stones in which more or less of the calcium carbonate cement is replaced by calcium silicate.

5. Stones cemented by bituminous, asphaltic, or other organic substance.

BULBOCAPNINE. *See* under *Corydaline.*

BUNTKUPFERERZ (Ger.). Variegated copper ore. This term is commonly applied, even by English mineralogists, to an ore of copper otherwise known as *Bornite* (*q.v.*), *Erubescite, Phillipsite*, and *Purple Copper Ore.* Called 'horse-flesh ore' by the Cornish miners. L. J. S.

BUPLEUROL. An alcohol found in the higher boiling fractions of the oil of *Bupleurum fruticosum.* Optically inactive, sp.gr. 0·8490/17°, n_D=1·4508; b.p. 209°–210°/762 mm. Has a faint odour of roses. Contains one double linkage and yields an urethane melting at 45°. Probably a dihydro-derivative of nerol of the constitution:

$$(CH_3)_2CH(CH_2)_3{\cdot}C(:CH_2){\cdot}CH_2{\cdot}CH_2OH$$

(Francesconi and Sernagiotto, Atti. R. Accad. dei Lincei, 1913, 22, i. 34, 148; J. Soc. Chem. Ind. 1913, 251).

BURGUNDY PITCH or **NORWAY SPRUCE RESIN.** (*Fichtenharz, Tannenharz*, Ger.; *Poix des Vosges, Poix blanche, Poix jaune, Barras*, Fr.) The resin of *Picea excelsa* (Link.) purified by melting in hot water and straining. It is an opaque, yellowish-brown, hard, brittle resin; its taste is sweet and aromatic. It is very soluble in glacial acetic acid, acetone, and alcohol. Used in making plasters. It is much adulterated. The substance usually sold by this name in England is made by melting colophony with palm-oil or some other fat, and stirring in water to make the mixture opaque (Morel, Pharm. J. [3] 8, 342) (*v.* Resins).

BURNETT'S FLUID. A solution of zinc chloride is commonly known as Sir William Burnett's disinfecting fluid. It is used as a disinfectant and as a preservative of constructional timber.

BURTON WATER CRYSTALS contain, according to Moritz and Hartley, 31·8 CaO, 40·4 SO_3, 1·04 Cl, 5·46 MgO, and 21·19 OH_2 (J. Soc. Chem. Ind. 2, 82).

BUSH SALT. A light-brown or greyish powder prepared by the natives of Ssongea by lixiviating the ashes of the sedge, *Cyperus Haspan*, L. Contains 77·77 p.c. KCl, and 18·48 K_2SO_4, with traces of sodium salts and organic matter (Lenz, Ber. deuts. Pharm. Ges. 1911, 21, 270).

BUSSORAH GUM *v.* Gums.

BUTALANINE *v.* Valine.

BUTANE *v.* Butyl- compounds.

BUTANONE (*Methylethylketone*) *v.* Ketones.

BUTEA FRONDOSA. The *Butea frondosa*, also called *Dhak* or *Pulas*, is a fine tree, 30–40 feet high, belonging to the order *Leguminosæ.* It is common throughout India and Burma, and is found in the North-West Himalaya, as far as the Jhelum River. The flowers, which in the dried condition are known as tísu, késú, kesuda or palás-képpúl, have a bright-orange colour, and, although they are much larger, closely resemble in appearance the common gorse-flower (*Ulex europæus*), with which, indeed, they are botanically allied. Large quantities of the flowers are collected in March and April, and employed by the natives to produce a yellow dye, much used during the 'Holi' festival. The dyeing operation, which consists in steeping the material in a hot or cold decoction of the flowers, is virtually a process of staining, because the colour can be readily washed out. On the other hand, a more permanent result is sometimes produced either by first preparing the cloth with alum and wood ash or by adding these substances to the dye-bath.

From the *Butea frondosa* is also obtained the so-called 'Butea gum' or 'Bengal kino,' employed by the natives for tanning leather, and the tree is of additional interest because in many parts of India the lac insect (*Coccus lacca*) is reared upon it. This latter, as is well known, causes the formation of stick lac, from which shellac and lac dye are prepared.

Butin $C_{15}H_{12}O_5$. The flowers are extracted with water, and the extract digested boiling with a little sulphuric acid. A light viscous precipitate devoid of dyeing property separates, and this is removed while hot and the filtrate left over-night. The clear liquid is now decanted from a small quantity of tarry substance, and partially evaporated on the water-bath. A further quantity of a black viscous precipitate thus separates, and when this has been removed the filtrate, after some days, deposits crystals of the colouring principle. For purification the product is dissolved in a little alcohol, the mixture poured into ether, and the solution well washed with water. The liquid is evaporated, and the residue repeatedly crystallised from dilute alcohol (Perkin and Hummel, Chem. Soc. Trans. 1904, 85, 1459).

Butin crystallises from alcohol in colourless needles with $\frac{1}{2}H_2O$, m p. 224°–226°, and from water in pale-yellow needles with $2H_2O$; dissolves in alkaline solutions with a pale orange-red tint, and gives with alcoholic acetate of lead a faintly yellow almost colourless precipitate. It forms a *triacetyl* derivative $C_{15}H_9O_5(C_2H_3O)_3$, colourless leaflets, m.p. 123°–125°, and a *tribenzoyl* compound $C_{15}H_9O_5(C_7H_5O)_3$, colourless needles, m.p. 155°–157°. On fusion with alkali at 200°–220° butin gives *protocatechuic acid* and *resorcinol.*

When butin is boiled with dilute potassium hydroxide solution, the pale-coloured liquid becomes much darker, and on acidifying an orange crystalline precipitate separates which consists of *butein.*

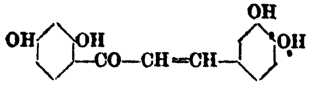
Butein $C_{15}H_{12}O_5,H_2O$, needles, melts at 213°–215°; dissolves in alkaline solutions with a deep orange-red colour, and with alcoholic lead acetate gives a deep-red precipitate. *Acetylbutein* $C_{15}H_8O_5(C_2H_3O)_4$, pale-yellow needles, melts at 129°–131°.

When fused with alkalis butein gives *resorcinol* and *protocatechuic* acid, whereas by the action of boiling 50 p.c. potassium hydroxide solution, *protocatechuic* acid and *resacetophenone* are produced.

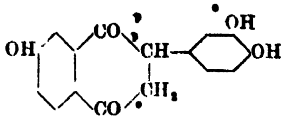
By methylation with methyl iodide butin gives *butin trimethylether* $C_{15}H_9O_2(OCH_3)_3$, colourless plates, m.p. 119°–121°, and also *butein trimethylether* $C_{15}H_9O_2(OCH_3)_3$, yellow leaflets, m.p. 156°–158°. In a similar manner, butein yields not only butein trimethylether, but also butin trimethylether.

The constitution assigned to butein by Perkin and Hummel is that of a *tetrahydroxybenzylidene acetophenone* (*tetrahydroxychalkone*) (1), and to butin that of the corresponding *flavanone* (2):

(1)

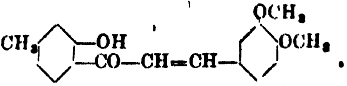


(2)

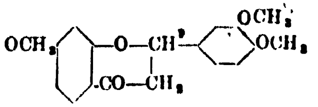


and that these formulæ are correct has been established by the synthesis of butein and butin trimethylethers by these authors. Thus by the condensation of resacetophenone monomethylether with veratric aldehyde, butein trimethylether (I) is produced:

I.



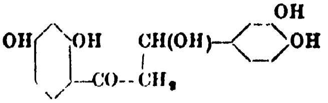
II.



and this, when digested with boiling dilute alcoholic sulphuric acid, a method devised by v Kostanecki and his colleagues (Ber. 1904, 37, 784, 773, 779), gives butin trimethylether (II).

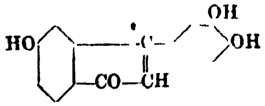
Somewhat later (Ber. 1911, 44, 3502) Göschker and Tambor prepared butein itself by treating protocatechuic aldehyde and resacetophenone in boiling alcohol with potassium hydroxide solution and found this to be identical in all respects with the natural product. *Butein methylether*, yellow needles, m.p. 185°, 3′:4′-*butein dimethylether*, yellow prisms, m.p. 203°, and *butein tetramethylether* (Ber. 1912, 45, 186), colourless needles, m.p. 89°, were also described.

Butein itself is also converted into butin by means of dilute alcoholic sulphuric acid, and the butin can again be transformed into butein by the action of potassium hydroxide solution. With alcoholic potash butin trimethylether also gives butein trimethylether, and these changes are readily explained if it is assumed that the intermediate compound or its trimethyl ether



is the first product of the reaction in each case, and that this subsequently, by loss of water, passes into either chalkone or flavanone, or both.

When butein dissolved in acetic acid is treated with a few drops of sulphuric acid, and the solution is boiled, a new substance gradually separates in the form of crystals, which possess a beetle-green iridescence, and dissolves in alkaline solutions with a deep-blue colour. The acid liquid decanted from the crystals, on dilution with water, gives a brown precipitate soluble in alkalis with a bluish-violet colouration, which dyes mordanted calico shades of a similar character to those yielded by anthragallol. It appears probable that this more soluble substance represents the first product of the reaction, and is subsequently converted into the green iridescent compound. A consideration of the formula of butein renders it unlikely that these new substances are anthraquinone derivatives; on the other hand, it is suspected that by loss of water ring formation takes place, and that an indone derivative of the following type is first produced:—



Butin and butein dye mordanted woollen cloth identical shades, though as butin gives with an alcoholic lead acetate a practically colourless precipitate, it is not to be regarded as a colouring matter. In other words, butin is merely a colouring principle, and is converted during the dyeing operation by the action of the mordant into the colouring matter butein.[1] The following shades are obtained:—

Chromium	*Aluminium*	*Tin*	*Iron*
Reddish-brown	Brick-red	Full yellow	Brownish-black

and these are strikingly similar to those yielded by some of the hydroxybenzylidenecoumaranones artificially prepared by Friedlander and Rüdt (Ber. 1896, 29, 879) (*see* above).

The butea flowers contain but a trace of free butin or butein, and the glucoside present, which has not yet been isolated, is probably that of butin. This glucoside does not decompose readily during the dyeing process, hence the flowers do not dye mordanted cotton. In wool-dyeing, where acid-baths are employed, a better result is obtained, although in this case the shades possess but little strength. If the glucoside is first hydrolysed by boiling the flowers with dilute hydrochloric acid, or if sulphuric acid is employed, and the acid then neutralised with sodium carbonate, on evaporation a material is obtained which readily dyes by the usual methods. Such products give the following shades: with chromium, deep terra-cotta; with aluminium, a bright orange; with tin, bright yellow; and with iron, a brownish-olive. The chromium colour is characteristic, and is much redder in tint than that yielded by any known natural yellow dye. A. G. P.

BUTEA GUM. The juice of *Butea frondosa* (Roxb.), often sent into the market instead of genuine kino. It forms black-brown, slightly lustrous, brittle lumps, has an astringent taste, and yields pyrocatechin by dry distillation. V. Kino.

BUTINENES C_4H_6.

1. *Erythrene*, *vinyl-ethylene* or *pyrrolene*, $CH_2:CH{\cdot}CH:CH_2$, occurs in coal-gas and is said to be formed by passing fusel-oil through a red-hot tube. Obtained by boiling erythrite with strong formic acid or by the action of potassium hydroxide on di-methylpyrrolidine methyliodide. Also by condensing acetaldehyde with ethyl alcohol in presence of alumina or other catalyst. Forms a tetrabromide, m.p. 119°.

2. *Ethyl-acetylene* $CH_3{\cdot}CH_2{\cdot}C{\equiv}CH$. Obtained by treating methyl ethyl ketone with alcoholic potash and phosphorus pentachloride, or by passing acetylene and ethylene through a red-hot tube. Forms a tetrabromide, m.p. 113°.

3. *Crotonylene* $CH_3{\cdot}C{\equiv}C{\cdot}CH_3$. Obtained by acting on butylene bromide or di-bromo-butane with alcoholic potash, or by distilling barium acetate with sulphur. Dilute sulphuric acid converts it into hexa-methyl-benzene.

A butinene is also formed by the destructive distillation of caoutchouc.

BUTTER. Butter is the fatty product prepared from the milk of the cow. When similar substances are obtained from the milk of other mammals, their origin is indicated in the description, *e.g.* goats' butter, buffalo butter. Fatty food substances of vegetable origin and similar to butter in consistency are also sometimes described as butter, but with a prefix, as *vegetable butter, cocoa-nut butter*.

Butter consists of milk- or butter-fat, with water, and small quantities of milk proteins, lactose, mineral salts, and natural colouring matter. The proteins and lactose, together with the mineral matter associated therewith, are spoken of collectively as *curd*. Commercial butter may also contain common salt, preservatives, and colouring matter, added during manufacture. The added salt and preservatives are not included with the curd in giving the composition of butter, but are separately estimated.

Fat exists in milk in the form of minute globules in a state of suspension in the milk serum. In the process of churning, the fat globules coalesce, producing irregularly-shaped granules of butter. These are strained from the serum, or buttermilk, washed with water, and worked into a mass on a table by means of mechanical rollers, or, as in older processes, by hand. Salt, preservatives, colouring matter, are added, if desired, after washing the butter granules with water.

As regards the influence of salt on the changes taking place in storage it has been found that unsalted butter in commercial cold storage keeps as well as, or better than, salted butter. According to Washburn and Dahlberg (Bull. Agric. Intell. 1918, 9, 996), salt, exclusive of its antiseptic property, hastened the deterioration of butter; when stored at −25° (−15° F.), unsalted butter kept as well as salted butter, and the bacteria decreased more rapidly. On the other hand, they, as well as the acidity, increased more rapidly in the unsalted butter at ordinary temperatures.

According to D. C. Dyer (J. Agric. Research, 1916, 6, 927) the unpleasant flavours which develop in butter during cold storage are produced by chemical change in non-fatty ingredients.

Milk may be directly churned for the purpose of obtaining butter, and, in some remote districts, this process is still followed. It is, however, usual to churn *cream*, that is, the fatty layer which rises to the surface on allowing milk to stand or on subjecting it to centrifugal action.

Cream may be churned in a fresh condition before souring has taken place. In such a case, the period of churning is longer, and the operation must be carried out at a lower temperature than when ripened cream or milk is employed. It is therefore usual to churn ripened cream. The ripening may be effected by standing the cream, and is accelerated by the addition of a little buttermilk or pure culture starters containing suitable bacteria. The taste of cream is affected by certain moulds (*Oidium lactic*, and *P. chrysogenum*), and the enzymes secreted by them may develop abnormal flavours in the butter. Mould spores do not germinate or grow in butter.

---

[1] This result has been criticised by Göschker and Tambor, who by the employment of mordanted calico obtained from butin very weak shades. It is, however, certain that by the use of mordanted wool a conversion of butin into butein occurs.

Various views are held as to what takes place during the operation of churning. Fleischmann (Book of the Dairy, 159) states that 'the milk-fat is converted from fluid to solid condition by the shaking which it undergoes,' that is, that churning results in the solidification of fat which in milk is in a superfused condition. On the other hand, Richmond's results (Dairy Chemistry, Ap. 339) would indicate that the fat before churning may be in a solid condition. Whether fat as present in milk is surrounded with some form of membrane (Béchamp, Storch) or with a thin watery covering (Fleischmann) the mechanical operation of churning appears to rub away or remove the protective coating, and thus enable the milk globules to coalesce, forming butter. As to the theories regarding the structure of the fat globules in milk, *see* papers by Storch (Analyst, 1897, 22, 197), Beau (Revue Générale du Lait, 2, 15, 1903), and Richmond (Analyst, 1904, 29, 185).

The quantity of water remaining in finished butter is governed by the conditions of manufacture. Churning at too high a temperature renders the removal of excess water during working difficult. It results in over-worked or 'greasy' butter; or butter with an excessive quantity of water. The maximum limit permissible in England for water in butter is 16 p.c. Canada, Queensland, Holland, have the same limit. Victoria has 15 p.c.; Germany, 16 p.c. for salted, and 18 p.c. for unsalted; and Belgium, 16 p.c.

The proportion of curd may vary from 0·2 to 2·0 p.c. according to method of manufacture, lower quantities being present where freshly separated cream is churned than in the case of ripened cream. Well-made butter rarely contains so high a quantity as 2 p.c., and where this quantity is found, examination should be made for the presence of added non-fatty milk solids. The Government Laboratory has found (Jour Board of Agric. 1912, 19, 750) the quantity of curd in imported butter to range from 0·4 to 1·86 p.c., average 1·04. Out of 366 samples only 11 contained more than 1·5 p.c. of curd. Butter taken from factories in Great Britain ranged from 0·34 to 1·86 p.c., in Ireland from 0·53 to 1·87 p.c. No limits have been fixed as to the non-fatty milk solids permissible in butter, but the Butter and Margarine Act, 1907, gives power to the Board of Agriculture and Fisheries to make regulations on the point.

Van Slyke and Hart (J. Amer. Chem. Soc. 1905, 27) state that when 0·5 p.c. or over of lactic acid is in the cream, the casein is present in the butter as casein lactate, but in butter made from sweet cream as calcium casein. They also make suggestions with regard to the relation between casein compounds and mottled butter. Richmond (Analyst, 1906, 31, 178) has found the average amount of casein to be 0·38 p.c., and not to exceed 0·5 p.c.

The mineral matter in butter (to which no foreign substance has been added during manufacture) consists of the inorganic substances derived from the buttermilk enclosed within the butter granules, and from the caseous matter adhering to the fat. It is really the ash of the curd, or the non-fatty milk solids of the butter.

When butter is heated, the fat melts and separates from the aqueous, curdy portion. After allowing this to settle, the fatty layer is filtered through a warm funnel, and the fat obtained as a clear oil, usually of a yellow colour, but under certain conditions almost colourless, setting to a granular crystalline mass. The fat so obtained consists of glycerides of fatty acids together with the natural or added colouring matter, if any, of the butter, and some unsaponifiable substances, *e.g.* cholesterol, associated with the natural fat. The total quantity of the unsaponifiable matter does not exceed 0·4 p.c. (Bömer, Zeitsch. Nahr. Genussm. 1904, 4, 1070).

The glycerides of butter-fat contain butyric, caproic, caprylic, capric, lauric, myristic, palmitic, stearic, and oleic acids, as triglycerides, with, possibly, a small quantity of mono- and diglycerides. Bell has shown the presence of 'mixed' glycerides, and describes (Chemistry of Foods, 45) an oleopalmitobutyrate. Browne (J. Amer. Chem. Soc. 1899, 613) finds 1·0 p.c. of dihydroxystearic acid; but Lewkowitsch throws doubt upon the presence of any hydroxy acids (Oils and Fats, 4th ed. ii. 667). The composition, as given by Bell (Chem. of Foods, 18), is compared with that given by Browne (J. Amer. Chem. Soc. 1899, 21, 807).

100 parts of fat on saponification yield:

	Bell	Browne	
Butyric acid . .	6·13	5·45	
Caproic „ . .	2·09	2·09	2·90
Caprylic „ . .		0·49	
Capric „ . .		0·32	
Lauric „ .		2·57	
Myristic „ . .	19·46	9·89	50·33
Palmitic „ . .		38·61	
Stearic „ . .		1·83	
Oleic „ . .	36·10	32·50	
Dihydroxy stearic acid	-	1·00	

Siegfield (Zeitsch. Nahr. Genussm. 1912, 24, 45) found no stearic acid, and Smedley (Bio. Jour. 1912, 6, 451) found 10 p.c. of stearic acid in butter fat. Holland, Reed and Buckley (J. Agric. Research, 1916, 101; *ibid.* 1918, 719) have also found high proportions of stearic acid present. They found the percentage quantities of various acids in butter-fat as follows: butyric acid, 3·153; caproic acid, 1·360; caprylic acid, 0·975; capric acid, 1·831; lauric acid, [illegible]; myristic acid, 22·618; palmitic acid, 19·229; stearic acid, 11·384; oleic acid, 27·374. These results were obtained by esterification of the butter-fat, and subsequent fractionation of the resulting esters. For details the original paper must be consulted.

Caldwell and Hurtley (Chem. Soc. Trans. 1909, 95, 853) have fractionally distilled samples of butter fat in the vacuum of the cathode light, and determined certain values of the distillates. They conclude that there is no tributyrin in butter-fat, and probably no triolein, the oleic acid being distributed among the glycerides present, most of it as oleostearopalmitin. Caldwell and Hartley (*l.c.*) have also similarly distilled the fatty acids. According to Amberger (Zeitsch. Nahr. Genussm. 1918, 35, 313) butter-fat contains a small quantity (2·4 p.c.) of triolein; the greater part of the oleic acid existing as mixed glycerides. Butyric and other volatile acids are also present as mixed glycerides; tributyrin cannot be isolated. Examination of the alcohol-soluble portion of hydrogenised butter-fat shows that the original fat contains butyrodiolein, butropalmito-olein and oleo-dipalmitin.

The most characteristic feature of butter-fat is the presence of fatty acids soluble in water and volatile in steam; and the earliest work on butter was directed to the estimation, directly or indirectly, of butyric acid, the largest constituent of the soluble or volatile portion.

Hehner and Angell (Butter: its Analysis and Adulterations, Churchill, 2nd ed. 1877), following the suggestion of Chevreul, proposed in 1874 to obtain the butyric acid by distillation of the acids liberated by dilute sulphuric acid after saponification of the fat with alkali. In consequence of the variation in the results, they proposed the determination of the acids insoluble in water, Dupré subsequently adding in the same process the titration of the water-soluble acids (Analyst, 1876). The quantity of insoluble fatty acids is frequently spoken of as the 'Hehner value.' The process consists in saponifying a weighed quantity of the fat with alcoholic potash, liberating the fatty acids from the aqueous, alcohol-free, soap solution with excess of dilute sulphuric acid, filtering and washing with hot water the insoluble acids, finally weighing these, and titrating the dissolved acids. The quantity of soluble acids usually falls between 4·2 and 6·0 p.c. (calculated as butyric acid), and the weight of the insoluble acids between 90 and 87·5 p.c.

Reichert adopted a modification of Chevreul and Hehner's distillation of the butyric acid, operating with a definite quantity of fat under prescribed conditions, and thus avoiding the necessity of the distillation of the whole of the volatile acids. Reichert took 2·5 grams of fat; and the number of cubic centimetres of decinormal alkali required to neutralise the distillate from this quantity, operating as described, was the original Reichert number (Chem. Soc. Trans. 1879, A, 406; Zeitsch. anal. Chem. 1879, 18, 68). Meissl suggested the use of 5 grams of fat (Chem. Soc. 1880, A, 828), and Wollny added a number of modifications (Chem. Soc. 1888, A, 200). This process was adopted by a committee consisting of the Principal of the Government Laboratory and members of the Society of Public Analysts, as the method to be used in the estimation of butter-fat in margarine (Analyst, 1900, 25, 309). The conditions of distillation must be strictly observed, as the whole of the volatile acid is not distilled during the experiment. Richmond (*ibid.* 1895, 20, 218) found only 87 p.c. of the total volatile acids in the distillate. Jensen's results confirm this (Zeitsch. Nahr. Genussm. 1905, 272). Leffmann and Beam used soda dissolved in glycerol for the saponification (Analyst, 1891, 16, 153). The details of the process, as adopted by the committee, are: 5 grams of clear, melted fat are weighed into a flask of a capacity of 300 c.c., and saponified with 2 c.c. of soda (prepared by dissolving sodium hydroxide in equal weight of water), and 10 c.c. of alcohol, by heating on a hot water-bath under reflux condenser for 15 minutes. After evaporation of the alcohol, the dry soap is dissolved in 100 c.c. of hot water, 40 c.c. of normal sulphuric acid and a few fragments of pumice are added, and the flask connected with a condenser. It is then heated so that 110 c.c of distillate are collected in about 30 minutes. The distillate is shaken, 100 c.c. filtered off, and titrated with decinormal alkali, using phenolphthalein as indicator. (Further details as to size of flask, tubes, still-head, condenser, will be found in the Analyst, 1900, 25, 309.) The number of cubic centimetres of decinormal alkali required for neutralisation, when multiplied by 1·1 and corrected to 5 grams, is the 'Reichert-Wollny number.'

The proportion of volatile acids in butter-fat varies. In the late autumn season, in the case of cows fed in the open, the butter-fat contains less butyric acid than it does during the spring and summer. Towards the close of the lactation period, butter fat also shows a depreciation in the amount of volatile acids. Among other factors affecting the character of the fat are the nature of the food, and the sensitiveness of the cows to varying climatic conditions and their surroundings. Hence the uncertainty as regards the limits that should be adopted. In the case of butter made from the milk of mixed herds, when the influence of individual cases does not seriously depreciate the butter from the whole herd, the proportion of volatile acids under ordinary conditions of feeding and housing reaches a maximum in April–May–June, and is at a minimum in October–November. Lewkowitsch has collected a number of results representing the produce of different countries (Oils and Fats, 4th ed. ii. 686). Although the milk from individual cows or small herds may, in consequence of special circumstances, occasionally yield butter fat giving a Reichert-Wollny number below 24, the butter from the mixed milk of herds under normal conditions usually has a Reichert-Wollny number falling between 24 and 32. The Committee on Butter Regulations appointed by the Board of Agriculture in this country recommended that the figure 24, arrived at by the Reichert-Wollny method, should be the limit below which a presumption should be raised that butter is not genuine (Com. on Butter Regns Report, Cd. 1749, 18). France has fixed a minimum limit of 24; Germany, of 25; Sweden, of 23; the United States, of 24; Italy declares butter with a Reichert-Wollny number below 20 adulterated, between 20 and 26 suspicious, above 26 pure; Belgium declares butter to be abnormal, and its sale is prohibited, if the Reichert-Wollny number falls below 28, and if in addition the fat has a Zeiss number above 44 at 40°, a sp.gr. below 0·865 at 100°, a saponification value below 222, and a Hehner number above 88·5.

Sandby Ball (Analyst, 1907, 32, 202) gives results of butters produced in Ireland, and shows that during the months of December and January, when the output of milk is lowest, the Reichert-Wollny number frequently falls below 24. The lowest numbers occur when the milk is derived from cows at the end of the lactation period.

Brownlee (Jour. Dept. Agric. for Ireland, 1910, 10, 438) has published results of analyses of Irish butter produced in 1908-9. He found 16·2 p.c. of samples below 24, 11·4 p.c. below 23, 5·5 p.c. below 22, and 1·4 p.c. below 21. The tables given by Brownlee show that throughout the year the Reichert-Wollny number varies in each case with the percentage output of butter from the particular dairy, and the results confirm the opinion that the chief factor influencing the Reichert-Wollny number is the lactation period of the cows supplying the milk.

The conclusion that butter is genuine because the Reichert-Wollny exceeds 24, may be erroneous, as this number may have been the result of mixing genuine butter having a high Reichert-Wollny number with some other fat. On the other hand, butter falling below 24 may be genuine but abnormal. In order to be in a position to establish the genuineness of butter, the Netherlands Government has organised a system of butter control, by means of which the associated creameries are frequently inspected and the butter produced regularly analysed. Consignments from the factories bear a government label, giving particulars of origin, so that the officials can trace the butter and ascertain the Reichert-Wollny number of the butter produced at the creamery.

Higher homologues of butyric acid volatilised in the steam during the Reichert process do not wholly dissolve in the distillate, and the determination of the insoluble portion affords another index to the character of the fat, as will be seen later.

Butter-fat has a sp.gr. at 37·8°/37·8° of 0·910-0·913 (Thorpe, Chem. Soc. Trans. 1904, 249). The individual data in Bell's results range from 0·9094 to 0·9139, but he states the ordinary range is 0·911 to 0·913. The sp.gr. is affected by prolonged heating of the fat and also by the storage of the fat for a lengthened period

The reading with the Zeiss butyro-refractometer at 45° falls usually between 38 and 42. In 371 samples of genuine butter examined, the range was 37 to 45 (Com. on Butter Regns., Ap. 585). Excluding 14 exceptional butters, the average range was 39·4 to 42·0 (Chem. Soc. Trans. 1904, 249). (Zeiss readings are taken at various temperatures by different observers. To convert the scale divisions observed at a lower temperature into the scale divisions at a higher temperature, deduct 0·55 of a division for each degree of temperature that the reading has been taken below the required temperature; conversely, add 0·55 of a division for each degree of temperature that the reading has been taken above the required temperature).

The saponification value of the fat was suggested by Koëtstorffer (Frdl. 1879, 199), and is frequently known as the Koëtstorffer number. It is the quantity of potash expressed in milligrams required to saponify 1 gram of fat. The glycerides in butter-fat contain acids of comparatively low molecular weights; in consequence, the quantity of potash for saponification will be relatively high when compared with fats in which the glycerides contain only acids of high molecular weight, as in animal fats in general. Butter-fat gives figures on the average between 219·9 and 232·5 (Thorpe). Koëtstorffer gave 227 as a mean figure. This value bears a close relationship to the Reichert number.

The iodine value varies considerably, falling between 26·0 and 35·0 (Hübl), 29·0 and 43·0 (Jensen), and 26·0 and 38·0 (Wollny).

The various data show their dependence upon one another, within certain limits, when a comparison is made. This parallelism is shown in the following table (Thorpe, Chem. Soc. Trans. 1904, 254):—

No. of samples	R. W. number	Specific gravity at 37·8°	Saponification value	Zeiss at 45°	Soluble acids, p.c. on fat	Insoluble acids, p.c. on fat	Mean molecular weight of insoluble acids
7	22·5	0·9101	219·9	42·0	4·3	90·1	266·9
17	23·5	0·9104	221·3	41·5	4·5	89·7	265·5
15	24·5	0·9108	223·3	41·5	4·7	89·4	265·0
27	25·5	0·9110	223·4	41·3	4·8	89·3	264·2
37	26·5	0·9113	225·3	41·0	4·9	88·9	261·9
51	27·5	0·9114	226·7	40·6	5·2	88·7	261·7
78	28·5	0·9118	228·3	40·1	5·4	88·4	260·9
56	29·5	0·9120	229·9	40·1	5·6	88·3	259·6
41	30·5	0·9123	231·4	39·9	5·8	87·9	260·1
18	31·3	0·9125	232·2	39·7	5·7	87·9	258·0
10	32·6	0·9130	232·5	39·4	6·0	87·7	257·8
357							

The examination of butter comprises: (1) the determination of water, fat, curd, salt; (2) examination of the fat; (3) examination of the butter for preservatives, colouring matter, and substances foreign to butter.

1. **Water.** The sample for examination should be not less than 50 grams, and should be placed in a bottle and closed securely with screw-cap or stopper. The bottle is then heated at a temperature of about 50° until the butter-fat has melted, when it is vigorously shaken to emulsify the fat and water. The shaking is continued while the bottle and contents cool, until the butter is of the consistency of thick cream. From 6 to 8 grams are then weighed into a flat-bottomed dish, in which is a glass rod with flattened end. The dish is heated on a steam-bath for an hour with frequent stirring of the butter, after which it is cooled and weighed. It is again heated until the weight is constant. The operation is considerably accelerated by using aluminium dishes, heated on an aluminium hot plate adjusted to a temperature of 100° to 105°.

Patrick (J. Amer. Chem. Soc. 1906, 1613) carries out the estimation of the quantity of water by cautiously heating 10 grams of butter in an aluminium vessel over the direct flame, taking care to avoid over-heating.

In Gray's method (U.S. Dept. of Agric., Bureau of Animal Industry, Circ. 100) 10 grams of butter, weighed on a parchment paper, are placed in a flask together with a little amyl-acetate, and the flask directly heated. The flask is connected with a calibrated tube arranged as a reflux condenser, the condensed water and amyl acetate being collected in a bulb at the bottom of the tube. When all the water is driven off, the tube with the bulb is removed, and inverted, the volume of water being measured in the calibrated portion.

Other methods are Henzold's (in which pumice is mixed with the butter) and Wibel's J. Soc. Chem. Ind. 1893, 630).

Fat. The butter from which the moisture has been expelled is extracted with ether, filtered from curd and salt, and, after evaporation of the solvent, is dried and weighed, or the matter insoluble in ether is weighed, and the fat taken by difference. The fat may also be estimated by the Gottlieb method: 2 grams of butter are washed into a graduated burette tube with about 8 c.c. of warm water, and mixed with 1 c.c. of ammonia (sp.gr. 0·880) and 10 c.c. of alcohol, mixing well after each addition. The tube is cooled, 25 c.c. of methylated ether added, and the liquids mixed; 25 c.c. of light petroleum are then added, and the tube carefully inverted several times to mix the solutions. The volume of the mixed ether solution which separates on standing is measured, and a known portion removed and evaporated.

Shaw (U.S. Dept. of Agric., Bureau of Animal Industry, Circ. 202) takes 25 grams of butter, and using a separator, washes out salt and curd first with hot water, and then with slightly diluted sulphuric acid, finally measuring the volume of fat. The Governments of Queensland, Victoria, and Germany have fixed a minimum limit for fat of 80 p.c.; Italy, of 82 p.c.; and the United States, of 82·5 p.c.

Curd. In the case of butters free from salt and preservative, the curd is the matter not soluble in ether or other solvent. The separate determination of the proteins and lactose must be carried out to decide whether a butter contains added non-fatty milk products. 15–20 grams of butter are weighed in a dish and dried on the water-bath with frequent stirring. The fat is extracted with ether, and the ether-insoluble matter transferred with concentrated sulphuric acid to a Kjeldahl digestion flask, adding the filter paper used for filtration. The quantity of nitrogen multiplied by 6·38 gives the proteins. Richmond gives 6·39 (Analyst, 1908, 33, 180).

The lactose is taken by difference, after deducting from the total curd the proteins and inorganic salts. But it is in all cases preferable to make a direct determination, and this becomes necessary when boric acid is present. The lactose and proteins may then be estimated as follows: The residue from extraction with ether of 20 grams of butter is mixed with about 40 c.c. of water, made just acid with acetic acid, and the proteins precipitated by adding a few drops, being careful to avoid excess, of Fehling's copper sulphate solution. It is then filtered on tared paper, washed, dried at 100°, weighed, and incinerated. The weight less the ash is the proteins. The filtrate is made up to 100 c.c. and an aliquot portion taken for gravimetric lactose determination. Where sugar only is required, the residue from ether extraction may be washed into 100 c.c. flask cleared with copper sulphate, made up to 100 c.c., filtered, and an aliquot portion taken. The quantity of lactose should not exceed 0·4 p.c., and is usually much less.

The matter insoluble in ether contains, in addition to the true curd and other non-fatty solids of milk, common salt, borax, a portion of the boric acid (partly in solution in ether), and certain other preservatives, if these have been added to the butter. The common salt is estimated by extracting the weighed quantity of curd in the total curd determination with hot water, and titrating the solution with standard silver nitrate.

2. Examination of the fat. The examination of the fat to ascertain its purity is one of considerable difficulty, since butter adulteration has been directed to the admixture of fats prepared so as to give no distinctive reaction. All animal fats, such as refined lard and beef fat, and many vegetable fats used for this purpose, have practically no volatile acids. Hence the addition to butter of fats of this class reduces the soluble volatile acids number. Other vegetable fats contain volatile acids only partially soluble in water. To this class belong cocoa-nut oil and palm-kernel oil.

Vegetable fats, unless specially prepared, contain phytosterol, and the detection of this substance establishes the presence of foreign fat. Other fats, as cotton seed and sesamé, give specific reactions, and may therefore be directly tested for. It has, however, been established that the constituent giving the reaction may be communicated to a slight extent to milk and thence to butter through feeding the animals with oil cakes made from these seeds. Positive reactions in these cases must therefore be supported by other evidence. With the object of detecting the addition of foreign fat, it is enacted in some countries that margarine and margarine fats must contain, when prepared for sale, a small quantity of sesame oil, as a tell-tale substance when butter with which such fat has been mixed is examined.

(*a*) The soluble volatile acids are estimated by the Reichert-Wollny process described above.

Reychler (Bull. Soc. chim. 1901, 25, 142) proposed the extension of the Reichert-Wollny process to include the estimation of the volatile insoluble acids. Wauters (Analyst, 1901, 26, 128) modified the Reichert process and made two distillations, determining the values for both soluble and insoluble volatile acids.

Polenske (Zeitsch. Nahr. Genussm. 1904, 273) adopts the Reichert-Wollny process and estimates in the same operation the soluble and insoluble volatile acids. 5 grams of the fat are weighed into a 300 c.c. flask and saponified with 2 c.c. of soda solution and 20 grams of glycerol by heating the flask over the free flame. The flask is cooled below 100°, and 90 c.c. of hot water and a little powdered pumice are added. When the soap is in solution the fatty acids are liberated with 50 c.c. of sulphuric acid (25 c.c. pure H_2SO_4 in one litre), the flask attached at once to a condenser arranged vertically, and heated so that 110 c.c. of distillate are collected in about 20 minutes. The heating is then stopped, and the receiving flask replaced by a measuring jar to catch the drainings of the condenser. The distillate is cooled to 15°, gently shaken, and 100 c.c. filtered off and titrated with decinormal soda. The number of cubic centimetres (multiplied by 1·1 and corrected to 5 grams) is the Reichert-Wollny number.

The remainder of the distillate is poured on the filter paper, and then washed with three quantities, of 15 c.c. each, of water, each of which has been passed in succession through the condenser tube, the measuring jar, and the 110 c.c. flask. These washings are rejected. The 110 c.c. flask is then placed under the filter funnel, and the water-insoluble acids dissolved in alcohol by passing three quantities, of 15 c.c. each, of neutral alcohol, successively through the condenser tube, measuring jar, and filter paper. The alcoholic filtrates are titrated with 1/10 normal soda, using phenolphthaleïn as indicator. The number of cubic centimetres required is the insoluble volatile acids number.

In butter-fat this number varies with the soluble acids number. Polenske (*l.c.*) gave a range of 1·35 insoluble for 20·0 of soluble, to 3·0 insoluble for 30 of soluble. Individual butters may, however, give numbers outside this range. Rideal and Harrison (Analyst, 1906, 31, 254) give results of examination of a number of English butters. Harris (*ibid.* 1906, 31, 353) shows the variation in insoluble acids number for the same soluble acids number. Hesse (Chem. Zentr. 1905, 1, 566) states the limits given by Polenske should be higher. Hesse and Harris (*l.c.*) point out the importance of following exact details of process, particularly in regard to size of pumice. Harris gives varying results obtained by operating with pumice of different sizes. Beerbohm (Milch. Zentr. 1913, 513) states that during lactation, the R.W. number falls but the Polenske number rises.

Cocoa-nut fat gives a soluble acids number by this process of 7–9 and an insoluble acids number of 15–18. Hence the addition of this fat to butter depresses the Reichert-Wollny number, and increases the insoluble volatile acids number. At the same time, the Zeiss and iodine numbers would be lowered, and the saponification value would be increased. Thus, while the Polenske value alone might not itself be sufficient evidence of adulteration in cases of small quantities of admixed cocoa-nut fat, the disturbance of the co-relation between the other numbers would establish the presence of the adulterant. Palm-kernel fat has a Reichert-Wollny number of 5, and insoluble volatile acid number of 10–12; other vegetable and animal fats have a total volatile acids number less than 1. The addition of palm-kernel oil would operate in a similar manner to that of cocoa-nut fat; animal fat would depress both the soluble and insoluble volatile acids, but the former to a greater extent than the latter. Thorp (Analyst, 1906, 31, 173) makes a second distillation in the ordinary Reichert process, after addition of more water, and obtains an increased value for the total insoluble volatile acids. He gives results of examination of butters and mixtures.

Muntz and Coudon (Mon. Sci. 1904, 18; Analyst, 1905, 30, 155) have devised a similar method for determining the ratio between the soluble and insoluble volatile acids. They saponify 10 grams of fat with hot strong aqueous potash, dissolve the soap in water, add phosphoric acid solution, and distil 200 c.c., using a spiral dephlegmator of considerable length. The distillate is filtered, and the soluble acids titrated. The insoluble acids in the condenser tube and flask, and on the paper are also dissolved in alcohol and titrated. They found that pure butters yielded from 4·79 to 6·01 p.c. of soluble volatile acids (as butyric acid) and 0·5 to 0·87 p.c. of insoluble; while cocoa-nut fat gave 1·15 to 1·27 p.c. soluble, and 3·06 to 3·63 p.c. insoluble. They determine the following ratios:

$$\frac{\text{insol. vol.}}{\text{sol. vol.}} \times 100 = 9{\cdot}1\text{–}15{\cdot}6$$

for genuine butter, and 250·3 to 282·3 for cocoa-nut fat.

Vandam (Analyst, 1901, 26, 320) determined the ratio between the total fatty acids soluble in 60 p.c. alcohol, and those soluble in the alcohol but insoluble in water. Robin (Compt. rend. 1906, 143) practically applies the same principle in his method. He found that the ratio $\frac{\text{insol.}}{\text{sol.}} \times 10$ was 8·3 to 12·7 butter, 232 for margarine, and 226 for cocoa-nut fat. Shrewsbury and Knapp (Analyst, 1910, 35, 385) remove the acids soluble in water, and then determine the solubility of the remaining fatty acids in dilute alcohol. They find a solubility figure of 28 for butter and 163 for cocoa-nut fat. It has been shown (Caldwell and Hurtley, Analyst, 1909, 34, 274) that lauric and myristic acids are the chief constituents of cocoa-nut fatty acids, but that these acids are only present to a slight extent in butter; and these processes are therefore based upon the solubility in 60 p.c. alcohol and insolubility in water of these acids. Fendler (Zeitsch. Nahr. Genussm. 1910, 19, 544; Analyst, 1910, 35, 355) has a similar process.

Avé-Lallemant (Zeitsch. Nahr. Genussm. 1907, 14, 317) precipitates the neutralised, alcohol-free soap solution with barium chloride, and determines the baryta values for the soluble barium salts, and for the insoluble barium salts. He finds that normal butter has insoluble baryta value of 247 to 251, and soluble baryta value of 50 to 65. The value [insol. —(200+soluble)] is negative for butter, whereas other fats have a positive value not less than 39. (*See* also Fritzsche, Zeitsch. Nahr. Genussm. 1907, 14, 329.)

Ewers (*ibid.* 1910, 19, 529) proposes a method depending upon the different solubility of the magnesium salts of the fatty acids, and on the varying solubility in petroleum spirit of the fatty acids from the soluble magnesium salts.

Various methods have been proposed to distinguish between cocoa-nut fat and butter fat by means of the solubilities of the silver salts of the distilled acids in the Reichert-Wollny process (K. Jenson, Analyst, 1905, 30, 396; O. Jenson, Zeitsch. Nahr. Genussm. 1905, 10, 265; Kirschner, *ibid.* 1905, 9, 65; Wijsman and Reijst, *ibid.* 1906, 11, 267; Dean, Ann. Chim. anal. 1906, 11, 121). Of these, the method of Kirschner has been much used in this country in connection with the Reichert-Wollny-Polenske process. As it gives a measure of the amount of butyric acid present, and eliminates the reading in the ordinary R.W. process due to the presence of other soluble volatile acids, it is of special value for the detection in butter of margarine mixtures containing coconut or palm-kernel fats. The Kirschner process is carried out as follows: To the 100 c.c. which have been neutralised with baryta for the R.W. No. 0·5 gram of Ag_2SO_4 is added, and after standing for 1 hour with occasional shaking, the liquid is filtered through a dry paper. 100 c.c. are taken; 35 c.c. water, 10 c.c of dilute H_2SO_4 (as in the Polenske method), and a piece of aluminium wire are added; and the distillation carried out as before, 110 c.c. being collected in 20 minutes. 100 c.c. are titrated and the Kirschner number obtained as follows:—

$$K = x \times \frac{121}{100} \times \frac{100+y}{100}$$

(x=titration value of 100 c.c. less blank.)

(y=number of c.c. of baryta solution used in titration of original R.W. No.)

Bolton and Revis (Analyst, 1911 333) and Bolton, Richmond, and Revis (Analyst, 1912, 183) give the results for a number of mixtures, and formulæ and curves for the calculation of the amount of cocoanut or butter-fat present They suggest the following table for the relation between the Kirschner and Polenske numbers:—

Kirschner	Polenske
20	1·60
22	2·10
24	2·65
26	3·20

Cranfield (Analyst, 1915, 441) gives the R.W., Kirschner, and Polenske values for a large number of butters analysed at the Midland Agricultural and Dairy College, showing similar relations between the Kirschner and Polenske figures.

Bolton, Richmond, and Revis point out that if an allowance of ±1 is made in the Polenske value corresponding to any particular Kirschner value, the presence of less than 5 p.c. of cocoanut fat will cause the Polenske value to fall outside the limit, except in cases of special feeding of cows.

Dons (Zeitsch. Nahr. Genussm. 1908, 15, 75) has modified the process. The mixed fatty acids are treated with water to remove the soluble portion. Caprylic acid, which remains behind with the insoluble acids, is removed by distillation, and estimated in the distillate by precipitation with silver nitrate solution. Pure butter-fat gives a value 1·6 to 2·0 and cocoa-nut fat 5·3.

Juckenack and Pasternack (Zeitsch. Nahr. Genussm. 1904, 7, 193) proposed to determine the presence of cocoa-nut oil in butter from the relationship between the Reichert - Wollny number and the saponification value. They point out that according to the formula [R.W. −(sapon. value−200)] butter fluctuates between −3·5 and +4·25. For cocoa-nut oil its value is −47. Harris (Analyst, 1906, 31, 355) has shown that the method of reasoning suggested is of no value for small admixtures of cocoa-nut fat with butter.

[illegible] and Amberger (Zeitsch. Nahr. Genussm. 1909, 17, 23) distil separated solid fatty acids in a current of steam in special flask, and precipitate the cadmium salts in distillate.

Hanuš (*ibid.* 1907, 13, 18) and Hanuš and Štekl (*ibid.* 1908, 15, 577) and Fendler (*ibid.* 1910, 19, 544) propose methods based upon the distillation of the ethyl esters of the fatty acids. Fendler prepares the esters after the manner of Henriques (Analyst, 1898, 23, 181) and collects the esters boiling below 300°. This fraction would include the ethyl esters of the acids up t and including myristic acid. The volume i the case of butter ranges from 2·5 to 6·1; cocoa nut fat, 40 to 42; and lard, 0·5 to 1·1 c.c.

Caldwell and Hurtley (*l.c.*) state that smal quantities of cocoa-nut fat can be detected b the fractional distillation in a high vacuum o the fatty acids.

(*b*) The foregoing tests for the detection o the adulteration of butter-fat are based upon th disturbance of the ratio existing in normal o average butter-fat between the proportions o soluble and insoluble acids. It has, however been shown that special feeding may affect thi relationship and produce butter giving abnorma results. Uncertainty as to the conclusions t be drawn may be removed if direct evidence i obtained from the application of specific tests The following qualitative tests may be applied :—

Phytosterol test for detection of vegetable fat (Bömer, Zeitsch. Nahr. Genussm. 1901, 4, 1070 and 1902, 5, 1018).—The absolute alcoho extract of the unsaponifiable matter from 10 grams of fat is treated with acetic anhydride the excess of which is removed, and the acetate dissolved in alcohol, crystallised, and recrystallised several times. Cholesteryl acetate melts a 113·5° to 114·5°, while the melting-point o Phytosteryl acetate is about 129°. If the melting-point of the mixed acetates from the sampl under examination is between 116° and 117°, i is probably adulterated with vegetable fat; i above 117°, vegetable fat is certainly present The test is not of value if paraffin wax is als present.

Hinks' test for cocoa-nut fat (Analyst, 1907 32, 160).—5 c.c. of the fat are dissolved i 10 c.c. of ether, and the solution cooled in ice After half an hour, it is rapidly filtered, th ether evaporated from the filtrate, and the fatt residue dissolved in 96 p.c. (vol.) alcohol. Th solution is cooled to 5° for 15 minutes, filtered rapidly, and the filtrate cooled to 0°. Th deposit which separates at this temperature i then examined on a cold slide under a powe of about 250. Butter fat yields a deposi of round granular masses; cocoa-nut fat, fin needle-shaped crystals; and mixtures of butte and cocoa-nut fat, fine feathery crystals attache to the granular butter masses. The test i capable of detecting 5 p.c. of cocoa-nut fat i butter fat.

Badouin test for sesamé oil.—5 c.c. of the fa are mixed in a tube with 5 c.c. of HCl (sp.gr 1·19) and 0·1 c.c. of a 2 p.c. furfural solution The mixture is well shaken and allowed to stand The aqueous layer which separates assumes reddish colour in presence of sesamé oil. Butter coloured with some aniline dyes give with hydrochloric acid a pink-to-violet colouration, and i such a case the acid and fat mixture must b heated until colourless before the addition o the furfural solution.

Halphen test for cotton seed oil.—5 c.c. of th fat are dissolved in 5 c.c. of amyl alcohol, 1 c.c of a solution of sulphur in carbon disulphide i added, and the mixture heated for 20 minute at 105° in a brine-bath. A red colouration i produced in presence of cotton-seed oil. Th chromogenetic substance may, however, i exceptional cases, be communicated to butter b feeding cows with cotton cake; and a positiv reaction must be confirmed by other data of the examination.

(c) The specific gravity and the Zeiss reading should be taken and considered in conjunction with and relation to the data for the Reichert-Wollny number, saponification and iodine values.

Of other physical methods there may be mentioned:

Valenta test.—3 c.c. of fat are dissolved in an equal volume of glacial acetic acid, and then allowed to cool while being stirred with a thermometer. Immediately a turbidity is noted, the temperature is read. A modification introduced by Jean is to measure the volume of acid dissolved in the fat at 50°. (For recent investigation of factors affecting the Valenta test, *see* Fryer and Weston, Analyst, 1918, 43, 3.)

Crismer test.—This method is an official one in Belgium. 0·5 c.c. of melted fat and 1 c.c. of absolute alcohol are placed in a tube fitted with cork and thermometer, the bulb of which dips into the liquid. The tube is gently heated inside a larger tube until the liquid becomes homogeneous. It is then allowed to cool, and the temperature noted when turbidity appears. This point is the critical temperature of dissolution (Crismer, Analyst, 1897, 22, 71). Vandam has shown how the alcohol used in the test may be standardised by means of petroleum spirit (Ann. des Falsifications, 1919, 260).

Butter fat gives a result varying from 50·5 to 57, whilst margarine has a value over 65 if it is composed of animal fat, and under 50 if prepared from vegetable fat. The fat must be free from moisture and quite clear, and can generally be so obtained by filtration in a hot-water oven through a dried filter paper. The Crismer values of other fats are as follows: sesamé oil, 67·5; almond oil, 64; cotton seed oil, 61·5; arachis oil, 57·5; olive oil, 56; cacao butter, 47, tallow, 34·5; lard, 76–77; palm oil, 22; cocoanut oil, 15–19·5; palm-kernel oil, 13·5 (Stewart, J. State Med. 1918, 26, 312).

3. **Examination for preservatives.**—(*a*) *Boron compounds.* Boric acid or borax is detected by moistening a strip of turmeric paper (filter paper soaked in an alcoholic solution of curcuma and dried) with a drop of water squeezed from the butter, or with the aqueous layer obtained on melting the butter. The paper is then dried. Free boric acid gives a pink colour changed to green with alkali. For borax a drop of dilute hydrochloric acid must be added to the paper before drying.

The boric acid is estimated by Richmond and Harrison's method (Analyst, 1902, 27, 179) or by washing the butter in a separator with hot water, evaporating the aqueous portion after addition of soda, incinerating, and proceeding as in Thomson's process.

A method suitable for rapid determinations is as follows: 10 grams of butter are shaken in a separator with 20 c.c. of hot water and 10 c.c. of decinormal sulphuric acid. The aqueous layer is run off after a few minutes, and the fat washed twice more with small quantities of hot water. The mineral acid in the combined water extracts is then neutralised, with lacmoid as indicator. 2 grams of mannite are now added, and phenolphthaleïn. Decinormal soda is then added until pink colour is permanent. The quantity of soda used after the solution was neutral to lacmoid indicates the proportion of boric acid present. A control experiment should be carried out with pure butter and indicators.

The Committee on Preservatives in Food recommended that borax or boric acid should be the only preservative allowed in butter, and that the quantity should not exceed 0·5 p.c. calculated as boric acid.

(*b*) *Formalin* is detected by the application of Hehner's test (Richmond, Analyst, 1896, 21, 92). A little milk is added to the aqueous layer from melted butter, and the mixture poured on to the surface of sulphuric acid containing a trace of ferric chloride. In presence of formaldehyde a blue ring appears at the juncture of the aqueous and acid layers.

(*c*) *Fluorides.* Fluorine is detected by evaporating the aqueous portion rendered alkaline from about 30 grams of butter, incinerating, and heating the ash in a platinum crucible with strong sulphuric acid. The crucible is covered with a watch-glass coated with wax through which a mark or design has been scratched with a fine instrument. In presence of fluoride the glass will be etched.

O. and C. W. Hehner (Analyst, 1902, 27, 173) indicate how to remove the boric acid if present before testing for fluoride.

(*d*) *Benzoic acid and benzoates.* 10 grams of butter are heated for some time with alcohol acidified with dilute sulphuric acid. The alcoholic extract, after dilution with water, is extracted with ether in a separator. The ether solution is then shaken with dilute ammonia, and the ammoniacal extract evaporated to dryness in a porcelain dish. The residue is dissolved in water, just acidified with acetic acid to ensure that no free ammonia remains, and a drop of ferric chloride solution added. Benzoic acid gives a buff-coloured precipitate.

(*e*) *Salicylic acid.* A portion of the alcoholic solution prepared for benzoic acid is tested directly with a drop of ferric chloride solution. Salicylic acid gives a violet colour.

(*f*) Richmond (Analyst, 1908, 33, 116) points out that formic acid and glucose are also used as preservative agents.

Colouring matters. The colour of butter prepared without addition of artificial colouring matter, varies according to the food of the cows. The yellow colour is due to the yellow pigments which accompany chlorophyll in all green plants, of which carotin and xanthophyll are the most important. The pigment is not made in the animal body, but is derived entirely from the food; fresh green grass contains most, and gives the highest coloured milk fat. There is a difference in breed, but this is not so important a factor as supposed (Palmer and Eckles, J. Biol. Chem. 1914, 17, 191). (For the detection of carotin in butter, *see* J. Ind. Eng. Chem. 1916, 614.) Winter butter from stall-fed cows is nearly colourless. Colouring matter is frequently added to butter during manufacture. Annatto, turmeric, carrot juice, saffron, marigold, safflower and aniline dyes are among the artificial colours employed. Agitation of the butter fat with hot alcohol will give an indication whether colour has been added. Cornelison (J. Amer. Chem. Soc. 1908, 30, 1478) shakes thoroughly 10 grams of melted fat with 10 to 20 grams of glacial acetic acid at about 35°. The acid layer is drawn off and tested with various reagents for the detection of aniline and vegetable dyes. Leeds (Analyst, 1887, 150) has also proposed a scheme for identification of dye.

Annatto and azo dyes may be rapidly tested for as follows: 5 c.c. of melted fat are placed in each of two test-tubes. To one 5 c.c. of hydrochloric acid are added, and the mixture shaken. Azo- dyes will impart a reddish colour to the acid layer. To the second tube add 5 c.c. of ether, and shake, and then 5 c.c. of 10 p.c. potash solution. Shake and allow to separate. If annatto is present, the alkaline layer will be coloured yellow. To confirm the annatto, the alkaline liquid is withdrawn, evaporated to dryness, and touched with a drop of sulphuric acid. Annatto gives an indigo-blue to violet colouration.

Crampton and Simons (J. Amer. Chem. Soc. 1905, 27, 270) point out the use of palm oil as a colouring substance, and its detection by the Halphen and Liebermann-Storch methods for rosin oil.

The further examination of the butter is concerned with its flavour, appearance, rancidity. As regards rancidity, the quantity of free acid dissolved in alcohol may be ascertained, but this is frequently no guide to or measure of the rancidity, which is best judged by smell and taste.

The definition of 'butter' in the Margarine Act, 1887 (50 & 51 Vict. c. 29) is as follows: 'The word "butter" shall mean the substance usually known as butter, made exclusively from milk or cream, or both, with or without salt or other preservative, and with or without the addition of colouring matter.'

The Butter and Margarine Act, 1907 (7 Edw. 7, c. 21) describes milk-blended butter as 'any mixture produced by mixing or blending butter with milk or cream (other than condensed milk or cream).' By the provisions of this Act milk-blended butter may contain a maximum of 24 p.c. of water.

'Renovated' or 'process' butter is a product mainly of the United States. It is defined by Act of Congress as 'butter which has been subjected to any process by which it is melted, clarified, or refined and made to resemble genuine butter.' Butter which is unsaleable through rancidity, mould growths, or other causes, is melted, and the oil separated from the curd and water. The oil is then aërated by 'blowing' with air, and afterwards emulsified with fresh milk inoculated with a bacterial culture. It is then churned and worked as for ordinary butter.

Crampton (J. Amer. Chem. Soc. 1903, 25, 358) gives details of analyses and tests. Several similar processes have been patented here, and in some factories the melting and purification of inferior butter is now carried on. Hence such products might contain crystalline fat, and the microscopical examination is now of no value as a test for foreign fat.

'Factory' butter is butter which has been reworked or blended with other butter; by 'dairy' butter is understood butter made at the farmer's homestead, whether from whole milk or cream; and the term 'creamery' butter is generally applied to butter made from cream separated by centrifugal force from the mixed milk of a number of herds in premises specially utilised for the purpose (*see* the Report of the Committee of the Department of Agriculture for Ireland, on the Irish Butter Industry, Cd. 5092, 1910).

In hot countries, owing to the rapid decomposition of ordinary butter, the clarified fat, free from water and curd, is prepared for sale, as 'schmelzbutter,' 'ghee.'

Trimen (Analyst, 1913, 242) has described the preparation of 'Samna' or 'Samn,' the Egyptian product corresponding to the 'ghee' of India. Whole milk is churned in goatskins until the butter (zibda) forms. The zibda is collected from the villages by the samna makers, who heat in large pans until it melts, the samna being poured off from the water and curd. Its keeping properties are much superior to those of butter, and it may be used years after it has been made. It is pale yellow in colour, possessing a smell, sometimes cheesy, sometimes acid, frequently rancid, and always unpleasant to European ideas. Both Egyptian samna and Indian ghee are largely made from buffalo milk, and unless artificially coloured are very pale. Syrian samna is generally believed to be made from sheep and goats' milk. Trimen gives the results of analysis of a number of samples. (For other analyses of ghee, *see* Bolton and Revis, Analyst, 1910, 343; *ibid.* 1911, 392; and Kesava Menon, J. Soc. Chem. Ind. 1910, 1428).

G. S.

BUTTERINE *v.* MARGARINE.

BUTTER SUBSTITUTES *v.* MARGARINE.

BUTTER SURROGATE *v.* MARGARINE.

BUTTER, VEGETABLE. A greasy substance expressed from the kernel of the *Bassia butyracea* (Roxb.), a native of North India. This grease is said to make excellent soap. Shea butter is obtained from the *Butyrospermum Parkii*, of West Africa, and has been used in making candles and soap. The butter-tree of Sierra Leone is the *Pentadesma butyracea* (Sabine), the fruit of which yields much grease, and is eaten by the negroes (*v.* OILS and FATS).

BUTTER YELLOW. *Benzeneazodimethyl aniline* $C_6H_5\cdot N:N\cdot C_6H_4\cdot N(CH_3)_2$. A yellow colouring matter (m.p. 115°); insoluble in water, soluble in dilute HCl, with red colour; soluble in fats. Used for colouring butter (Witt. Griess. Ber. 1877, 10, 528) (*v.* AZO- COLOURING MATTERS).

BUTTERS, MINERAL. A term formerly applied to several of the metallic chlorides, *e.g.* chlorides of antimony, tin, bismuth, zinc, &c.

BUTYL. A univalent radical yielding four isomeric mono- derivatives:

(1) $CH_3\cdot CH_2\cdot CH_2\cdot CH_2X$ (normal);
(2) $CH_3\cdot CH_2\cdot CHX\cdot CH_3$ (secondary);
(3) $(CH_3)_2CH\cdot CH_2X$;
(4) $(CH_3)_3CX$ (tertiary).

BUTYL COMPOUNDS.

Butyl alcohol. Tetryl alcohol C_4H_9OH. All the four possible bodies corresponding to this formula are known.

1. *Normal butyl alcohol*: *butanol*; *propyl carbinol* $CH_3\cdot CH_2\cdot CH_2\cdot CH_2OH$; b.p. 117·42° (corr.) (Thorpe and Rodger, Phil. Trans. 1894, 185, ii. 536; Brühl, Annalen, 203, 16); sp.gr. 0° =0·8233, 20°=0·8109, 40°=0·7994, 98·7° = 0·7738, 20°/4°=0·8099 (B.); μ_a = 1·39909, mol. refraction =35·45 (B.). Occurs in the heavy

oil of Cognac brandy to the extent of 49 p.c. Is not formed in the fermentation of sugar produced by elliptical yeast (Claudon and Morin, Chem. Soc. Trans. 1887, ii. 714). Is produced by the action of sodium amalgam upon butyryl chloride and butyric acid (Saytzeff, Zeitsch. Chem. 1870, 108; Linnemann, Annalen, 161, 178). Also by the fermentation of glycerol by *Bacillus butylicus* and certain other bacteria in presence of calcium carbonate and various foodstuffs, *e.g.* ammonium tartrate; the yield amounts to 9 p.c. of the glycerol used. Butyric acid and a little ethyl alcohol are also formed (Fitz, Ber. 9, 1348; Vigna, Ber. 16, 1348). Is also produced by the action of nascent hydrogen (iron and acetic acid) upon crotonaldehyde and trichlorobutyraldehyde (Lieben and Zeisel, Monatsh. 1, 825, 842).

Beyerinck has shown that the *Bacillus butylicus* of Fitz (Ber. 1882, 867) is in reality the butyric ferment. The true butylic ferment, *Granulobacter butylicum*, has been isolated in a pure condition, and an account of the whole fermentation process is given (J. Soc. Chem. Ind. 1894, 167; *ibid.* 969). (*See* also Emmerling, Ber. 1896, 2726; 1897, 451; Buchner and Meisenheimer, Ber. 1908, 1410.)

Properties.—Colourless liquid, soluble in 12 parts of water, from which solution it can be separated by means of calcium chloride. Soluble in concentrated hydrochloric acid; is readily oxidised to butyric acid. Fused zinc chloride abstracts water, and yields β-butylene and smaller amounts of normal butylene (Le Bel and Greene, Amer. Chem. J. 2, 24).

Bromine acting on *n*-butyl alcohol yields, with some difficulty, mono-brombutaldehyde, b.p. 235° (Étard, Compt. rend. 114, 753). The action of aluminium amalgam on the butyl alcohols, producing liquid aluminium alkoxides, has been studied by Tistshenko (Chem. Soc. Abstr. 1899, i. 408).

2. ***Iso-butyl alcohol****, isopropyl carbinol-α-hydroxy β-methylpropane* $(CH_3)_2CH\cdot CH_2OH$, b.p. 108·4° (Linnemann, Annalen, 160, 238), 107·5° at 756 mm., Michael and Zeidler (Annalen, 1912, 393, 81), 107·6° (corr.), Thorpe and Rodger (Phil. Trans. 1894, 185, A, 538); sp.gr. 0·7265 at 106·6°/4° (Schiff, Annalen, 220, 102), 0·8168 at 0° (L.), 0·8069 at 15°/15°, 0·8008 at 25°/25° Perkin (Chem. Soc. Trans. 1884, 468); sp. heat=0·686; molecular rotation=4·936 at 17·7° (P.); molecular refraction=35·41; μ_β=1·4007.

Sp.gr. of aqueous solutions (Duclaux, Ann. Chim. Phys. [5] 13, 91):

Percentage of alcohol (by vol.)	2·5	5	6	10
Sp.gr. of aqueous solution at 15°	0·9950	0·9930	0·9915	0·9875

Occurs in fusel oil from potatoes and beet (Wurtz, Ann. Chim. Phys. [3] 42, 129), and combined with angelic and *iso*butyric acids in Roman oil of chamomile (Köbig, Annalen, 195, 96).

Preparation.—By the action of sodium amalgam and water upon β-chlor*iso*butyl alcohol, which results from the action of hypochlorous acid upon *iso*butylene (Butlerow, Annalen, 144, 24). Is formed in small quantity by the action of elliptical yeast upon sugar or glycerol (Claudon and Morin, Chem. Soc. Trans. 1887, ii. 714) By the reduction of *iso*butyric aldehyd with sodium amalgam (Linnemann and Zotta Annalen, 162, 11).

Properties.—Colourless liquid, soluble i 10·5 parts of water, from which calcium chlorid causes it to separate. Smells like fusel oil Is oxidised by chromic acid into *iso*butyric acid acetic acid, carbon dioxide, acetone, and othe products (Kramer, Ber. 7, 252; Schmitt, *ibid* 8, 1361). Zinc dust yields water and *iso*butylene (Jahn, *ibid.* 13, 989).

Treated with iodine and aluminium, aluminium tri*iso*butoxide $Al(C_4H_9O)_3$ is formed. It i a liquid which may be distilled *in vacuo* (Gladstone and Tribe, Chem. Soc. Trans. 1881, 6).

*Iso*butyl alcohol may be catalyticall oxidised to *iso*butyl aldehyde. The vapour o the alcohol mixed with air, is passed over warm freshly reduced copper spirals and the product collected. A yield of 50 p.c. is obtainable (E Orlow, J. Soc. Chem. Ind. 1908, 957).

When chlorine is passed into dry *iso*buty alcohol, and the solution subsequently heate gently, the product can be separated into tw fractions, boiling at 80°–100° and 170°–250° The lower fraction consists of *chlorisobutaldehyde*, boiling at 90°–91°; sp.gr. 1·186, 15°/4°. I combines with sodium hydrogen sulphite, an when oxidised with alkaline permanganate yield acetone and hydroxy*iso*butyric acid $C(CH_3)_2OH\cdot COOH$, melting at 78°. A termolecular polymeride $C_{12}H_{21}Cl_3O_3$, which melts at 107°, i obtained by shaking with strong sulphuric aci (A. Brochet, Compt. rend. 114, 1538). If th alcohol is kept cold, the chief product is *dichlorisobutyl oxide* $C(CH_3)_2Cl\cdot CHCl\cdot O\cdot CH_2CH(CH_3)$ boiling at 192·5°/760, and of sp.gr. 1·031, 15°/4° Water is without action on this product at lo temperatures, but at 100° produces hydroge chloride and α-chlor*iso*butaldehyde and di*iso*butylmonochlor*iso*butyral $C(CH_3)_2Cl\cdot CH(OC_4H_9)$ boiling at 218°, and of sp.gr. 0·9355, 15°/4 (A. Brochet, Compt. rend. 118, 1280; *v.* als Brochet, Bull. Soc. chim. 1896, 16; *ibid.* 20).

When chlorine is led into hot *iso*butyl alcohol, chlor*iso*butyric*iso*butyl ester, αβ-dichlor*iso*butyric acid, *iso*butyl ester, mono- and dichlor*iso*butyric aldehyde, *iso*butyric acid, oxy*iso*butyric acid, crotonic acid, CO, CO_2, and methyl chloride are produced. Treating aqueous *iso*butyl alcohol with chlorine water produces *iso*butyric acid, and α-chlor*iso*butyric acid *iso*butyl ester. Chlorine acting on cold dry *iso*butyl alcohol in the light produces 1:2-dichlor*iso*butyl ester (Brochet, Ann. Chim. Phys. [7] 10, 363).

*Iso*butyl alcohol, when acted on by bromine, readily yields *iso*butyl bromide, mixed with *iso*butyl *iso*butyrate, and brom*iso*butaldehyde (Étard, Compt. rend. 114, 753).

(For combinations and derivatives of *iso*butyl alcohol, *v.* Gladstone and Tribe, Chem. Soc. Trans. 1881, 6; Pierre and Puchot, Annalen, 163, 274; and Heindl, Monatsh. 2, 208.)

3. ***Secondary butyl alcohol****, 2-hydroxybutane, methyl ethyl carbinol, butylene hydrate.*

$\begin{matrix}C_2H_5\\CH_3\end{matrix}\!>CHOH$; b.p. 99° at 738·8 mm. (Lieben, Annalen, 150, 114); sp.gr. 0·827 at 0°, 0·810 at 22° (L.).

Formed by the action of water upon the compound of zinc-ethyl and aldehyde:

$$CH_3CH(C_2H_5)O{\cdot}Zn(C_2H_5)$$

thus:

$$CH_3CH(C_2H_5)O{\cdot}ZnC_2H_5 + H_2O = C_4H_9OH + ZnO + C_2H_6$$

(Wagner, Annalen, 181, 261). Also by acting upon secondary butyl iodide with silver acetate and saponifying the resulting acetate by means of potash. Normal butyl alcohol may be changed into the secondary alcohol; the normal iodide is heated with potash, and the normal butylene so obtained on treatment with hydriodic acid yields secondary butyl iodide (Saytzeff, Zeitsch. anal. Chem. 1870, 327). It may also be prepared from the normal isomeride by treating *n*-butylamine with nitrous acid (Meyer, Ber. 10, 130; Kanonnikoff and Saytzeff, Chem. Soc. Trans. 1875, 626).

Properties.—Liquid, with strong odour; upon oxidation yields a ketone $C_2H_5{\cdot}CO{\cdot}CH_3$ (b.p. 80°), and acetic acid (Kanonnikoff and Saytzeff, Chem. Soc. Trans. 1875, 626). Heated with a trace of hydrochloric, hydrobromic, or hydriodic acid, in a sealed tube, to 240°, yields C_4H_8 (pseudo-butylene). It has been separated into its optical antipodes by R. Meth (Ber. 1907, 695); the alcohol has $[\alpha]_D$, 0·32°.

4. *Tertiary butyl alcohol, trimethyl carbinol* $(CH_3)_3C{\cdot}OH$. A solid; m.p. 25·45° (De Forcrand, Compt. rend. 136, 1034); b.p. 82·94° (corr.) (Linnemann, Annalen, 162, 26); 81·5°–82° (Perkin, Chem. Soc. Trans. 1884, 468); 82·25° (Thorpe and Rodger, Phil. Trans. 1894, ii. 539). Sp.gr. 0·7792 at 37° (L.); 0·7788 at 30° (Butlerow, Annalen, 162, 229); 0·7864 at 20°/4°. 0·7802 at 26°/4° (Brühl, Annalen, 203, 17); 0·7836) at 25°/25°, 0·7761 at 35°/35°; molecular rotation at 24·3°=5·122 (P.); μ_β=1·3924, molecular refraction=35·53; crit. temp.=234·9° (Pawlewski, Ber. 16, 2634).

Formed from *iso*butyl iodide by treatment with acetic acid and silver oxide (Linnemann; Butlerow, Annalen, 168, 143); also from *iso*butylamine by treatment with nitrous acid, and from *iso*butyl carbimide $CO{\cdot}N{\cdot}C_4H_9$, by action of potash (Linnemann, Annalen, 162, 12). Can be prepared by allowing 20 grams of tertiary butyl iodide and 50 grams of water to stand in contact for two or three days (Dobbin, Chem. Soc. Trans. 1880, 238).

*Iso*butyl alcohol heated with excess of hydrochloric acid yields a mixture of secondary and tertiary butyl chlorides, and when heated with six volumes of water only the latter is decomposed, yielding the alcohol and hydrochloric acid (Freund, J. Pharm. Chim. [2] 12, 25).

Properties.—Forms rhombic plates or prisms. Unites with water to form a liquid hydrate $2C_4H_{10}O,H_2O$ (b.p. 80°; sp.gr. 0·8276 at 0° (Butlerow, Annalen, 162, 229). On oxidation yields acetone, carbon dioxide acetic acid, and a small quantity of *iso*butyric acid (Butlerow, Zeitsch. Chem. 1871, 485).

The existence of the hydrate $C_4H_{10}O,2H_2O$, m.p. 0°, is confirmed by cryoscopic, density and viscosity determinations (Paternò and Mieli, Atti. R. Accad. Lincei. 1907 (v.), 16, ii. 153).

In sunlight it combines with chlorine, forming tertiary butyl chloride and other substances (D'Otreppe, J. 1881, 512).

Trimethyl carbinol explodes feebly when treated with bromine, yielding *isobutylene bromide* $C(CH_3)_2Br{\cdot}CH_2Br$ boiling at 148° (Étard, Compt. rend. 114, 753).

Tertiary butyl alcohol has a slightly narcotic action when taken internally, and is found in the urine in combination with glycuronic acid (Thierfelder and v. Mering, Chem. Soc. Abstr. 1885, i. 1002).

Nitrohydroxybutanes may be obtained quantitatively as follows: By the action of nitromethane on formaldehyde, in presence of a little potassium carbonate, tertiary nitrotrihydroxybutane $NO_2{\cdot}(CH_2OH)_3$, a white crystalline solid, melting at 158°–159°, is produced. Nitroethane produces tertiary nitrodihydroxybutane $NO_2{\cdot}C(CH_3)(CH_2OH)_2$, melting at 139°–140°. Secondary nitropropane yields nitro*iso*butyl alcohol $NO_2{\cdot}C(Me)_2{\cdot}CH_2OH$, melting at 82° (L. Henry, Compt. rend. 1895, 121, 210).

Butyl bromides. Tetryl bromides C_4H_9Br.

1. *Normal butyl bromide, α-bromobutane*

$$CH_3{\cdot}CH_2{\cdot}CH_2{\cdot}CH_2Br;$$

b.p. 99·9° (corr.) (Linnemann, Annalen, 161, 193); sp.gr. 1·3050 at 0°, 1·2792 at 20°, 1·2571 at 40° (Lieben and Rossi, *ibid.* 158, 161).

Formed from normal butyl alcohol and hydrobromic acid (L. and R. Taboury, Bull. Soc. chim. 1911 [iv.] 9, 124).

By the action of bromine, *αβ*-dibrombutane $C_4H_8Br_2$ (b.p. 166°) is formed (L.).

2. *Isobutyl bromide, α-bromo-β-methyl propane* $(CH_3)_2CH{\cdot}CH_2Br$; b.p. 92·3° (corr.) (Linnemann, Annalen, 162, 34); 91·3° (Perkin, Chem. Soc. Trans. 1884, 459); 91·7° (corr.) (Thorpe); sp.gr. 1·2038 at 16° (L.), 1·2722 at 15°/15°, 1·2598 at 25°/25° (P.). Molecular rotation=8·003 at 16·2° (P.). From *iso*butyl alcohol, bromine, and phosphorus (Wurtz, Annalen, 93, 114). Unites with bromine at 150° to form $C_4H_7Br_3$ (L.). Pure *iso*butyl bromide is an unstable substance, both in the liquid and gaseous states, when heated.

3. *Tertiary butyl bromide, β-bromo-β-methyl propane* $(CH_3)_3CBr$; b.p. 72° at 761·5 mm.; sp.gr. 1·215 at 20°, 1·2020 at 15°/15°, 1·1892 at 25°/25°; molecular rotation=8·238 at 17·8° (P.). Formed when *iso*butyl bromide is heated to 240° (Eltekow, Ber. 8, 1244). Also from trimethyl carbinol and phosphorus pentabromide (Reboul, J. 1881, 409). May also be prepared by leading *iso*butylene into a solution of hydrobromic acid of sp.gr. 1·7 (Roozeboom, Ber. 14, 2396). Is readily decomposed at 300° into *iso*butylene and hydrobromic acid. Water, in the cold, forms the alcohol.

Tribromo tert-butyl alcohol (brometone) $C_4H_7OBr_3$, m.p. 167°–176°, forms white crystals, has a camphor-like taste and odour, is slowly volatile in air, and can be distilled with steam (Aldrich, J. Amer. Chem. Soc. 1911, 33, 386). For pharmacological properties, *see* Houghton and Aldrich, Proc. Amer. Physoil. Soc. 1902).

4. *Secondary butyl bromide, β-brombutane* $CH_3{\cdot}CH_2{\cdot}CHBr{\cdot}CH_3$; b.p. 90°–93° (V. Meyer and Müller, J. pr. Chem. [2] 46, 183); obtained from secondary butyl alcohol by the action of hydrobromic acid, and yields *β* (*γ*)-dibrombutane by warming with iron and bromine.

For observations on the course of the intramolecular transformations of the butyl bromide and chlorides, *see* Michael and Leopold, Annalen, 1911, 379, 263; Michael and Zeidler, Annalen, 1912, 393, 81, Michael, Scharf and Voigt. J. Amer. Chem. Soc. 1916, 38, 653.

Butyl chlorides. Tetryl chlorides C_4H_9Cl.

1. *Normal butyl chloride, a-chlorbutane*

$$CH_3{\cdot}CH_2{\cdot}CH_2{\cdot}CH_2Cl$$

b.p. 77·96° (corr.) (Linnemann, Annalen, 61, 197); sp.gr. 0·9074 at 0°, 0·8874 at 20° (Lieben and Rossi, *ibid.* 158, 161); 0·9074 at 0° (L.), 0·8972 at 14°. Formed by the action of chlorine upon *n*-butane (Pelouze and Cahours, J. 1863, 524). More easily by the action of hydrochloric acid upon *n*-butyl alcohol (Lieben and Rossi).

2. *Isobutyl chloride, β-methyl-a-chlorpropane* $(CH_3)_2CH{\cdot}CH_2Cl$; b.p. 68·5° (Linnemann, Annalen, 162, 17); 68·5°–69° (Perkin, Chem. Soc. Trans. 1884, 451); 69·02° (corr.) (Thorpe); sp.gr. 0·8798 at 15° (L.), 0·8953 at 0°, 0·8651 at 27·8°, 0·8281 at 59° (Pierre, Puchot, Annalen, 163, 276), 0·8835 at 15°/15°, 0·8739 at 25°/25° (P.). Molecular rotation at 21·3° = 6·144 (Perkin). Formed by the action of hydrochloric acid or PCl_5 upon the alcohol (Wurtz, *ibid.* 93, 113). By the action of chlorine, hexachlorbutane is produced.

*Iso*butyl chloride is also produced by the interaction of chlorine and *iso*butane in diffused sunlight (Mabery and Hudson, Amer. Chem. J. 19, 245); and also by treating *iso*butylamine cooled to −15° with nitrosyl chloride (Solonina, Chem. Zentr. 1898, ii. 887).

3. *Tertiary butyl chloride, β-methyl-β-chlorpropane* $(CH_3)_3CCl$; b.p. 51°–52° (Perkin, Chem. Soc. Trans. 1884, 451); sp.gr. 0·8658 at 0° (Puchot), 0·8471 at 15°/15°, 0·8368 at 25°/25°; molecular rotation at 15° = 6·257 (Perkin).

Formed (1) by the chlorination of tertiary butane (Butlerow); (2) by the action of iodine monochloride upon *iso*butyl iodide (Linnemann, Annalen, 162, 18); (3) by the action of hydrochloric acid upon *iso*butylene at 100° (Zalessky, Ber. 5, 480; Le Bel, Bull. Soc. chim. 28, 462); (4) by saturating trimethyl carbinol at 0° with HCl gas (Schramm, Monatsh. 9, 619).

Heated with five or six vols. of water to 100°, the alcohol is produced (Butlerow, Annalen, 144, 33). Chlorine in diffused daylight, in the cold, forms $C_4H_8Cl_2$ (b.p. 106°–107°), $C_4H_7Cl_3$ and $C_4H_5Cl_5$, whilst in direct sunlight $C_4H_4Cl_6$ (b.p. in partial vacuum about 115°), and other products are formed (L'Ottreppe, J. 1882, 441).

Tertiary butyl chloride is also formed by the action of PCl_5 on trimethyl carbinol (Janschenko, Chem. Zentr. 1897, ii. 334). It also results, together with *iso*butyl chloride from the action of nitrosyl chloride on tertiary butylamine in xylene solution at −15° *to* −20° (Salonina, *ibid.* 1898, ii. 888).

4. *Secondary butyl chloride, β-chlorobutane* $CH_3{\cdot}CH_2{\cdot}CHCl{\cdot}CH_3$, is produced by the action of nitrosyl chloride on secondary butylamine in xylene solution at −20° (Solonina, Chem. Zentr. 1898, ii. 888).

Butyl cyanates. Only the *iso*-cyanates have been described.

1. *Isobutyl isocyanate. Iso*butyl carbimide $(CH_3)_2CH{\cdot}CH_2{\cdot}NCO$; b.p. 110° obtained by the distillation of *iso*butyl iodide with silver cyanate and sand (Brauner, Ber. 12, 1877).

2. *Tertiary butyl isocyanate*

$$(CH_3)_3C{\cdot}NCO;$$

b.p. 85·5° (corr.); sp.gr. 0·8676 at 0°; remains liquid at −25°. Is formed, together with other substances, when silver cyanate acts upon *iso*butyl iodide (Brauner, Ber. 12, 1874). By the action of hydrochloric acid, forms tertiary butylamine $(CH_3)_3C{\cdot}NH_2$. Potash produces symmetrical di*iso*butyl urea, melting at 242°.

Butyl cyanides. C_4H_9CN.

1. *Normal butyl cyanide, valeronitrile*

$$CH_3{\cdot}CH_2{\cdot}CH_2{\cdot}CH_2CN;$$

b.p. 140·4° at 739·3 mm.; sp.gr. 0·8164 at 0° (Lieben and Rossi, Annalen, 158, 171).

2. *Isobutyl cyanide* $(CH_3)_2{\cdot}CH{\cdot}CH_2{\cdot}CN$; b.p. 126°–128° at 714 mm. (Erlenmeyer and Hell, Annalen, 160, 266); 129·3°–129·5° at 764·3 mm. (R. Schiff, Ber. 19, 567); sp.gr. 0·8227 at 0°, 0·8069 at 20° (Erlenmeyer and Hell); 0·6921 at 129°/4° (S.). Formed by the oxidation of gelatin (Schlieper, Annalen, 59, 15) or casein (Gunckelberger, *ibid.* 64, 76) with chromic acid; also by the action of P_2O_5 upon ammonium *iso*valerate (Dumas, Malaguti, and Leblanc, *ibid.* 64, 334). May be prepared by heating 300 grams *iso*butyl iodide, 98 grams of potassium cyanide, 98 grams of alcohol, and 25 grams of water for three days on the water-bath (Erlenmeyer and Hell).

3. *Tertiary butyl cyanide* $(CH_3)_3C{\cdot}CN$; m.p. 15°–16°; b.p. 105°–106°. Formed by mixing 100 parts of tertiary butyl iodide, 110 parts of mercury potassium cyanide $Hg(CN)_2{\cdot}2KCN$ with 75 parts of dry magnesia, and allowing the mixture to remain for two or three days at a temperature not exceeding 5°. The mass is then treated with water, and distilled on the paraffin-bath (Butlerow, Annalen, 170, 154).

4. *Secondary butyl cyanide*, methylethyl acetonitrile $C_2H_5{\cdot}CH_3{\cdot}CH{\cdot}CN$; b.p. 125°; sp.gr. 0·8061 at 0°. Sodium ($\frac{1}{2}$ eqv.) is dissolved in acetonitrile in benzene, and ethyl iodide (1 eqv.) added (Hanriot and Bouveault, Bull. Soc. chim. (3), 1, 172).

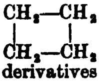
Butyl hydrides. Butanes, tetranes.

1. *Normal butane, diethyl, methylpropane* $CH_3{\cdot}CH_2{\cdot}CH_2{\cdot}CH_3$; b.p. 1° (Butlerow. Zeitsch. Chem. 1867, 363); −0·3°, Burrell and Robertson; sp.gr. 0·60 at 0° (Ronalds, Chem. Soc. Trans. 1865, 54). Critical temp. 153·2; critical press. 35·67 atm. Occurs in crude petroleum (Ronalds, Lefebvre, Zeitsch. Chem. 1869, 185). Formed by heating ethyl iodide with zinc to 150° (Frankland, Annalen, 71, 173; Schöyen, *ibid.* 130, 233). Also by the action of sodium amalgam upon ethyl iodide (Löwig, J. 1860, 397). A colourless gas, insoluble in water. 1 vol. of alcohol at 14·2° and 744·8 mm. absorbs 18·13 vols. of butane (Frankland).

2 *Isobutane, trimethylmethane* $(CH_3)_3CH$. Formed by heating 0·9 part of *iso*butyl iodide with 2·4 parts of aluminium chloride to 120° (Köhnlein, Ber. 16, 562). Also by the action of zinc and water upon tertiary butyl iodide (Butlerow, Annalen, 144, 10). The gas, is readily soluble in alcohol, from which it can be expelled by dilution with water, b.p. −13·4°; critical temp. 133·7; critical press. 36·54 atm. Vapour pressure may be represented by the formula:

$$\log P = -1632{\cdot}661/T + 1{\cdot}75 \log T - 0{\cdot}0158873 + 9{\cdot}06814$$

(Burrell and Robertson, J. Amer. Chem. Soc. 1915, 37, 2482).



C. *Cyclobutane*, tetramethylene, has not yet been obtained, but many derivatives have been prepared by Perkin (Chem. Soc. Trans. 1893, 693; 1894, 950).

Butyl iodides. C_4H_9I.

1. *Normal butyl iodide*

$$CH_3\cdot CH_2\cdot CH_2\cdot CH_2I;$$

b.p. 129·8° (corr.) (Linnemann, Annalen, 161, 196); 130·4°–131·4° at 745·4 mm. (Brühl, *ibid.* 203, 21); sp.gr. 1·643 at 0°, 1·6136 at 20° (Lieben and Rossi, *ibid.* 158, 163), 1·6166 at 20°/4° (Brühl). From *n*-butyl alcohol and hydriodic acid (Linnemann, *ibid.* 161, 196). By the action of iodine trichloride at 250° it yields hexachlorethane C_2Cl_6 (Krafft, Ber. 10, 805).

2. *Isobutyl iodide, a-iodo-β-methylpropane* $(CH_3)_2\cdot CH\cdot CH_2I$; b.p. 120·0° (corr.) (Linnemann, Annalen, 160, 240; 192, 69); 83°–83·2° at 250 mm. (Perkin, Chem. Soc. Trans. 1884, 451); 119·94° (Thorpe and Rodger, Phil. Trans. 1894, A, 11, 470); sp.gr. 1·6401 at 0° (L.), 1·6056 at 20°/4° (Brühl, Annalen, 203, 21), 1·6138 at 15°/15°, 1·6007 at 25°/25° (P.). Molecular rotation at 19·4°=12·191 (P.). From *iso*butyl alcohol, phosphorus, and iodine (Wurtz, Annalen, 93, 116).

3. *Secondary butyl iodide, β-iodobutane*

$$C_2H_5\cdot CHI\cdot CH_3;$$

b.p. 117°–118° (Luynes, Bull. Soc. chim. 2, 3); 119°–120° (Lieben, Annalen, 150, 96); sp.gr. 1·6263 at 0°/0°, 1·5952 at 20°/0°, 1·5787 at 30°/0° (Lieben). Formed by distilling erythritol with hydriodic acid (Luynes) or from *n*-butylene and hydriodic acid (Wurtz, Annalen, 152, 23). (See also Clarke, Chem. Zentr. 1908, ii. 1015.)

4. *Tertiary butyl iodide, β-methyl-β-iodopropane* $(CH_3)_3CI$; b.p. 98°–99° (with decom.) (Butlerow); 100·3° (Puchot, Ann. Chim. Phys. [5] 28, 546); sp.gr. 1·571 at 0°, 1·479 at 53° (P.). From tertiary butyl alcohol and hydriodic acid or *iso*butylene and hydriodic acid (Butlerow, Annalen, 144, 5, 22); is easily decomposed (by silver oxide, potash, or by heating with zinc and water), into hydriodic acid and *iso*butylene (Butlerow, Zeitsch. Chem. 1867, 362). Is also decomposed by water in the cold, yielding hydriodic acid and tertiary butyl alcohol. On heating with sodium, yields a mixture of hydrogen, *iso*butylene, and tri*iso*butylene ($C_{12}H_{24}$) (Dobbin, Chem. Soc. Trans. 1880, 236).

Butyl mercaptans $C_4H_9\cdot SH$.

1. *Normal butyl mercaptan*

$$CH_3\cdot CH_2\cdot CH_2\cdot CH_2\cdot SH;$$

b.p. 97°–98°; sp.gr. 0·858 at 0° (Saytzeff and Grabowsky, Annalen, 171, 251; 175, 351).

2. *Isobutyl mercaptan*

$$(CH_3)_2CH\cdot CH_2SH;$$

b.p. 88°; sp.gr. 0·848 at 11·5° (Humann, Annalen, 95, 256), 0·83573 at 20°/4° (Nasini, Ber. 15, 2882).

3. *Secondary butyl mercaptan*

$$C_2H_5\cdot CH(SH)CH_3;$$

b.p. 84°–85°; sp.gr. 0·8299 at 17°. The mercury compound $(C_4H_9S)_2Hg$ melts at 189° (Reymann, Ber. 7, 1287).

4. *Tertiary butyl mercaptan*

$$(CH_3)_3C\cdot SH$$

is prepared from tertiary butyl iodide, zinc sulphide, and alcohol (Dobbin, Chem. Soc. Trans. 1890, 641). It boils at 65°–67°, and solidifies in a freezing mixture.

Butyl nitrates.

1. *Normal butyl nitrate*

$$CH_3\cdot CH_2\cdot CH_2\cdot CH_2\cdot O\cdot NO_2;$$

boils at 136°; sp.gr. 1·048 at 0° (Bertoni, Gazz. chim. ital. 20, 374).

2. *Isobutyl nitrate* $(CH_3)_2CH\cdot CH_2\cdot O\cdot NO_2$ b.p. 123°; sp.gr. 1·0384 at 0°, molecular rotation at 8·9°=5·18 (P.); molecular refraction=46·72 (P.); b.p. 123·5°–124·5° (Perkin, Chem. Soc. Trans. 1889, 684), sp.gr. 1·0334 at 4°/4°, 1·0264 10°/10°, 1·0124 25°/25° (P.). From silver nitrate, urea, and *iso*butyl iodide (Wurtz, Annalen, 93, 120; Chapman and Smith, Zeitsch. Chem. 1869, 433).

3. *Secondary butyl nitrate* boils at 124°; sp gr. 1·0382 at 0° (Bertoni, Gazz. chim. ital. 20, 375).

Butyl nitrites, nitrobutanes $C_4H_9NO_2$.

1. *Isobutyl nitrite* $(CH_3)_2CH\cdot CH_2\cdot NO_2$; b.p. 67°; sp.gr. 0·89445 at 0° (Chapman and Smith, Zeitsch. Chem. 1869, 433), 0·8878 at 4°/4°, 0·8806 at 10°/10°, 0·8752 at 15°/15°, 0·8702 at 20°/20°, 0·8652 at 25°/25°; molecular rotation at 8·2°=5·51; molecular refraction =43·9 (Perkin, Chem. Soc. Trans. 1889, 686 and 757). Prepared by mixing *iso*butyl alcohol and sulphuric acid, and gradually pouring the cooled mixture, into an aqueous solution of sodium nitrite (1 : 3); the upper layer, consisting of *iso*butyl nitrite, is decanted, washed with potassium carbonate solution, and dried. It is a pale-yellow liquid, is apt to become acid by keeping, when rapid decomposition sets in. Taken medicinally, lowers the blood pressure and produces respiratory paralysis (Dunstan and Woolley, Pharm. J. [3] 19, 487).

2. *Tertiary butyl nitrite* $(CH_3)_3C\cdot NO_2$; b.p. 63°; sp.gr. 0·8914 at 0° (Bertoni, Gazz. chim. ital. 15, 351); 67°–68° (Tscherniak, Annalen, 180, 155). From the alcohol and glyceryl nitrite (B.); also from the iodide and silver nitrite (T.). A yellow, mobile liquid; soluble in alcohol, ether, and chloroform; sparingly soluble in water.

Aromatic nitrobutyl derivatives.

The butyl derivatives of many aromatic nitrohydrocarbons have a musk-like odour, and are sold as 'artificial musk.' '*Musk Baur*, trinitro *meta*butyl toluene $C_6H(CH_3)(NO_2)_3C(CH_3)_3$, is formed by nitrating *meta* butyl toluene with fuming nitric and fuming sulphuric acids. Butyl toluene is formed by Friedel and Craft's method, as described below, by the action of tertiary butyl bromide on toluene in the presence of aluminium chloride. Butyl benzene, ethyl benzene, and xylene are formed at the same time.

An unsymmetrical butyl cresol is formed by adding butyl alcohol and zinc chloride to meta-cresol. When etherified and nitrated, possesses the odour of civet (A. Baur, J. Soc. Chem. Ind. 1892, 307; Dingl. poly. J. 273, 522; J. Soc. Chem. Ind. 1894, 1218).

Butyl xylene may be prepared by passing a current of *iso*butylene gas through a mixture of 5 kilos. *m*-xylene, 50 grams *iso*butyl chloride, and 200 grams aluminium chloride at 10°. The product is washed with water, and the fraction of the oil boiling at 200°–302° collected. Gaseous hydrochloric and hydrobromic acids may be employed to start the reaction (Act. Gesell. für Anilin-Fabriken, Fr. Pat. 372603).

Butyl ethers $(C_4H_9)_2O$.

1. *Normal butyl ether*; b.p. 140·5° at 741·5 mm. (Lieben and Rossi, Annalen, 165, 110); sp.gr. 0·784 at 0°, 0·7685 at 20° (L. and R.), 0·7865 at 0° (Douiner, Annalen, 243, 8). By the action of the sodium derivatives of the alcohol upon *n*-butyl bromide (Reboul, Compt. rend. 108, 39).

2. *Isobutyl ether* $[(CH_3)_2CH{\cdot}CH_2]_2O$; b.p. 122°–122·5° (Reboul, Compt. rend. 108, 162); sp.gr. 0·7616 at 15° (R.). From *iso*butyl bromide and sodium *iso*butylate (R.). The action of *iso*butyl iodide upon potassium *iso*butylate—which, according to Wurtz, yields this ether—really gives a mixture of di*iso*butylene and *iso*butyl alcohol (Reboul).

3. *Secondary butyl ether*

$$[C_2H_5{\cdot}CH(CH_3)]_2O;$$

b.p. 120°–121°; sp.gr. 0·756 at 21° (Kessel, Annalen, 175, 50). From ethylidene chlorhydrin, and zinc ethyl (K.). Formed in mere traces only by the action of secondary butyl bromide upon the sodium derivative of the secondary alcohol (Reboul, Compt. rend. 108, 162). Reboul obtained also the following mixed ethers:—

Secondary butyl *iso*butyl ether; b.p. 121°–122°; sp.gr. 0·7652 at 21°;

Normal butyl *iso*butyl ether; b.p. 131·5°; sp.gr. 0·763 at 15·5;

Normal butyl secondary butyl ether; b.p. 131°; sp.gr. 0·7687 at 15°;

Normal butyl tertiary butyl ether; b.p. 124°, but could not obtain the secondary, tertiary, and the ditertiary ethers (Bull. Soc. chim. [3] 2, 25).

Butyl sulphides.

1. *Normal butyl sulphide*

$$[CH_3(CH_2)_3]_2S;$$

b.p. 182°; sp.gr. 0·8523 at 0° (Saytzeff, Annalen, 171, 253). From butyl iodide and potassium sulphide. Fuming nitric acid yields the sulphone $(C_4H_9)_2SO_2$ (m.p. 43·5°) (Grabowsky, Annalen, 175, 348). Nitric acid of sp.gr. 1·3 converts it into the oxide $(C_4H_9)_2SO$, melting at 32°.

2. *Isobutyl sulphide* $[(CH_3)_2CH{\cdot}CH_2]_2S$; b.p. 172°–173° at 747 mm. (Grabowsky and Saytzeff, Annalen, 171, 254), 170·5° at 752 mm. (Beckmann, J. pr. Chem. [2] 17, 445); sp.gr. 0·8363 at 10° (B.).

Isobutyl disulphide $(C_4H_9)_2S_2$; b.p. 220° (Spring and Legros, Ber. 15, 1940).

3. *Secondary butyl sulphide*

$$(CH_3{\cdot}CH{\cdot}C_2H_5)_2S;$$

b.p. 165°; sp.gr. 0·8317 at 23° (Reymann, Ber. 7, 1288).

Butyl thiocarbimides. Butyl mustard oils; *iso*thiocyanates.

1. *Normal butyl thiocarbimide*

$$(C_4H_9)NCS;$$

b.p. 167° (Hofmann, Ber. 7, 512). From *n*-butylamine, carbon disulphide, and alcohol (H.).

2. *Isobutyl thiocarbimide*

$$(CH_3)_2CH{\cdot}CH_2{\cdot}NCS;$$

b.p. 162°; sp.gr. 0·9638 at 14° (Hofmann, Ber. 7, 511).

3. *Secondary butyl thiocarbimide*

$$C_2H_5{\cdot}CH(CH_3)NCS;$$

b.p. 159·5°; sp.gr. 0·944 at 12°. Occurs in the ethereal oil from spoonwort (*Cochlearia officinalis*) (Hofmann, Ber. 2, 102; 7, 512).

4. *Tertiary butyl thiocarbimide*

$$(CH_3)_3C{\cdot}NCS;$$

m.p. 10·5°; b.p. 140° at 770·3 mm.; sp.gr. 0·9187 at 10°, 0·9003 at 34° (Rudnew, Bull. Soc. chim. 1880, 300). Has a pleasant aromatic odour.

BUTYLAMINES.

1. **Monobutylamines.**

(*a*) *Normal butylamine, aminobutane*

$$CH_3{\cdot}CH_2{\cdot}CH_2{\cdot}CH_2{\cdot}NH_2;$$

b.p. 75·5° at 740 mm. (Lieben and Rossi, Annalen, 158, 172); sp.gr. 0·7553 at 0°, 0·7333 at 26° (L. and R.), 0·7401 at 20° (Linnemann and Zotta, Annalen, 162, 3). Formed by the action of potassium hydroxide upon butyl cyanate (Lieben and Rossi); also from propyl cyanide by zinc and sulphuric acid (Linnemann and Zotta, Annalen, 162, 3), or from nitrobutane by action of tin and hydrochloric acid (Züblin, Ber. 10, 2083). Is miscible with water; reduces copper, silver, and mercury solutions in presence of alkalis. The chloride forms a yellow crystalline compound with $PtCl_4$, which is almost insoluble in cold water.

(*b*) *Isobutylamine, a-amino-β-methylpropane* $(CH_3)_2CH{\cdot}CH_2{\cdot}NH_2$; b.p. 68° (Schiff, Ber. 19, 565), 68°–69° (Perkin, Chem. Soc. Trans. 55, 694); sp.gr. 0·7357 at 55° (Linnemann, Annalen, 162, 23), 0·7464 at 4°/4°, 0·7408 at 10°/10°, 0·7363 at 15°/15°, 0·7283 at 25°/25°; mol. rot. at 15·3° 5 692; heat of combustion 726,000. From *iso*butyl cyanate and potash (Linnemann, Annalen, 162, 23); also from *iso*butyl iodide and ammonia (Hughes and Romer, Ber. 7, 511); also from *iso*butyl chloride and ammonia dissolved in water or *iso*butyl alcohol. All three *iso*butylamines are produced, the tri*iso*butylamine in largest quantity. The bases can then be separated by means of ethyl oxalate. The product is first separated into two fractions, the one rich in the mono*iso*butylamine, the other rich in the di- and tri- compounds. To the former water and then ethyl oxalate are added; the primary base is thus converted into the oxamide $C_2O_2(NHC_4H_9)_2$, which is almost insoluble in boiling water, the secondary amine being changed into the ethyl oxamate $C_2H_5O{\cdot}C_2O_2{\cdot}N(C_4H_9)_2$. The other fraction (anhydrous) being poured into ethyl oxalate, the primary and secondary bases are converted into oxamates. The tertiary base is distilled off, and the oxamates are saponified by heating with slaked lime. The calcium oxamates can be separated by crystallisation, the di*iso*butyloxamate being the more soluble in alcohol, from which it separates in slender silky needles (Malbot, Compt. rend. 104, 228).

Can be produced by heating *iso*butyl alcohol with ammoniacal zinc chloride to 260° (Merz and Gasiorowski, Ber. 17, 624), or by the action of caustic potash (10 p.c. solution) upon a mixture of bromine and *iso*valeramide (equal molecules) at 60° (Hofmann, Ber. 15, 769).

Mixed with water, contraction and development of heat are produced. A mixture of equal volumes of water and *iso*butylamine has a sp.gr. of 0·9002 at 15°/15°, instead of the calc. density

0·8081 (Perkin, Chem. Soc. Trans. 1889, 696). With absolute alcohol and the amine similar results were obtained, the sp.gr. of a mixture of equal volumes being 0·791 at 15°/15°, instead of 0·7652, the calculated number.

(*c*) *Secondary butylamine*

$C_2H_5·CH(NH_2)·CH_3$;

b.p. 63°; sp.gr. 0·718 at 23° (Menschutkin, Chem. Zentr. 1898, i. 702). Formed by the action of potash upon secondary butyl cyanate, or of ammonia upon secondary butyl iodide (Hofmann, Ber. 7, 513). Also by the action of dilute sulphuric acid upon secondary butyl mustard oil (Reymann, Ber. 7, 1289).

By the reduction of methyl ethyl ketoxime by hydrogen and finely divided nickel at 160°–170°, secondary butylamine and disecondary butylamine are produced. They are liquids, the latter boiling at 132°/758 mm. and forming an oxalate melting at 104° (Mailhe, Compt. rend. 1905, 113).

Secondary butylamine has been separated into its optical antipodes by Thomé (Ber. 1903, 582); $[\alpha]_D$ 7·42° at 20°.

(*d*) *Tertiary butylamine* $(CH_3)_3C·NH_2$; b.p. 45·2° at 760 mm. (Rudnew, Chem. Soc. Abstr. 1879, 40, 141); 43·8° at 760 mm.; sp.gr. 0·7137 at 3°, 0·7054 at 8°, 0·6931 at 15° (R.). Formed in small quantity by the action of potash upon *iso*butyl cyanate (Linnemann, Annalen, 162, 19; Hofmann, Ber. 7, 513). Also as a by-product in preparing trimethyl acetic acid from trimethyl carbinol iodide and mercuric cyanide (Rudnew).

2. **Dibutylamines.**

(*a*) *Di-normal butylamine*

$(CH_3·CH_2·CH_2·CH_2)_2NH$;

b.p. 160°. Formed in small quantities by the action of potash upon butyl cyanate (Lieben and Rossi, Annalen, 158, 175); also by the action of butyl chloride on ammonia (Berg, Ann. Chim. Phys. [7], 3, 294). Gives $[(C_4H_9)_2NH·HCl]_2PtCl_4$; yellow needles, almost insoluble in cold water.

(*b*) *Di-iso-butylamine*

$[(CH_3)_2CH·CH_2]_2NH$;

b.p. 135°–137°; sp.gr. 0·7577 at 4°/4°, 0·7491 at 15°/15°, 0·7425 at 25°/25° (Perkin, Chem. Soc. Trans. 1889, 697). From *iso*butyl bromide and alcoholic ammonia at 150° (Ladenburg, Ber. 12, 949); also from *iso*butyl alcohol and ammoniacal zinc chloride at 270° (Merz and Gasiorowski, Ber. 17, 627). The hydrochloride $(C_4H_9)_2NH·HCl$ forms plates or leaflets easily soluble in alcohol and water, slightly in ether. The platinum compound forms dark-red prisms, soluble in water, alcohol, and ether (Malbot, Compt. rend. 104, 366). The nitroso- derivative $(C_4H_9)_2N·NO$ is a disagreeably smelling oil; m.p. 0°; b.p. 213°–216° (with decomposition); obtained by the action of potassium nitrite upon the hydrochloride (Ladenburg, Ber. 12, 949).

(*c*) *Di-tertiary butylamine*

$[(CH_3)_3C]_2NH$;

produced as iodide when tertiary butyl iodide and tertiary butylamine are heated to 50°; at 70° the mixture is decomposed, forming isobutylene and tertiary butylammonium iodide (Rudnew). The iodide is easily soluble in water or alcohol; on heating the aqueous solution evolves tertiary butylamine.

3. **Tributylamines.**

(*a*) *Tri-normal butylamine* $(C_4H_9)_3N$; b.p. 211°–215° at 740 mm.; sp.gr. 0·791 at 0°, 0·7782 at 20°, 0·7677 at 40°. From butyl cyanate and potash, together with the mono- and di- compounds (Lieben and Rossi, Annalen, 165, 115). With butyl iodide forms iodide of tetrabutylammonium $N(C_4H_9)_4I$, which crystallises in small plates (L. and R.). Also by the action of ammonia on butylchloride; b.p. 216·5° (Berg, Ann. Chim. Phys. [7] 3, 299).

(*b*) *Tri-iso-butylamine* $(C_4H_9)_3N$; b.p. 177°–180° (Reimer, Ber. 3, 757); 184°–186° (Sachtleben, Ber. 11, 733). Sp.gr. 0·785 at 21° (S.). From di*iso*butylamine and *iso*butyl bromide (R.) From the alcohol and ammoniacal zinc chloride at 270° (Merz and Gasiorowski, Ber. 17, 627); also from *iso*butyl iodide and aqueous ammonia at 160° (Malbot, Compt. rend. 105, 574). Is not miscible with water. Forms salts with hydrochloric, nitric, and sulphuric acids, which are extremely soluble and crystallise with difficulty. The platinum double salt forms large ruby-red crystals (Malbot, Compt. rend. 104, 366).

Butylenes C_4H_8. Three isomeric butylenes are possible and all are known.

1. *Normal* (*a*)-*butylene. Ethyl ethylene* $CH_3·CH_2·CH:CH_2$; b.p. −5°.

Formation.—From normal butyl iodide and alcoholic potash (Saytzeff, J. pr. Chem. [2] 3, 88; Grabowsky and Saytzeff, Annalen, 179, 330). From bromethylene and zinc-ethyl (Wurtz, Annalen, 152, 21), together with butyl alcohol. From normal butylamine and nitrous acid (V. Meyer, Ber. 10, 136). Prepared by digesting on the water-bath 100 grams normal butyl iodide, 200 grams potash, and 150 grams alcohol (90 p.c.) (S.). A gas at ordinary temperatures, which combines readily with hydriodic acid to form secondary butyl iodide; and with hypochlorous acid to form chloromethylethyl carbinol $CH_3·CH_2·CH(OH)·CH_2Cl$. Passed over copper heated to redness forms butadiene $CH_2:CH·CH:CH_2$, which may be polymerised to rubber by means of metallic sodium (Eng. Pat 9722, 1911).

2. *β-Butylene. Symmetrical dimethylethylene* $CH_3·CH:CH·CH_3$; b.p. 1° at 741·4 mm. (Lieben, Annalen, 150, 108): sp.gr. 0·635 at −13·5 (Puchot, Bull. Soc. chim. 30, 188).

Formed by the action of potash upon secondary butyl iodide (Luynes, Annalen, 129, 200; Lieben, *ibid.* 150, 108). Together with *iso*butylene by dropping *iso*- or normal butyl alcohol upon strongly heated zinc chloride (Nevole, Bull. Soc. chim. 24, 122; Le Bel and Greene, Amer. Chem. J. 2, 23). From trithioaldehyde $(C_2H_4S)_3$ and copper (Eltekow, Ber. 10, 1904). By heating a mixture of methyl iodide and allyl iodide with sodium (Wurtz, Annalen, 144, 235).

Preparation.—*Iso*butyl alcohol is allowed to drop upon heated zinc chloride, and the evolved gas is led into sulphuric acid diluted with half its volume of water; this retains the *iso*butylene. The unabsorbed gas is led into bromine, and is again liberated by action of sodium (Le Bel and Greene, Bull. Soc. chim. 29, 306). Two stereoisomeric modifications are known (Wislicenus Chem. Zentr. 1897, ii. 267).

β-Butylene combines with bromine to form a dibromide boiling at 156°–158°. This compound, by the action of potash, forms mono-bromo-pseudo-butylene $CH_3\cdot CBr:CH\cdot CH_3$; b.p. 87°–88° (Hölz, Annalen, 250, 230). Chlorine forms a dichloride; b.p. 112°–114° (Chechoukow, Bull. Soc. chim. 43, 127).

3. *γ-Butylene.* *Iso*butylene, *unsymmetrical dimethyl ethylene* $(CH_3)_2C:CH_2$; b.p. −6° (Butlerow, Zeitsch. Chem. 1870, 236). Liquefied by a pressure of 2–2½ atmospheres at 15°–18°. Is produced by the dry distillation of fats (Faraday, Phil. Trans. 1825, 440); by heating the vapour of fusel oil to redness (Wurtz, Annalen, 104, 249), together with ethylene and ethane; also from light petroleum, 'ligroin' (b.p. 60°–90°) (Prunier, J. 1873, 347); from *iso-* or tertiary-butyl iodide and alcoholic potash (Butlerow, Annalen, 144, 19); by heating trimethyl carbinol and dilute sulphuric acid (1 vol. H_2SO_4 to 2 vols. water) (Butlerow); from *iso*butyl alcohol and zinc chloride, though in very small quantity (Nevole, Bull. Soc. chim. 24, 122).

Preparation.—(1) 5 parts of *iso*butyl alcohol, 5 parts sulphuric acid, 1 part of water and sand are heated together (Lermontow, Annalen, 196, 117). (2) Puchot's method (Ann. Chim. Phys. [5] 28, 508) of heating *iso*butyl alcohol with a mixture of sulphuric acid, potassium sulphate, and gypsum, gives a mixture of pseudo- and *iso*-butylene. (3) A mixture of 2 parts of caustic potash and 3 parts of alcohol (90 p.c.) is slowly added to 2 parts of *iso*butyl iodide, and gently warmed (Butlerow, Zeitsch. f. chem. 1870, 238). Butylene is a gas, with unpleasant smell, slightly soluble in water; combines with hydriodic acid to form tertiary butyl iodide. A mixture of three parts of sulphuric acid and 1 part of water completely absorbs the gas; on distilling the diluted solution trimethyl carbinol is evolved. It forms a mercury compound $C_4H_8(HgNO_3)(Hg_2NO_3)$ (Denigès, Compt. rend. 126, 1043). Oxidising agents—*e.g.* potassium permanganate—form carbon dioxide, formic and acetic acids, and oxalic acid (and in the case of chromium trioxide, acetone) (Zeidler, Annalen. 197, 251). By the action of a mixture of 5 parts sulphuric acid and 1 part of water forms dodecylene (tri*iso*butylene) $C_{12}H_{24}$; b.p. 177·5°–178·5°; sp.gr. 0·774 at 0° (Butlerow, Ber. 6, 561).

Butylene alcohol *v.* ***Butylene glycols.***

Butylene dibromides.

1. *Normal butylene dibromide, αβ-dibrombutane* $CH_3\cdot CH_2\cdot CHBr\cdot CH_2Br$; b.p. 165·6°–166°; sp.gr. 1·876 at 0° (Wurtz, Annalen, 152, 23), 1·8503 at 0°, 1·8204 at 20°/0° (Grabowsky and Saytzeff, Annalen, 179, 332). Formed from α-butylene and bromine (Wurtz); from normal buty bromide and bromine at 150° (Linnemann, Annalen 161, 199). Gives α-butylene by action of sodium.

2. *β-Butylene dibromide, βγ-dibrombutane* $CH_3\cdot CHBr\cdot CHBr\cdot CH_3$; b.p. 158°; sp.gr. 1·821 at 0°. Formed from β-butylene and bromine (Wurtz, Annalen, 144, 236), or by heating α- or β-brombutane with iron and bromine (V. Meyer and Muller, J. pr. Chem. [2] 46, 180). Decomposed by heating to 140° with water and lead oxide, forming lead bromide and methyl ethyl ketone (Eltekow, Chem. Soc. Abstr. 1879, 34).

3. *Iso-butylene di-bromide, αβ-dibrom-β-methyl propane* $(CH_3)_2CBr\cdot CH_2Br$; b.p. 148°–149° at 737 mm.; sp.gr 1·798 at 14° (Linnemann, Annalen, 162, 30), b.p. 149·6° (corr.) (Thorpe), sp.gr. 1·7434 15°/15° (Perkin). From *iso*-butylene and bromine (L.; also Wurtz, Annalen, 104, 249; Hell and Rothberg, Ber. 22, 1737). By heating with water to 150° *iso*-butyraldehyde and *iso*butylene glycol are formed.

4. *Tetramethylenedibromide, αδ-dibrombutane*, $CH_2Br\cdot CH_2\cdot CH_2\cdot CH_2\cdot Br$; boils at 188°–190° (Gustavson and Demjanoff, J. pr. Chem. [2] 39, 543). (*See* also Hainsocourt, Compt. rend. 132, 345.)

5. *ββ-Dibrombutane* $CH_3\cdot CBr_2\cdot CH_2\cdot CH_3$; boils at 144°–145° (Wislicenus and Holz, Annalen, 250, 232).

6. *αγ-Dibrombutane*

$CH_2Br\cdot CH_2\cdot CH_2Br\cdot CH_3$;

boils at 174°–175° (Perkin, Chem. Soc. Trans. 1894, 963).

Butylene cyanide.

Isobutylene dicyanide (*dimethyl succinonitrile*) $CN\cdot C(CH_3)_2\cdot CH_2\cdot CN$; b.p. 218°–220°. By treating an aqueous alcoholic solution of potassium cyanide with γ-butylene bromide, and allowing the mixture to stand for a fortnight. A colourless oil, moderately soluble in water. Heated to 150° with strong hydrochloric acid, it is decomposed into ammonia and dimethylsuccinic acid (Hell and Rothberg, Ber. 22, 1737).

Butylene glycolchlorhydrin, β-chloroisobutyl-alcohol $(CH_3)_2\cdot CCl\cdot CH_2OH$; b.p. 137. From *iso*butylene and hypochlorous acid (Butlerow, Annalen, 144, 25). Soluble in large excess of water. See also Michael and Leighton (Ber. 1906, 2157).

β-Chloro*iso*butyl alcohol is also formed by the union of hydrogen chloride with *iso*butylene oxide, which results from the action of dry powdered potassium hydroxide on chlorotrimethyl carbinol. The last may be prepared from magnesium methyl bromide, chloroacetone and ethyl chloroacetate. β-chloro*iso*butyl alcohol boils at 132°–133°. It forms a nitrate by the action of concentrated sulphuric and nitric acids $C(Me)_2Cl\cdot CH_2NO_3$, and a nitrite $C(Me)_2Cl\cdot CH_2NO_2$ with nitrous acid, which distinguishes it from the isomeric chlorotrimethyl carbinol (L. Henry, Compt. rend. 1906, 142, 493).

Butylene diamines.

1. *Tetramethylenediamine* (*putrescine*), *αδ*-diaminobutane $NH_2\cdot CH_2\cdot CH_2\cdot CH_2\cdot CH_2\cdot NH_2$, occurs in urine and fæces in cases of cystinuria, and also arises during the putrefaction of herrings. It is prepared by reducing an alcoholic solution of dicyanoethylene with sodium (Ladenburg, Ber. 1886, 780; Lellmann and Winthaer, Annalen, 228, 229); or in a similar manner from succinaldehyde dioxime (Ciamician and Zanetti, Ber. 1889, 22, 1968, 1970). Colourless crystals melting at 27°–28° (C. Z.) and boiling at 158°–160°. Smells like piperidine. It is strongly basic, readily absorbs CO_2, and forms a well-defined dihydrochloride, aurichloride, and platinichloride. The picrolonate is of some physiological importance (Otori, Chem. Soc. Abstr. 1905, ii. 126).

Willstätter and Heubner have prepared the tetramethyl derivative of tetramethylene diamine, and the biquaternary hexamethylammonium salt corresponding to it (Ber. 1907, 3871, 3874). The identity of *aδ*-diaminobutane with putrescine rests on the experiments of Udranszky and Baumann (Ber. 1888, 2938). Brieger (Chem. Zentr. 1907, i. 1703) considers the identity not proven, as also do Willstätter and Heubner (*l.c.*).

2. *Dimethylethylenediamine, βγ-diaminobutane* $CH_3·CHNH_2·CHNH_2·CH_3$, has been prepared by Angeli (Ber. 1890, 1358).

Iso-**Butylacetic acid** *v.* CAPROIC ACID.

Butyl chloral *v.* CHLORAL.

Butyl-lactinic acid *v.* HYDROXYBUTYRIC ACIDS.

Butylene glycols.

1. *Normal-(α)-butylene glycol, aβ-dihydroxybutane* $CH_3·CH_2·CHOH·CH_2OH$; b.p. 191°–192° at 747·1 mm.; sp.gr. 1·0189 at 0°/0°, 1·0059 at 17·5/0°. From normal butylene dibromide (Saytzeff and Grabowsky, Annalen, 179, 332).

2. *β-Butylene glycol, aγ-dihydroxybutane* $CH_3·CH(OH)·CH_2·CH_2OH$; b.p. 203·5°–204° (Kekulé, Annalen, 162, 310); sp.gr. 1·0259 (Wurtz, J. 1873, 474; Bull. Soc. chim. 41, 362). Produced in small quantity by the reduction of dilute aqueous solution of aldehyde by sodium-amalgam (K.). Prepared from *β*-oxybutyric aldehyde by reduction with sodium amalgam (W.).

3. *Isobutylene glycol, aβ-dihydroxy-a-methylpropane* $(CH_3)_2C(OH)·CH_2OH$; b.p. 176°–178°; sp.gr. 1·0129 at 0°, 1·003 at 20°. Produced by the fermentation of sugar in presence of tartaric acid (Henninger and Sanson, Compt. rend. 106, 208). Formed by heating *iso*butylene bromide with potassium carbonate and water (Nevole, Bull. Soc. chim. 27, 63); also by oxidation of *iso*butylene by means of potassium permanganate in neutral aqueous solution (Wagner, Ber. 21, 1232).

4. *Symmetrical dimethylethylene glycol, βγ-dihydroxybutane* $CH_3·CHOH·CHOH·CH_3$; b.p. 183°–184°. Formed by heating for 6 or 7 hours 1 vol. of symmetrical dimethylethylene oxide C_4H_8O with 3 vols. of water to 100° (Eltekow, Chem. Soc. Abstr. 1883, 566).

5. *Tetramethylene glycol, aδ-dihydroxybutane* $OH·(CH_2)_4·OH$; boils at 203°–205°; sp.gr. 1·0111 (Dekkers, Chem. Soc. Abstr., 1891, 164).

6. A-*butylene glycol*, differing from the above, boiling at 183°–184°; has also been prepared by Wurtz (Ann. Chim. Phys. [3] 55, 452); sp.gr. 1·048 at 0°.

7. *a-Methyl propanediol*

$$OH·CH_2·CH(CH_3)·CH_2OH$$

(Henry, Bull. Soc. chim. [3] 13, 1002 Cesaro, Chem. Zentr. 1897, ii. 179).

Butylene diiodide, *aγ-diiodobutane*

$$CH_3·CHI·CH_2·CH_2I;$$

sp.gr. 2·291. From *β*-butylene glycol and hydriodic acid (Wurtz, Bull. Soc. chim. 41, 362).

Isobutylene dinitrite $C_4H_8(NO_2)_2$. By treatment of *iso*butylene with concentrated nitric acid (Haitinger, Monatsh. 2, 287). Forms a crystalline mass. Probably the same body was obtained by Beilstein and Kurbatow (Ber. 14, 1621) by treating the petroleum of Tiflis (b.p. 40°–50°) with nitric acid (sp.gr. 1·52). It formed needles which melted at 96°. They were insoluble in water, but soluble in alcohol and ether.

Butylene oxides C_4H_8O.

1. *Isobutylene oxide*

$$(CH_3)_2\overset{\quad O \quad}{C\text{——}CH_2};$$

b.p. 51°–52°; sp.gr. 0·8311 at 0°. From the chlorhydrin C_4H_9ClO, and potash (Eltekow, Chem. Soc. Abstr. 1883, 566).

2. *s-Dimethylethylene oxide*

$$CH_3·\overset{\quad O \quad}{CH·CH}·CH_3;$$

b.p. 56°-57°; sp.gr. 0·8344 at 0°. [illegible] the chlorhydrin (prepared from the symmetrical dimethyethylene and hypochlorous acid) and potash (Eltekow, Chem. Soc. Abstr. 1883, 566).

BUTYRALDEHYDE. *Butyric aldehyde* C_4H_8O. This compound exists in two isomeric forms, termed normal and *iso*butyric aldehyde respectively.

Normal butyraldehyde $CH_3·(CH_2)_2·CHO$ is formed together with acetaldehyde and propaldehyde by the action of chromic acid upon fibrin, casein, and albumen (Guckelberger, Annalen, 64, 39). It is readily prepared by distilling a mixture of calcium formate (2 mols.) and calcium butyrate (1 mol.) in quantities of 50 grams at a time with twice the weight of iron filings. The distillate is fractionated, the fraction 70°–110° treated with sodium hydrogen sulphite (bisulphite), then shaken with ether to extract impurities, and finally distilled with excess of soda (Lipp, Annalen, 211, 355; Linnemann, *ibid.* 161, 186; Kahn, Ber. 1885, 3364). Bodroux has applied Grignard's reagent to a solution of orthoformic and acetaldehyde, thereby obtaining a 75 p.c. yield of butyraldehyde (Chem. Zentr. 1904, i. 1077).

Properties.—Normal butyraldehyde is a liquid which boils at 73°–74° (Lipp, at 73°–77°) and has a sp.gr. 0·8170 at 20°/4° (Brühl, Annalen, 203, 18). It is soluble in 27 parts of water. With sodium hydrogen sulphite (bisulphite) it unites, yielding a crystalline compound (Justin, Ber. 1884, 2505). When treated with aqueous ammonia at 0°, it yields butyraldehyde-ammonia $C_4H_{11}NO,3\frac{1}{2}H_2O$, which crystallises in acute rhombic tetrahedra and melts at 30°–31° (Guckelberger). If, however, alcoholic ammonia and the aldehyde are allowed to stand for a month, and then heated for a day at 100°, condensation occurs, and, after removal of ammonia, alcohol and unattacked butyraldehyde by distillation, two bases, tetrabutyraldine and dibutyraldine $C_8H_{17}NO$ can be separated by fractional precipitation with platinic chloride. The latter only can be crystallised, and when heated is converted into paraconine $C_8H_{15}N$ and water (Schiff, Annalen, 157, 352). The trichlorobutyraldehyde (butylchloral) and its hydrate have been prepared by Pinner (Annalen, 179, 26).

***Iso*butyraldehyde** $(CH_3)_2CH·CHO$ can be prepared by the oxidation of *iso*butyl alcohol with potassium dichromate and sulphuric acid (Lipp, Annalen, 205, 2; Pinner, Ber. 5, 699; Fossek, Monatsh. 2, 614; 4, 661), or by distilling calcium formate with calcium *iso*butyrate (Linnemann and Zotta, Annalen, 162, 7). It dissolves in 9 parts of water at 20°, and is soluble in alcohol and ether. The boiling-point is 63°–64° at 757 mm. (Brühl, Annalen, 203, 18), and the sp.gr. 0·7938 at 20°/4° (Brühl), 0·79722 at 15° (Perkin, Chem. Soc. Trans. 1884, 476). Condensation compounds have been obtained by Perkin (Chem. Soc. Trans. 1883, 91).

BUTYRIC ACID $C_4H_8O_2$. Two isomeric forms of this acid are known, normal butyric and *iso*butyric acid.

Normal butyric acid $CH_3{\cdot}CH_2{\cdot}CH_2{\cdot}COOH$

Occurrence.—In ordinary butter in combination with glycerol to the extent of 2 p.c.; also in the fruits of *Heracleum villosum* (Fisch) and of *Peucedanum sativum* (Benth. Cl. Hook, *f.*) as hexyl butyrate and octyl butyrate respectively; in the oil of *Eucalyptus Perriniana* as *n*-butyl butyrate (Smith, J. Roy. Soc. New South Wales, 1914, 48, 464). Butyric acid is also found in flesh juice, and is frequently a constituent of decomposing organic matter (*v.* art. FERMENTATION) (J. 1857, 353, 402, 403, 559; 1858, 231; 1859, 363, 364; 1861, 454; 1866, 311). The occurrence of butyric acid in sour milk is treated of by Thorpe (Chem. Zentr. 1909, ii. 1774).

Preparation.—(1) Butyric acid is a frequent product of the oxidation of organic substances; casein, fibrin, and albumen, for example, yield this acid among other products on oxidation with manganese dioxide and sulphuric acid (Guckelberger, Annalen, 64, 68).

(2) All amylaceous and saccharine substances which yield lactic acid as a product of their fermentation can undergo a further fermentation to butyric acid, and this fact is made use of for the preparation of the acid. 5 kilos. of rice or potato starch are boiled with 60 litres of water for some hours, allowed to cool, and the product after 24 hours is treated with 60 grams of malt stirred up with 2 litres of milk, with 1 kilo. of finely divided flesh, and with 2 kilos. of chalk, the chalk being added to neutralise the lactic and butyric acids as rapidly as they are formed, and the whole is allowed to remain with occasional stirring for several weeks at a temperature of 25°–30°. When the evolution of gas has ceased, the product is heated to 80°, filtered, precipitated with sodium carbonate to decompose the calcium salt, again filtered, evaporated to a small bulk, and treated with sulphuric acid. The oily layer of acid so obtained is fractionated to free it from the acetic and caproic acids formed simultaneously, and the fraction 155°–174° is extracted with water, which dissolves the butyric acid but leaves the caproic acid undissolved; the aqueous extract is then neutralised with lime, the solution concentrated, and the salt finally decomposed by hydrochloric acid (Grillone, Annalen, 165, 127).

(3) In the presence of a schizomyces—the so-called *Bacillus subtilis*, which can readily be obtained by stirring hay in water, straining the liquor through a sieve, and boiling for 5 minutes—Fitz (Ber. 11, 52) has found that starch readily undergoes fermentation, yielding normal butyric acid as chief product.

Butyric acid has also been obtained by the fermentation of glycérol in 3 p.c. aqueous solution with a species of schizomyces (Fitz, Ber. 9, 1348; 10, 276), and has been prepared by various synthetical methods (Frankland and Duppa, Annalen, 138, 218; Geuther and Frölich, *ibid.* 202, 306). (For conditions affecting the production of butyric acid by fermentation, see FERMENTATION.)

Properties.—Butyric acid is a colourless, transparent liquid, having an odour resembling that of rancid butter, and a sour burning taste. Cooled to −19° it solidifies, and the crystals melt at about −2°. The acid boils at 161·5° at 760 mm. (Kahlbaum, Ber. 16, 2480); at 162·3° (corr.) (Linnemann, Annalen, 160, 228; Zander, *ibid.* 224, 64); 162·02 (corr.) (Thorpe and Rodger); and has a sp.gr. 0·96704 at 15°/15° (Perkin, Chem. Soc. Trans. 1884, 483), 0·9590 at 20°/4°; μ_D, 1·39906 (Scheig, R. 1899, 169). Butyric acid is inflammable and burns with a blue flame. Alcohol, wood-spirit, and water dissolve it in all proportions, and from the aqueous solution it can be separated by addition of calcium chloride. Prolonged boiling with nitric acid converts it into succinic acid. By the action of calcium carbide, dipropyl ketone may be obtained (Haehn, Chem. Zentr. 1906, ii. 17).

Salts.—The metallic salts of normal butyric acid are generally soluble in water, and are crystalline. $Na\overline{B}$ and $K\overline{B}$ crystalline in indistinct cauliflower-like groups. $Ag\overline{B}$ crystallises in needles or monoclinic prisms, and dissolves in 200 parts of water at 14° (Linnemann and Zotta, Annalen, 161, 177); 100 parts of water dissolve 0·413 part at 16° (Grünzweig, Annalen, 162, 203). $Mg\overline{B}_2,5H_2O$ crystallises in very soluble scales (Pelouze and Gélis, Annalen, 47 249). $Ba\overline{B}_2,4H_2O$ crystallises in nacreous scales, and dissolves in 2·48 parts of water at 14° (Linnemann and Zotta). $Ca\overline{B}_2,H_2O$ crystallises in rhombic forms; 100 parts of water dissolve 19·4 parts at 0°. (For solubility table, *see* Hecht, Annalen, 213, 72.) $Si\overline{B}_2$ forms monoclinic prisms; 100 parts of water at 20° dissolve 39·2 parts of the salt (Grünzweig). $Zn\overline{B}_2,2H_2O$ forms monoclinic prisms; 100 parts of water at 16° dissolve 10·7 parts of the crystallised salt (Grünzweig). $Pb\overline{B}_2$ is an oil which slowly solidifies (Markownikow, Annalen, 138, 361). $Cu\overline{B}_2,H_2O$ crystallises in triclinic forms (Alth, Annalen, 91, 176), and $Cu\overline{B}_2,2H_2O$ crystallises in monoclinic forms (Pelouze and Gélis).

Separation from formic, acetic, and propionic acids.—Mach and Portele (Chem. Soc. Abstr. 1890, 1344) give the following method for the estimation of butyric acid in the presence of acetic acid (as in wine): 500 c.c. of the solution is distilled to a bulk of 125 c.c., diluted to the original volume, and again distilled till only 125 c.c. remains. This is done four times. The total acid in the distillate is estimated by titration with soda or baryta. If soda is used, the neutralised distillate is evaporated down, sulphuric acid is added, and the mixture steam-distilled. The distillate is neutralised with baryta and evaporated so far that it will solidify when cold. The barium butyrate is then extracted with absolute alcohol, and the aqueous solutions of the separated salts treated with sulphuric acid and steam-distilled, the acid in the distillate being subsequently titrated.

The separation of formic, acetic, propionic and butyric acids is also dealt with by Willcox (Chem. Soc. Proc. 1895, 202); Luck (Zeitsch. Anal. Chem. 10, 185); Haberland (*ibid.* 1899, 217); and Muspratt (J. Soc. Chem. Ind. 1900, 204). An expression connecting the percentage of butyric acid in an aqueous distillate with the proportion of the distillate to the original solution is given by Leonard, Smith, and Richmond (Analyst, 1897, 92).

Butyryl chloride, obtained by treating 96 grams of butyric acid with 100 grams of phosphorus trichloride (Burcker, Ann. Chim. Phys. [5] 26, 468); boils at 100°–101·5° (Linnemann); and has a sp.gr. 1·0277 at 23°/4° (Brühl).

Butyric anhydride, prepared by the action of butyryl chloride on butyric acid (Linnemann, Annalen, 161, 179), or by the action of 1 molecule of acetic anhydride or [illegible] mols. sodium butyrate (Michael, Chem. Zentr. 1901, i. 1088), boils at 191°–193° (L.); and has a sp.gr. 0·978 at 12·5° (Gerhardt, Annalen, 87 156).

Butyramide, formed by heating dry ammonium butyrate for six hours at 230° (Hofmann, Ber. 1882, 982); crystallises in tables; melts at 115°; boils at 216° (J. 1856, 516); and is readily soluble in water.

α-Chlorobutyric acid $CH_3\cdot CH_2\cdot CHCl\cdot CO_2H$ is a thick liquid difficultly soluble in water (Markownikow, Annalen, 153, 241).

β-Chlorobutyric acid $CH_3\cdot CHCl\cdot CH_2\cdot CO_2H$, thick liquid (Pinner, Ber. 1879, 2056; 1884, 2008).

γ-Chlorobutyric acid $CH_2Cl\cdot CH_2\cdot CH_2\cdot CO_2H$. Esters only known (Henry, Chem. Zentr. 1898, ii. 273).

αβ-Dichlorobutyric acid $CH_3\cdot CHCl\cdot CHCl\cdot CO_2H$, melts at 72°–73° (Melikow, Annalen, 234, 201; 266, 372).

βγ-Dichlorobutyric acid $CH_2Cl\cdot CHCl\cdot CH_2\cdot CO_2H$; melts at 49°–50° (Lespieau, Compt. rend. 129, 225).

ααβ-Trichlorobutyric acid $CH_3\cdot CHCl\cdot CCl_2\cdot CO_2H$; melts at 60° (Kahlbaum Ber. 1879, 2337: Gargarolli, Annalen, 182, 185).

ααγ-Trichlorobutyric acid $CH_2Cl\cdot CH_2\cdot CCl_2\cdot CO_2H$; melts at 73°–75° (Natterer, Monatsh. 4, 551; 5, 256).

αββ-Trichlorobutyric acid $CH_3\cdot CCl_2\cdot CHCl\cdot CO_2H$; melts at 52° (Szenic and Taggesell, Ber. 1895, 2665).

Tetrachlorobutyric acid $C_4H_4Cl_4O_2$; melts at 140° (Pelouze and Gélis, Arch. Pharm. [3] 10, 434).

Bromobutyric acids have also been obtained by Naumann (Annalen, 119, 120), Schneider (J. 1861, 458), and Michael and Norton (Amer. Chem. J. 2, 16). (*See* also Cloves, Chem. Zentr. 1902, I. 406.)

***Iso*butyric acid** $(CH_3)_2\cdot CH\cdot COOH$.

Occurrence.—*Iso*butyric acid occurs in the fruit of *Siliqua dulcis* (Grünzweig, Chem. Soc. Trans. 1873, 373), and in arnica root (*Arnica montana*) (Sigel, Annalen, 170, 348).

Preparation.—*Iso*butyric acid is most readily prepared by the oxidation of *iso*butyl alcohol with a mixture of sulphuric acid and potassium dichromate. Pierre and Puchot (Ann. Chim. Phys. [4] 28, 366) give the following proportions: *Iso*butyl alcohol (300 parts) is mixed with water (1500 parts) and sulphuric acid (540 parts) and into the well-cooled mixture finely powdered potassium dichromate (400 parts) is gradually introduced. An ethereal layer separates, consisting of *iso*butyl *iso*butyrate, which is decomposed by allowing 55 parts to fall slowly on 100 parts of caustic potash to which one-tenth its weight of water has been added; the resulting potassium salt is then distilled with dilute sulphuric acid, and the aqueous acid purified by fractional distillation.

Synthetical methods for preparing this acid (Annalen, 138, 337), and Markownikow (Annalen, 138, 361).

Properties.—*Iso*butyric acid resembles its isomeride in appearance, but has a less disagreeable odour. It boils at 152° at 760 mm. (Kahlbaum, Ber, 16, 2480); at 153·5°–153·8° at 750·3 mm. (Brühl, Annalen, 200, 180); at 15[illegible]°–154·2° (Zander, *ibid.* 224, 77); 154·0° (corr.) (Thorpe and Rodger); sp.gr. 0·965 at 0° (Zander); 0·9503 at 20° (Linnemann, Annalen, 162, 9). It dissolves in five times its volume of water (L.). The metallic salts of *iso*butyric acid are more soluble in water than those of the normal acid. The potassium and sodium salts form cauliflower-like masses. $Ag\bar{B}$ crystallises in characteristic tabular forms; 100 parts of water dissolve 0·928 part at 16° (Grünzweig, Annalen, 162, 210). $Mg\bar{B}_2$ forms white scales. $Ca\bar{B}_2,5H_2O$ forms four-sided monoclinic crystals; 100 parts of water at 18° dissolve 36 parts of crystallised salt (G.), and the solubility increases as the temperature rises. $Sr\bar{B}_2,5H_2O$; 100 parts of water at 17° dissolve 44·1 parts of the crystallised salt (G.). $Ba\bar{B}_2,\frac{1}{2}H_2O$ forms monoclinic crystals (Fitz, Ber. 1880, 1316). $Zn\bar{B}_2,H_2O$; 100 parts of water at 19·5° dissolve 17·3 parts of the crystallised salt (Grünzweig). $Pb\bar{B}_2$ crystallises in rhombic tables and dissolves in 11 parts of water at 16°.

***Iso*butyryl chloride**, prepared by treating *iso*butyric acid (12 parts) with phosphorus trichloride (7 parts), and subsequently distilling (Tönnies and Staub, Ber. 1884, 850); boils at 91·5°–92·5° at 748·2 mm.; and has a sp.gr. 1·0174 at 20°/4° (Brühl, Annalen, 203, 20).

***Iso*butyryl anhydride**, obtained by boiling *iso*butyric acid with *iso*butyryl chloride for 12 hours in a reflux apparatus and fractionating the product (Tönnies and Staub, Ber. 1884, 850); boils at 181·5° at 734 mm.; and has a sp.gr. 0·9574 at 16·5°.

***Iso*butyramide**, formed by heating dry ammonium *iso*butyrate at 230° for six hours; melts at 128°–129° (Hofmann, Ber. 1882, 982).

α-Chloro*iso*butyric acid $(CH_3)_2CCl\cdot CO_2H$; melts at 31° and boils at 118° (Henry, Bull. Soc. chim. 26, 24; Balbiano, Ber. 1878, 1693).

αβ-Dichloro*iso*butyric acid $CH_3\cdot CH(CH_2Cl)\cdot CCl\cdot CO_2H$ (Brochet, Ann. Chim. Phys. [7] 10, 375).

Trichlor*iso*butyric acid $C_4H_5Cl_3O_2$; melts at 50° (Gottlieb, J. pr. Chem. [2] 12, 1).

Bromo*iso*butyric acids have been prepared by Markownikow (Annalen, 153, 229); Engelhorn (*ibid.* 200, 65, 68); Cahours (*ibid.* Supplt. 2, 349, 352).

Butyric esters. These compounds are for the most part prepared by the action of butyric acid on the corresponding alcohols in presence of some dehydrating agent such as sulphuric acid, the temperature being raised eventually to complete the reaction. Butyric esters are liquids which dissolve in alcohol and ether in all proportions, but are only very sparingly soluble in water. On saponification with caustic potash they yield the corresponding alcohol and potassium butyrate.

Methyl butyrate $C_4H_7O_2Me$, prepared similarly to the ethyl ester, is a colourless liquid with a pleasant odour resembling that of pinemann, Pogg. Ann. [2] 12, 41]; and has a sp.gr. 0·9194 at 0°/4° (Elsässer, Annalen, 218, 314).

Ethyl butyrate, *butyric ether*, is prepared by adding 1 part by weight of sulphuric acid to 2 parts each by weight of butyric acid and alcohol. The liquid becomes heated, and the mixture at once separates into two layers of which the upper one consists of ethyl butyrate. To complete the reaction it is necessary to heat the product at about 80° for a short time. The upper layer is separated, washed with water, dried over calcium chloride, and distilled. The presence of considerable quantities of water does not seem to hinder esterification (Pelouze and Gélis, Annalen, 47, 250).

Ethyl butyrate is a colourless liquid having an odour like that of pine-apples. It boils at 119·9° at 760 mm. (Schumann); and has a sp.gr. 0·8996 at 0°/4° (Elsässer), b.p. 120·0°–120·5°; sp.gr. 0·8784 20°/4° (Matthews and Faville, J. Phys. Chem. 1918, 22, 1). A solution of ethyl butyrate is used in perfumery and in confectionery under the name of pine-apple oil.

Propyl butyrate boils at 142·7° at 760 mm. (Schumann); and has a sp.gr. 0·8930 at 0°/4° (Elsässer).

***Iso*propyl butyrate** boils at 129° at 755 mm.; and has a sp.gr. 0·8787 at 0° (Silva, Ber. 1869, 283), 0·9027 at 0° (Přibram and Handl, Monatsh. 2, 690).

Butyl butyrate boils at 164·8° (corr.), and has a sp.gr. 0·8760 at 12° (Linnemann, Annalen, 161, 195; compare also Lieben and Rossi, *ibid.* 158, 170).

***Iso*butyl butyrate** boils at 156·9° at 760 mm. (Schumann); and has a sp.gr. 0·8798 at 0°, 0·8664 at 16° (Grünzweig, Annalen, 162, 207).

***Iso*amyl butyrate** boils at 178·6° at 760 mm. (Schumann); and has a sp.gr. 0·8823 at 0°/4° (Elsässer).

The hexyl- and octyl-butyrates occur in the oils from the fruits of *Heracleum giganteum* (Franchimont and Zincke, Ber. 4, 824) and *Pastinaca sativa* (Renesse, Annalen, 166, 80) respectively.

Ethereal salts of *iso*butyric acid have been prepared:

Methyl *iso*butyrate boils at 92·3° at 760 m.m. (Schumann); and has a sp.gr. 0·9112 (Elsässer).

Ethyl *iso*butyrate boils at 110·1° at 760 mm. (Schumann); its sp.gr. is 0·8903 (Elsässer).

Propyl *iso*butyrate boils at 133·9° at 760 mm. (Schumann; its sp.gr. is 0·8843 (Elsässer).

***Iso*propyl isobutyrate** boils at 118°–121° at 727 mm.; and has a sp.gr. 0·8787 at 0° (Přibram and Handl).

***Iso*butyl *iso*butyrate** boils at 146·6° at 760 mm. (Schumann); its sp.gr. at 0° 0·8752 (Grünzweig).

***Iso*amyl *iso*butyrate** boils at 168·8° at 760 mm. (Schumann); and has a sp.gr. 0·8759 at 0°/4° (Elsässer).

λ-BUTYROBETAINE *v.* BETAINES.

BUTYROLACTONE *v.* HYDROXYBUTYRIC ACIDS.

BUTYRONE. *Dipropyl ketone* $C_7H_{14}O$.

Butyrone is obtained by distilling calcium butyrate, or preferably a mixture of calcium butyrate and calcium carbonate (Schmidt, Ber. 5, 597); the crude product is dehydrated by treatment with calcium chloride, and purified by fractional distillation. Butyrone boils at 144°, and has sp.gr. 0·8195 at 20°, does not combine with ammonia or sodium hydrogen sulphite (bisulphite), yields a mixture of propionic and butyric acids on oxidation with chromic acid, and is converted into a secondary alcohol $C_7H_{16}O$ and butyrone-pinacone $C_{14}H_{30}O_2$ on treatment with sodium amalgam and water (Kurtz, Annalen, 161, 205).

An isomeride *di-isopropylketone* can be prepared by distilling calcium *iso*butyrate (Münch, Annalen, 180, 327); it boils at 124°–126°, has a sp.gr. 0·8254 at 17°, and does not combine with sodium hydrogen sulphite.

BUTYRO-REFRACTOMETER *v.* REFRACTOMETERS.

BUXIN. An alkaloid obtained from the box-tree (*Buxus sempervirens*). Hager (Chem. Zentr. 1877, 119) found it in beer as an adulterant. It is said by Walz (N. J. P. 14, 15) to be identical with bebeerine (*q.v.*).

BYNIN. Trade name for liquid malt extract.

C

CABBAGE, *Brassica oleracea.* This plant has been modified by careful selection and cultivation so as to produce several apparently very different varieties:

1. Those which form a compact head by overlapping of the leaves, as in the ordinary cabbage.
2. Those of a straggling, open habit of growth, with a branching stem but no distinct 'heart' or head, *e.g.* thousand-headed kale.
3. Those in which a dense head of imperfect flowers are formed, as cauliflower and broccoli.
4. Those in which the stem is enormously developed so as to form a globe, as in kohl-rabi.
5. Those in which a large number of small 'heads' are formed on a tall stem—Brussels sprouts.

Of the cabbage itself, there are many varieties, differing in size, shape, and colour.

Like all the members of the *Cruciferæ*, cabbages contain sulphur compounds, some of which easily undergo decomposition with production of sulphuretted hydrogen.

The average composition of cabbages, as used for cattle food, is, according to Kellner—

Water	Protein	Fat	Sol. carbohydrates	Fibre	Ash
84·7	2·5	0·7	8·1	2·4	1·6

whilst, according to American analyses, the edible portion of culinary cabbages contains:

Water	Protein	Fat	Sol. carbohydrates Fibre	Ash
90·3	2·1	0·4	5·8	1·4

Included in the carbohydrates mannitol and glucose have both been detected (Bysolt, J. Laudw. 1914, 62, 117).

Cabbages, as a farm crop, respond to liberal manuring, and in inland districts are benefited by a small dressing of the soil with common salt. They do best, as a rule, on heavy land, and are usually transplanted from seed-beds.

Formentated cabbage (sauerkraut) yields acetic and propionic acids with occasional traces of formic acid together with an inactive form of lactic acid. Ethyl and propyl alcohols are also formed together with small quantities of esters (Nelson and Beck, J. Amer. Chem. Soc. 1918, 40, 1001).

CACAO BUTTER (spelt also Cocoa Butter), is expressed from the cacao bean, the seeds of the cacao tree, *Theobroma cacao* (Linn.).

The cacao tree is indigenous to the West Indies, but has been introduced into various tropical countries, especially Central and South America and to the West Coast of Africa and the islands in the Bay of Benin. It has also been introduced into Nigeria, and an inducement has been held out by the Government to the Nigerian peasants to grow cacao. As the beans are chiefly worked up for the preparation of cacao, the cacao butter must be considered, to some extent, a by-product of the chocolate industry. For the production of cacao butter, the beans are roasted over a coke fire, and the husks are separated by winnowing. The kernels thus laid bare are ground under millstones and reduced to a paste, when the bulk of the fat is removed by hot expression in hydraulic presses. As the fat in the bean has undergone slight hydrolysis, it is usual to add a carbonate, either of potassium or ammonium, to the beans before roasting. Hence, in the examination of cacao butter, the presence of ammonia or potash soap may be expected.

In Cook's patent process (U.S. Pat. 1006913, 1911) the roasted beans are decorticated, and then pressed sufficiently to powder the mass, and express part of the fat.

A special form of press for separating the fat from the beans has been devised by Hänel (Eng. Pat. 3188, 1915).

The average composition of the cacao bean is, according to König, as follows :—

	Per cent.
Fat	49·0
Water	5·4
Proteins	12·8
Carbohydrates . . .	25·7
Crude fibre . . .	3·71
Ash	3·41

The composition of the shell is as follows :—

Fat	4·21
Water	11·19
Proteins	13·61
Carbohydrates . . .	43·95
Crude fibre	17·63
Ash	9·88
	100·47

The proportion of fat in the bean varies from about 50 to 56 p.c. In the production of cacao powder, only a portion of the cacao butter is expressed, whereas the beans intended for the manufacture of *best* chocolate are not expressed, so that the full amount of fat is allowed to remain in the ground mass. Manufacturers of cheap chocolates remove a portion of the costly cacao butter by expression, replacing it by cheaper substitutes (*see* CHOCOLATE FATS). The kernels contain a small amount of theobromine, a portion of which passes into the cacao butter on expression.

Cacao butter has a yellowish-white colour, turning white on keeping, an agreeable taste and pleasant odour, recalling that of chocolate. At the ordinary temperature, the fat is somewhat brittle. It appears to consist, to a very large extent, of oleodistearin and oleodipalmitin. The solid acids of cacao butter consist of stearic and palmitic acids; small quantities of arachidic acid are stated to occur also amongst the solid fatty acids.

The proportion of stearic acid in the fat is as high as 39–40 p.c. Amongst the liquid fatty acids there seem to be present about 6 p.c. of acids less saturated than oleic acid, most likely linolic acid. From the iodine value of the cacao butter, viz. 32–42, the conclusion may therefore be drawn that it contains not more than about 30 p.c. of oleic acid. The unsaponifiable matter of cacao butter amounts to less than 1 p.c. Matthes and Rohdich (Ber. 1908, 41, 19) found in the unsaponifiable matter a hydrocarbon (most likely identical with amyrilene), stigmasterol, and a phytosterol melting at 130°.

In the older literature the statement frequently occurs that cacao butter does not turn rancid. But it is a matter of common experience that cacao butter, exposed to light and air at the ordinary temperature, becomes rancid in the course of time. Equally erroneous is the statement that rancid cacao butter is obtained from mouldy beans. Most shipments of cacao beans become mouldy in transit, but as the beans in the initial state of manufacture are roasted, the mould is destroyed, so that cacao butter prepared from these beans need not, of necessity readily become rancid. With the growth of the consumption of chocolate and cacao, the trade in cacao beans has become of very great importance.

Holland is the largest exporter of cacao butter, whilst Germany was the largest producer, but exports relatively very little. Of late years the demand for the fat has greatly increased, and the price has risen correspondingly.

Cacao butter, being very high in price, in normal times even higher than cows' butter, is frequently adulterated with, if not completely substituted by, 'chocolate fats.' The adulterants formerly employed, such as tallow and paraffin wax, are easily detected, and hence these adulterants have disappeared. The same holds good of coco-nut and palm-nut stearins, which, for some time, were largely used to adulterate cacao butter. Latterly, adulteration with cacao-shell butter has been practised and is still in vogue; for this purpose, the husks are ground and again expressed, or even extracted with volatile solvents. As the fat thus obtained yields, in analysis, practically the same characteristic numbers as genuine cacao butter itself, chemical analysis alone is unable to reveal adulteration with cacao-shell butter.

Products commercially known as 'green butter' are now extensively used for mixing with cacao butter. They consist of a refined vegetable tallow coloured with chlorophyll or with an aniline dye. The adulteration may be detected by a modification of Halphen's test (J. Pharm. Chim. 1908, 28, 345). On adding bromine to a solution of the fat in carbon tetrachloride, pure cacao butter immediately gives a turbidity, whilst in the case of 'green butter' the liquid remains clear (Revis and Bolton, Analyst, 1913, 38, 201).

Cacao butter, being chiefly produced as a by-product in the manufacture of cocoa, is obtainable in large quantities: it is at present mainly used in the manufacture of cheaper chocolate. Smaller quantities are used in confectionery, in pharmacy for making suppositories and nitroglycerin tablets, and in the 'enfleurage' process of preparing delicate ethereal oils. J. L.

CACHALOT OIL. Oil obtained from the blubber of the cachalot. (For its properties and composition, v. Fendler, Chem. Zeit. 1905, 29, 555.)

CACODYLIAGOL. Syn. for guaiacol cacodylate.

CACODYLIC ACID and **CACODYLATES** v. ARSENIC, ORGANIC COMPOUNDS OF.

CADAVERINE v. PUTREFACTION BASES.

CADE, OIL OF v. JUNIPER.

CADIE GUM v. GUMS.

CADINENE v. TERPENES, JUNIPER.

CADMIUM, (*Kadmium*, Ger.) Sym. Cd. At. wt. 112·3 (Quinn and Hulett); 112·42 (Baxter and Hartmann); 112·32 (De Coninck and Gérard).

Cadmium occurs in small quantities as sulphide in *Greenockite* at Bishopton, Renfrewshire, and in Pennsylvania and Bohemia. This is the only ore containing cadmium as the principal element. Cadmium occurs in small quantities in nearly all zinc ores, but the percentage is considerably lower than that usually stated. Jensch and Kliecisen have shown that the cadmium in zinc ores averages about 0·1 p.c., 0·5 p.c. being only reached in the richest samples, though occasional specimens are stated to have yielded considerably higher values. It occurs also in the silicate and carbonate of zinc at Freiberg, Derbyshire, and Cumberland, and in most commercial zinc.

Preparation.—In the reduction of zinc ores, the first portions of the distillate consist of a mixture of the metals zinc and cadmium and their oxides, but containing a higher percentage of cadmium (on account of its greater volatility) than the original ore, and by further similar treatment it is still further increased. When sufficiently rich, it is used for the extraction of the cadmium. At Silesia, the first portion of the distillate, which contains from 2 to 6 p.c. of cadmium, is mixed with about one-fourth of its weight of coal, and distilled at a dull-red heat; the cadmium then distils with a little zinc, but the greater part of the latter metal remains behind. The cadmium is purified by fractional distillation until a product of 99·5 p.c. or more is obtained; it is then cast into small cylinders about ½ inch thick.

The chief output of cadmium comes from Silesia. A little cadmium is recovered in this country in the purification of zinc sulphate, in the manufacture of lithopone, or from baghouse dusts at lead smelters. Another source which may become important in view of the increasing number of electrolytic zinc plants is the precipitate obtained in purifying the electrolyte prior to deposition of the zinc, as well as the anode mud. Flue dust from brass works contains as much as 2–3 p.c. of cadmium. The supply can easily be increased to meet any reasonable demand.

Various wet methods for the extraction of the cadmium from the concentrated flue dust have been proposed and tried. Some of these are dependent on the precipitation of cadmium from acid solutions by means of zinc; others on the solubility of zinc in neutral ammonium carbonate.

Electrolytic methods for the refining of cadmium are employed, the cadmium being deposited on platinum electrodes and distilled *in vacuo*.

Properties.—Cadmium is a white metal with a tinge of blue, of strong lustre, and capable of taking a high polish. It produces a metallic streak on paper like lead, but less readily. Cadmium is compact in texture and of fibrous fracture, harder and more tenacious than tin; it may be drawn into thin wire or hammered into leaves, but when heated to 80° it becomes brittle, and may be powdered in a mortar. On account of its crystalline structure, it crackles, like tin, when bent.

By distillation in a current of hydrogen, cadmium may be produced in regular octahedra and other forms of the cubic system.

Cadmium melts at 321·7° (Holborn and Day); 320·9° (Holborn and Henning), and boils at 765·9° under a pressure of 760 mm. (Heycock and Lamplough). Its vapour density at 1040° is 3·94 referred to air, or 56·3 referred to hydrogen. Hence it appears that the molecule of cadmium contains but one atom at that temperature, whilst further the values for the latent heat of vaporisation (calculated from the vapour pressure) indicate similar molecular states in liquid and gas (Traube). It is obtained in colloidal solution by electric sparking with a cadmium cathode in water.

According to Demarcay, it emits vapours when heated below the melting-point (Compt. rend. 95, 183). When heated in air, it burns readily, evolving brown fumes of the oxide. Cadmium dissolves in hydrochloric and sulphuric acids with evolution of hydrogen. It is readily attacked by nitric acid. It combines directly with chlorine, bromine, and iodine when placed in solutions of those elements. Cadmium gives a brilliant spectrum of red, green, and blue lines, and its use has been suggested as a convenient standard in refractometry (Lowry).

The salts of cadmium, as a rule, are but slightly dissociated in solution—this is especially so in the case of the iodide—and are hence liable to be incompletely precipitated by reagents.

Detection.—All compounds of cadmium, when heated on charcoal in the reducing flame, give a brown incrustation. Sulphuretted hydrogen produces a yellow precipitate in acid solutions, soluble in strong hydrochloric acid insoluble in alkaline sulphides; it is thus distinguished from antimony and arsenic.

Estimation.—Cadmium may be precipitated as carbonate and weighed as oxide. Owing, however, to the reduction of the oxide and the great volatility of the metal, if filter papers are employed, the results are low, even when careful precautions are taken. A Gooch crucible and asbestos filter should therefore be employed. Cadmium may also be estimated by precipitation from a neutral solution by excess of diammonium phosphate, and, after standing some time, collecting the precipitate on a weighed filter paper, dried at 105° (Page and Miller).

Electrolytic methods of estimation have also been found to be suitable and to yield accurate results. A cyanide solution with an E.M.F. of 3 to 3·5 volts and a current of 0·02 to 0·05 ampere, is a convenient arrangement (Rimbach).

To separate it from other metals not precipitable by sulphuretted hydrogen in acid solution, it is precipitated as sulphide by that gas, washed, dissolved in nitric acid, and precipitated with sodium carbonate.

Alloys of cadmium. The addition of cadmium to metals usually increases their fusibility without destroying their malleability.

The alloys with gold and copper are brittle; the others are usually ductile and malleable. With gold, a crystalline brittle silvery alloy, corresponding with AuCd, has been prepared, and the existence of a compound, Au_4Cd_3, is also indicated. Alloys, containing between 51 and 63 p.c. of cadmium, are very brittle. With platinum, a white crystalline compound appears to exist; and with copper compounds Cu_2Cd and Cu_2Cd_3, are indicated. The alloys rich in cadmium are steel-grey and soft, but become harder and more brittle with increase of copper up to 26·5 p.c., when the hardness again decreases and the yellow colour of copper appears. Researches by Rose on alloys of silver and cadmium indicate the existence of the compounds $AgCd_3$, Ag_2Cd_3, AgCd, Ag_3Cd_2, Ag_3Cd, and Ag_4Cd. Alloys containing over 80 p.c. silver are uniform and homogeneous, and well suited as material for trial plates for silver coinage and ware, for which the silver-copper alloy is not quite satisfactory. With sodium a compound, Cd_2Na, has been prepared, and compounds CdMg and $CdMg_4$ are indicated in the alloys with magnesium. The addition of ¼ p.c. cadmium to zinc increases the breaking strain, but more than ½ p.c. has the opposite effect. The amalgam, with mercury, was formerly used in dentistry, but its use has been discontinued, as it produces discolouration of the dentine. Multiple alloys, containing bismuth, frequently melt below 100°, and are used as fusible alloys; for these and other alloys containing bismuth and cadmium, *v. Alloys of bismuth*, art. BISMUTH. The metal is occasionally used as a substitute for tin in solder.

Cadmium oxide CdO is prepared by heating the carbonate, in which case it is of a pale-brown colour; or by igniting the nitrate, when it is much darker and forms minute crystals. By heating cadmium in a current of oxygen, the oxide may be condensed in octahedral crystals; at low temperatures, some peroxide is also formed (Manchot). Cadmium oxide is infusible, insoluble in water, soluble in acids. It constitutes the brown deposit found in the condensers in the distillation of zinc.

Cadmium suboxide Cd_2O appears to be formed in small quantity when cadmium oxalate is heated in a stream of carbon dioxide (Tanatar, Zeitsch. anorg. Chem. 1901, 27, 433), or when cadmium oxide is heated with carbon monoxide (Brislee, Chem. Soc. Trans. 1908, 93, 162), or by dehydrating cadmious hydroxide, obtained by the action of water on the product formed by fusing cadmium chloride with cadmium (Moore and Jones, Amer. Chem. J. 1890, 12, 488). *Cf.* Denham, Chem. Soc. Trans. 1919, 516.

Cadmium chloride $CdCl_2$ is prepared by evaporating the solution of the metal or oxide in hydrochloric acid. It melts below a red heat and sublimes at a higher temperature, condensing in micaceous plates.

Cadmium iodide CdI_2 is obtained by digesting 1 part of the metal with 2 parts of iodine in water and evaporating the solution. It crystallises in large transparent tablets, soluble in water and alcohol. It is used in medicine and, on account of its stability and solubility in alcohol, for iodising collodion plates in photography.

Cadmium sulphide. *Cadmium yellow, Jaune brillant.* This pigment may be produced by the addition of sulphuretted hydrogen or an alkaline sulphide to a solution of a cadmium salt. It may also be prepared by heating a mixture of cadmium oxide and excess of sulphur, but that produced by the former method is of a finer colour and has greater covering power. It may also be formed by the action of hydrogen sulphide on cadmium vapour. The various hues of different preparations depend on whether the substance is crystalline or amorphous, and on the size and nature of the surface of the grains.

It is an orange- or lemon-yellow powder, but may be obtained in prismatic crystals of sp.gr. 4·82. When heated to redness, it becomes first brown, then carmine; it melts at a bright-red heat, and solidifies, on cooling, in laminæ of the original colour.

It is a very brilliant permanent colour. According to Jacquet, it is acted upon by light and by chlorine. It is much used as an oil and water colour, for colouring certain toilet soaps, for the production of a blue flame in pyrotechny, and in calico printing. The chief adulterants are compounds of zinc. According to Buchner (Chem. Zentr. 15, 329), two modifications exist: (1) the α-variety, precipitated by hydrogen sulphide in faintly acid solution; it is lemon-yellow, and possesses good covering power. When heated, it darkens temporarily to violet-red, but no permanent change occurs unless the temperature is high enough to produce oxidation. (2) The β-variety, produced in strongly acid solution; it resembles red lead, possesses good covering power, and is ordinarily quite permanent; if heated, it changes to the α-variety. Various shades are obtainable by mixture. The sulphide can also be obtained in colloidal solution.

Schmid (Dingl. poly. J. 241, 149), prepares a steam yellow for calico-printing as follows: 16 parts wheaten starch and 40 parts burnt starch are boiled in 1000 parts of water and mixed while hot with 350 parts of sodium thiosulphate. To the cooled solution, 350 parts of finely powdered cadmium nitrate are added with constant stirring until dissolved. This solution does not react in the cold, and may be applied to the fabric and steamed, the yellow sulphide being then precipitated.

Cadmium sulphate $CdSO_4,4H_2O$ is a very soluble salt prepared by dissolving the oxide or carbonate in sulphuric acid. It is used to some extent in medicine in place of zinc sulphate, especially on the Continent. It is also used in the construction of the Weston cell as a standard of E.M.F. The cell is usually made in the form of an H. One of the limbs contains mercury, covered by a paste of cadmium and mercurous sulphates. The other contains cadmium amalgam. Above both, to nearly the top of the limbs, which are closed by cork and wax, is a saturated solution, with crystals of cadmium sulphate. Through the glass of the lower limbs, platinum wires pass. The cell has an E.M.F. of 1·019 volts at 15°–18°, and has the advantage of a very low temperature coefficient.

Forms a double salt with ammonium sulphate $CdSO_4(NH_4)_2SO_4 6H_2O$. A salt of the composition $2CdSO_4(NH_4)_2SO_4$, hygroscopic, microscopic crystals, yellow when hot, white when cold, of sp.gr. 3·11 at 22° is also known (Veres, Compt. rend. 1914, 158, 39).

Cadmium nitrate $Cd(NO_3)_2,4H_2O$ is prepared by dissolving the oxide or carbonate in nitric acid. It crystallises in deliquescent fibrous needles, soluble in alcohol.

Cadmium salicylate is prepared from the acid and oxide or carbonate. It is readily soluble in alcohol, ether, or glycerol, and is used in medicine as an external antiseptic.

CÆSIUM. Symb. Cs. At. wt. 132·8. Cæsium was discovered in 1860 by Bunsen and Kirchhoff, in the Durkheim water, being the first element detected by means of the spectroscope.

It is widely but sparsely distributed, usually in association with rubidium, as in the *lepidolite* from Hebron in Maine, U.S.A., which contains 0·4 p.c. cæsium oxide and 0·2 p.c. rubidium oxide; in *petalite*; in the mother liquors of the Nauheim salt spring, and in the ash of seaweed, tobacco, tea, and other plants. Setterberg (Annalen, 210, 100) describes a method for the separation of cæsium and rubidium from the alums obtained as a by-product in the manufacture of lithia from lepidolite. For observations on the solubilities of cæsium alum, *see* Hart and Huselton (J. Amer. Chem. Soc. 1914, 36, 2082). For details of the method of separation of cæsium and rubidium by fractional crystallisation of the aluminium and iron alums, *see* Browning and Spencer (Amer. J. Sci. 1916, 42, 279). Cæsium and rubidium chlorides are also obtained from carnallite by repeated fractional crystallisation. The cæsium is separated from the rubidium by the addition of antimony chloride, which precipitates only the cæsium in the form of the double salt $SbCl_3·6CsCl$ (Fict and Kubeirscky).

Cæsium occurs free from rubidium in the rare mineral *pollucite*, from Elba, to the extent of 34 p.c. of cæsium oxide; to the extent of 1·71 parts of cæsium chloride per million in the water of the Wheal Clifford Mine (Yorke), and in the mineral waters of Frankhausen.

Cæsium may be prepared by electrolysis of a fused mixture of cæsium cyanide 4 parts and barium cyanide 1 part, using electrodes of aluminium (Setterberg). It is more readily obtained by heating the hydroxide with aluminium in a nickel retort, and condensing the metal in a glass receiver (Békétoff); or by heating the carbonate or hydrate with magnesium in a current of dry hydrogen (Graebe and Eckhardt). A more rapid method, giving a better yield, is stated to be the reduction by calcium; 3 grams of this metal in small pieces with 12 grams of cæsium chloride are heated in a wide inverted Y-tube, the vertical limb being connected to a Sprengel pump. Reduction occurs at about 400°, and the cæsium volatilises and condenses in the vertical tube. It resembles rubidium and potassium in appearance, being silvery white, and soft at ordinary temperatures. It quickly oxidises in air, and decomposes water at –116° with ignition of the liberated hydrogen at higher temperatures. Its sp.gr. at 15° is 1·88, 1·0029 (Hackspill, Compt. rend. 1911, 152), its melting-point is 26°–27° (Setterberg); 28·45° (Rengade, Compt. rend. 1913, 156, 1897).

The coefficient of expansion of the solid metal is 0·000291, of the liquid metal 0·000345 between 28° and 50° (Hackspill, *l.c.*). Specific heat (solid) $0·0522+0·000137t$; liquid $0·0604-0·000034t$; heat of fusion 3·766; ratio of atomic heat of fusion to abs. m.p.=1·66 (Rengade).

Cæsium is the most electro-positive of all the elements. Its salts are stable and have a strong tendency to form double salts. The salts are isomorphous with those of potassium and rubidium, and impart a more reddish tinge to the bunsen flame than salts of those metals. The hydroxide CsHO is a greyish-white highly deliquescent solid, melting below a red heat. The oxide Cs_2O is prepared by exposing the metal to insufficient oxygen and distilling off excess of cæsium; a peroxide CsO_2 is formed by heating to 300° in excess of oxygen (Rengade). For its *absorption spectrum*, *see* Bevan (Proc. Roy. Soc. 1911, 85, A, 54).

CAFFEARINE. Found in the mother liquors of caffeine from coffee berries; is identical with trigonelline (*q.v.*) (Gorter, Annalen, 1910, 372, 237).

CAFFEINE AND THE ALKALOIDS OF TEA, COFFEE, AND COCOA. The chief alkaloids of practical importance in this series are caffeine $C_8H_{10}O_2N_4$, theobromine $C_7H_8O_2N_4$, and theophylline $C_7H_8O_2N_4$. Adenine $C_5H_5N_5$, xanthine $C_5H_4O_2N_4$, and hypoxanthine $C_5H_4ON_4$ have also been found in tea in small amounts.

These alkaloids are all derived from a parent substance purine $C_5H_4N_4$, which has not been found occurring naturally, but was synthesised by Fischer (Ber. 1898, 31, 2550). Derivatives of purine occur widely distributed in plants and animals. Of these, uric acid (2 : 6 : 8-trioxypurine) $C_5H_4O_3N_4$ is of considerable importance, as it is used in the industrial manufacture of the alkaloids of this series; guano, in which it occurs in considerable quantities, being the source from which it is obtained. The constitution of these compounds and their relationship to purine and to each other will be considered in detail below.

Caffeine $C_8H_{10}O_2N_4$ is the principal alkaloid of tea and coffee and of similar stimulants, such as kola (West Africa), maté or Paraguay tea, and guarana (both used in South America).

Average samples of tea leaves contain from 2·5 to 3 p.c. of caffeine, though some varieties may contain as much as 4 p.c. Coffee beans, in which caffeine occurs partly free and partly as potassium caffeine chlorogenate, rarely contain more than 1·5 p.c. (*v.* Bull. Imp. Inst.

1908, 6, 1). Maté contains from 1 to 2 p.c., guarana paste from 3 to 4 p.c., and kola about 3 p.c. of caffeine. Only very small amounts occur in cocoa beans (Schmidt, Annalen, 1883, 217, 306).

Caffeine is obtained industrially almost entirely from tea dust or damaged tea. The material is 'denatured' by addition of about 10 p.c. of slaked lime and 0·1 p.c. of assafœtida. The well-mixed material is then extracted either with boiling water or more usually with hot alcohol in a reflux apparatus. The extraction is repeated three or four times, the extracts combined, and the solvent recovered by distillation. The residual liquid is treated with litharge or lead acetate, avoiding excess; the precipitate is filtered off, and the filtrate concentrated, when caffeine crystallises out on cooling. The product is purified by recrystallising, decolourising with charcoal, &c., when necessary, or by sublimation.

An alternative method sometimes employed consists in the exhaustive percolation of the denatured tea by means of hot benzene. The concentrated extract is freed from benzene, the residue, consisting of caffeine, together with fatty and resinous material, is boiled with water and filtered from insoluble material. On concentrating the filtrate caffeine crystallises out, and may be purified by the methods described above.

Caffeine is also a by-product obtained in the manufacture of 'caffeine free' coffee, and is further manufactured synthetically from uric acid (*see* below). For the preparation of small quantities of caffeine, 100 grams of tea dust is extracted three or four times with boiling water. The extracts are combined, 10–15 grams of magnesia added, and the mixture taken to dryness. The residue is transferred to a Soxhlet apparatus and extracted with chloroform. On evaporating off the solvent a somewhat impure caffeine remains, which may be purified by crystallisation from water or by sublimation.

Caffeine crystallises from water with $1H_2O$, from alcohol anhydrous, in long silky needles. It loses water at 100°, and when anhydrous melts at 234°–235°. It sublimes readily at about 180°.

One part by weight of caffeine dissolves in 50 parts of alcohol (90 p.c.), 300 parts of ether, 9 parts of chloroform, or 80 parts of water at about 15°. It is very soluble in hot water (1 : 2), so that a hot concentrated aqueous solution on cooling sets to a solid crystalline mass. Its aqueous solution reacts neutral to litmus.

Caffeine is a weak base. Its salts are dissociated on evaporation of their aqueous solutions, and the free base may be obtained from acid solutions by shaking with chloroform. Certain double salts of caffeine are more stable; the mercurichloride $B{\cdot}HgCl_2$ forms colourless needles, m.p. 246°; the aurichloride $B{\cdot}HAuCl_4{\cdot}2H_2O$, m.p. 243° (248·5° anhydrous), on warming with water forms an amorphous yellow precipitate 'aurichlorcaffeine,' $C_8H_9(AuCl_2)O_2N_4$, m.p. 207° (Dunstan and Shepheard, Chem. Soc. Trans. 1893, 63, 199). For other caffeine salts, *see* Nicholson (Annalen, 62, 71) and Schmidt (*ibid.* 1883, 217, 283; and Ber. 1881, 14, 813).

Caffeine citrate, largely used in medicine, is obtained by evaporating an aqueous solution of equimolecular proportions of caffeine and citric acid to dryness. It forms a white powder easily soluble in water. Similar compounds are caffeine sodio salicylate and benzoate, which are also used medicinally.

Caffeine dissolves without colouration in concentrated sulphuric acid or cold concentrated nitric acid. If to the solution in sulphuric acid a crystal of potassium dichromate be added a green colouration is produced. Caffeine, in common with the other alkaloids of this group, gives the murexide reaction. If a small quantity of the base be moistened with concentrated hydrochloric acid a crystal of potassium chlorate added and the mixture evaporated to dryness, a reddish-brown residue is obtained, which, on moistening with dilute ammonia, gives a fine reddish-purple colouration.

Caffeine in dilute acid solution is precipitated by phosphomolybdic and phosphotungstic acids and by potassium bismuth iodide. With tannic acid a precipitate is formed, which is soluble in excess of the reagent. No precipitate is obtained with Mayer's reagent or iodine in potassium iodide.

Estimation. A very large number of processes have been suggested from time to time for the estimation of caffeine in tea, coffee, &c., and widely divergent results have been obtained with methods differing only in minor details. This appears to be due, in many cases, to unsatisfactory preliminary treatment of the material under investigation, the caffeine not being set free from the complex compounds (*e.g.* caffeine potassium chlorogenate) in which it occurs naturally.

Stahlschmidt's process, as modified by Allen, appears to give satisfactory results, and is carried out as follows:—

Six grams of finely-powdered tea are boiled under reflux with 500 c.c. of water for 6–8 hours. The decoction is then filtered and the residue washed with hot water until the volume of the filtrate and washings is 600 c.c. The solution is then heated nearly to boiling, 4 grams of lead acetate added, and the mixture boiled under reflux for 10 minutes. If the precipitate does not coagulate and settle down readily more lead acetate is added and the boiling repeated. The liquid is filtered, 500 c.c. evaporated to 40 c.c., and the caffeine extracted by shaking with chloroform. On evaporating off the solvent caffeine remains behind and is weighed. Tatlock and Thomson (Analyst, 1910, 35, 105) boil 2 grams of tea with 800 c.c. of water for one hour, filter and evaporate to small bulk. The solution is made alkaline with caustic soda, and the caffeine extracted by shaking with chloroform. This method is said to give results identical with those obtained by more complicated processes. Other methods in use are due to Paul and Cownley (Pharm. J. 1887, (iii.) 18, 417); Dvorkowitsch (Ber. 1891, 24, 1945); Keller (Ber. Deut. pharm. Ges. 1897, 7, 105); Power and Chesnut, J. Amer. Chem. Soc. 1919, 41, 1298; and for the estimation of caffeine in coffee a modification of the last method by Kats (*ibid.* 1902, 12, 250).

Theobromine $C_7H_8O_2N_4$ is the principal alkaloid found in cocoa beans in which it is present to the extent of about 1·5–3·0 p.c.

It also occurs in small quantities in kola nuts and leaves, in guarana, and in tea.

For the preparation of theobromine the cocoa beans (commercially the husks which contain about 0·5–1 p.c. of theobromine are employed) are freed from fat as far as possible, either by pressure or by extraction with light petroleum, the residue mixed with half its weight of slaked lime, and the mixture exhausted by boiling alcohol (80 p.c.). A considerable portion of the theobromine separates on cooling, and is filtered off. The filtrate is then acidified, the alcohol removed by distillation, the residual liquid filtered hot, and the filtrate neutralised. Theobromine separates as a yellowish-white crystalline powder. The product is purified by crystallisation from boiling water or alcohol, but best from hot glacial acetic acid. On the large scale purification is most readily achieved by dissolving in alkaline solution and reprecipitating by addition of acid.

Theobromine forms a white crystalline powder which sublimes unchanged at about 290°, and melts at 329°–330°. It is very sparingly soluble in water and most organic solvents. It is soluble in about 20 parts by weight of boiling glacial acetic acid, from which it separates almost completely on cooling. It behaves both as a weak base and an acid. The hydrochloride $B{\cdot}HCl,H_2O$ is crystalline, and is obtained by dissolving theobromine in hot concentrated hydrochloric acid and cooling the solution. On drying at 100° the free base is obtained. Theobromine dissolves in dilute nitric acid, and treated with silver nitrate slowly forms a compound $C_7H_8O_2N_4HNO_3AgNO_3$; if, however, theobromine be dissolved in dilute ammonia, silver nitrate added, and the solution then boiled, a white crystalline precipitate of silver theobromine $C_7H_7O_2N_4Ag{\cdot}1{\cdot}5H_2O$, which is almost insoluble in water, is obtained. Theobromine also forms a calcium salt, which can be crystallised from water.

Theobromine gives the murexide reaction, and is precipitated by the usual alkaloid precipitants, with the exception of Mayer's reagent.

The base finds employment in medicine chiefly as a diuretic, and for this purpose numerous soluble compounds of theobromine have been produced. Chief among these may be mentioned *Diuretin* (theobromine sodium salicylate), prepared by dissolving theobromine in the calculated equivalent amount of caustic soda solution, adding a molecular proportion of sodium salicylate and evaporating the solution to dryness *in vacuo*. *Uropherin* (theobromine lithium salicylate), *Uropherin*-B (theobromine lithium benzoate), and *Barutin* (barium theobromine sodium salicylate), &c., are compounds of the same type.

Estimation. The following process, due to Dekker (Rec. trav. chim. 1903, 22, 143), is generally employed for the estimation of theobromine in cocoa and similar products (*cf.* Débourdeaux, J. Pharm. Chim. 1917, 15, 306).

Ten grams of the powdered material is mixed with 5 grams of magnesia and boiled under reflux for one hour with 300 c.c. of water. The extract is filtered off and the extraction repeated for fifteen minutes with a fresh quantity of water. The filtrates are combined and evaporated to dryness on the water-bath. The residue is mixed with sand, the material transferred to a Soxhlet, and completely extracted with chloroform. On evaporation of the solvent theobromine remains, and is dried and weighed.

A method for the estimation of theobromine depends upon the formation of its periodide $C_7H_8O_2N_4.HI,I_4$. 0·1 gram of the sample with an equivalent quantity of sodium acetate, is dissolved in 2 c.c. of glacial acetic acid, 5 c.c. of hot water are added, and the solution is transferred to a 100 c.c. flask containing 50 c.c. of *N*/10-iodine solution; 20 c.c. of saturated sodium chloride solution and 2 c.c. of conc. hydrochloric acid are added, and after about 18 hours, the mixture is diluted to 100 c.c., filtered, and the excess of iodine titrated in an aliquot portion of the filtrate (Emery and Spencer, J. Ind. Eng. Chem. 1918, 10, 605).

Theophylline $C_7H_8O_2N_4$, isomeric with theobromine, is of much less importance than theobromine and caffeine. It was found in small quantity in tea by Kossel (Zeitsch. physiol. Chem. 1889, 13, 298), and was obtained from the mother liquors from which caffeine had crystallised out. The complete isolation was effected as follows:—

The mother liquors were diluted with water, acidified with dilute sulphuric acid, and filtered after standing for some time. The filtrate was made alkaline with ammonia, silver nitrate added, and the mixture allowed to stand 24 hours. The precipitate was collected and dissolved in warm dilute nitric acid. On cooling the silver compounds of adenine and hypoxanthine crystallised out. To the filtrate from these ammonia was added, and silver theophylline was precipitated. The precipitate was decomposed by sulphuretted hydrogen, and on concentrating the filtrate xanthine and finally theophylline crystallised out. Further quantities were obtained from the mother liquor by precipitation with mercuric nitrate and decomposition of the mercury precipitate.

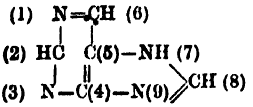
Theophylline crystallises with $1H_2O$ in thin plates or needles, m.p. 264°. It is sparingly soluble in cold, readily soluble in hot, water or alcohol. It behaves as a weak base, and yields salts with acids and derivatives with metals. It gives the murexide reaction, and in general is very similar to theobromine. It forms soluble double salts, of which *theosin* (sodium theophylline sodium acetate) has been successfully employed in medicine as a diuretic.

Adenine $C_5H_5N_5$ (6-aminopurine), as mentioned above, has been found in small quantities in tea. It crystallises with $3H_2O$, sublimes at 250°, and melts at 360°–365°. It is sparingly soluble in cold, readily soluble in hot, water. The picrolonate, m.p. 265°, crystallises from water. Adenine has been synthesised by Fischer (Ber. 1897, 30, 2226), and by Traube (Annalen, 1904, 331, 64).

Hypoxanthine $C_5H_4ON_4$ (6-oxypurine), needles, m.p. 150°, was found in small quantities in tea (Kossel, *l.c.*). Kruger, however (Zeitsch. physiol. Chem. 1895, 21, 274), suggests that it was produced from adenine by the method of isolation employed. It is a weak non-acid base and forms metallic derivatives. It is sparingly soluble in cold, rather more readily soluble in hot, water.

Xanthine $C_5H_4O_2N_4$ (2 : 6-dioxypurine), found to be present in tea (Kossel, *l.c.*), has similar properties to hypoxanthine.

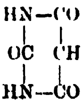
Constitution and Synthesis of Caffeine, Theobromine, and Theophylline. It has been mentioned previously that the alkaloids described above are closely related members of a group of bases derived from a parent substance purine, which has the constitution denoted by the formula shown (Fischer, Ber. 1898, 31, 2550).



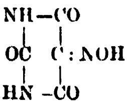
Caffeine, theobromine, and theophylline are, in fact, methylated derivatives of xanthine, which itself is 2 : 6-dioxypurine. Theobromine and theophylline are dimethyl xanthines, from which caffeine and trimethyl xanthine may be obtained by methylation. Thus caffeine is formed when silver theobromine is heated with methyl iodide (Strecker, Annalen, 1861, 118, 170), by heating potassium theobromine with methyl iodide at 100° (E. Schmidt, Annalen, 217, 295), or by the action of dimethyl sulphate upon theobromine in alkaline solution (Ultée, Chem. Wkbld. 1910, 7, 32). The silver compound of theophylline, on treatment with methyl iodide, similarly yields caffeine.

Our knowledge of the constitution of the purine derivatives is largely due to the work of Fischer. One of the most important members of the series is uric acid 2 : 6 : 8-trioxypurine, which occurs naturally in large quantities in guano and serves as a starting-point for the synthetic manufacture of the alkaloids under consideration.

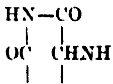
The synthesis of uric acid was accomplished by Fischer and Ach (Ber. 1895, 28, 2473). Malonic acid was condensed with urea to form malonyl carbamide (I.), which, by the action of nitrous acid, yields an *iso*nitroso derivative violuric acid (II.). On reduction uramil (III.) is obtained, which by the action of potassium cyanate is converted into *pseudo* uric acid (IV.). This, on treatment with hot dilute acid, gives uric acid (V.).



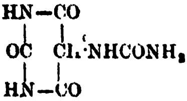
I.



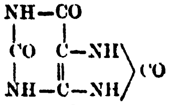
II.



III.

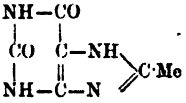


IV.

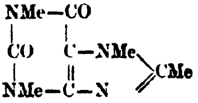


V.

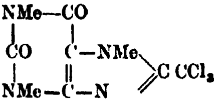
From uric acid caffeine is manufactured synthetically by the following reactions (Boehringer u. Söhne, D. R. P. 121224). Uric acid is converted by heating with acetic anhydride into 8-methylxanthine (VI.). This, on methylation in alkaline solution, gives 1 : 3 : 7 : 8-tetramethylxanthine (VII.). By the action of chlorine under specified conditions this is converted into a trichloro derivative of the constitution shown in formula (VIII.) which, on heating with dilute caustic potash solution, yields caffeine (IX.) Under slightly different conditions a tetrachlor derivative (X.) is obtained, which on treatment with potash yields theophylline (XI.).



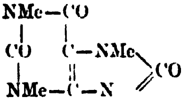
VI.



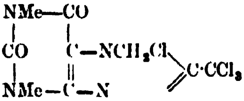
VII.



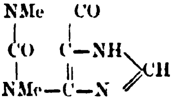
VIII.



IX.

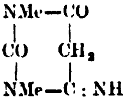


X.

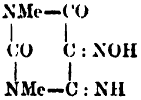


XI.

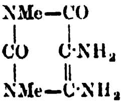
Theophylline (XI.) is also obtained commercially from dimethyl carbamide (Traube, Ber. 1900, 33, 3035). This is condensed with cyanacetic acid in presence of phosphoryl chloride and gives dimethylimino barbituric acid (XII.), which by the action of nitrous acid yields an oximino derivative (XIII.). On reduction a dimethyl-diamino-dioxy-pyrimidine (XIV.) is produced, which with formic acid yields a formyl derivative (XV.). This on heating loses water with formation of theophylline (XI.).



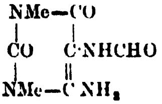
XII.



XIII.

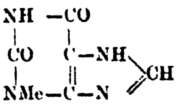


XIV.

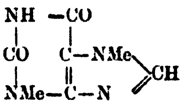


XV.

Theobromine has been synthesised by a series of reactions similar to those above. Starting with methyl carbamide 3-methylxanthine (XVI.) is obtained, which on methylation gives theobromine XVII.



XVI.



XVII.

Theobromine may also be obtained synthetically from uric acid. This is converted into 8-methylxanthine (VI.) as in the caffeine synthesis. The dry dipotassium salt of 8-methylxanthine is heated with methyl iodide when trimethyl xanthine (XVIII.) is obtained. Chlorination of this compound results in the formation of a trichloro derivative (XIX.), which on heating with dilute caustic potash solution yields theobromine (XVII.).

XIX.

A. J. E.

CAFFEONE (*Caffeol*). A brown oil, heavier than water, and slightly soluble in boiling water. Constitutes the aromatic principle of coffee. May be obtained by distilling freshly roasted coffee with water, and agitating the distillate with ether, which dissolves out the oil. According to Lehmann and Wilhelm (Chem. Zentr. 1898, ii. 372), it has no physiological action on a healthy man (*v.* COFFEE). According to Grafe (Monatsh. 1912, 33, 1389), it consists of about 50 p.c. of furfuryl alcohol and 38 p.c. of valeric and acetic acids, with phenolic substances of a creosote odour and a nitrogenous substance allied to pyridine to which the aroma is due. It appears to be formed by the distillation of the crude fibre of the bean.

CAFFETANNIC ACID *v.* TANNINS.

CAÏL-CEDRA, *Khaya senegalensis* (A. Juss.). A tree of the meliaceous order, growing on the banks of the Gambia and on the lowlands of the peninsula of Cape de Verde. Its bark is very bitter, and is much prized by the natives as a febrifuge, on which account it has been called the *cinchona of Senegal*. Its wood resembles American (Honduras, Cuba, Spanish) mahogany, is one of the so-called African mahoganies, and is used in making the finer kinds of furniture. The bark contains, amongst other substances, an extremely bitter, neutral resinous substance, called cail-cedrin, to which its active properties appear to be due.

Cail-cedrin is very sparingly soluble in water, but readily soluble in alcohol, ether, and chloroform. It is obtained by repeatedly exhausting the coarsely pulverised bark with boiling water; evaporating the filtered liquids over the water-bath to the consistence of a syrup; exhausting this extract with alcohol of 90 p.c.; precipitating the alcohol filtrate with basic lead acetate; filtering, distilling off the alcohol, and agitating the residue with chloroform, which dissolves nothing but the bitter principle. 1 kilogram of the bark yields about 8 milligrams of cailcedrin (Caventou, J. Pharm. [3] 16, 355; 33, 123).

CAÏNCETIN *v.* GLUCOSIDES.

CAINCIN *v.* GLUCOSIDES.

CAÏRNGORM *v* QUARTZ.

CAJEPUT or **CAJUPUT OIL** *v.* OILS, ESSENTIAL.

CAJEPUTOL *v.* CAMPHORS.

'CAL' *v.* TUNGSTEN.

CALABAR BEAN *v.* ORDEAL BEAN.

CALABAR FAT *v.* PHYSOSTIGMINE.

CALABARINE, CALABAROL, *v.* ORDEAL BEAN.

CALAFATITE. A double sulphate of aluminium and potash, so named after its discoverer, Calafat. Occurs near Almeria. Contains SO_4 34·77, Al_2O_3 37·98, K_2O 9·64, H_2O 17·61, sp.gr. 2·75. (*V.* ALUNITE.)

CALAMINE (*Galmei*, Ger.). Under this name two common zinc minerals—the carbonate (*v.* Smithsonite) and the hydrous silicate (*v.* Hemimorphite)—are frequently much confused. The Latin form *lapis calaminaris* is supposed to be a corruption of the old name *cadmia* (καδμία) used for zinc ores in general. The minerals in question often so closely resemble one another in external appearance that it is only possible to distinguish them by chemical tests; and it was not until 1803 that James Smithson definitely established the existence of, the two distinct species. The name calamine was then applied by some authors to the carbonate (sparry calamine), and by other authors to the hydrous silicate (electric calamine). In 1832 F. S. Beudant proposed the name smithsonite for the carbonate, restricting the name calamine to the hydrous silicate; but most unfortunately Brooke and Miller, in 1852, reversed these designations. Beudant has been followed by Dana and many other mineralogists, but in England the name calamine is unfortunately still much in use for the carbonate, and hemimorphite (G. A. Kenngott, 1853) for the hydrous silicate. The use of the latter name partly clears up the confusion, since it is descriptive of the very characteristic hemimorphic development of the crystals. The old name zinc spar is also descriptive of the carbonate. L. J. S.

CALAMUS. The Indian variety of *Acorus calamus* (Linn.); is used as a medicine in the Levant; the Turks candy it and employ it as a remedy against contagion. The volatile oil occasionally enters into the composition of aromatic vinegar. According to Thoms, *cicorin* $C_{36}H_{60}O_6$, in contact with ferments, splits up into sugar and oil of calamus

$$C_{36}H_{60}O_6 = C_6H_{12}O_6 + 3C_{10}H_{16}$$

(*cf.* von Soden and Rojahn, Chem. Zentr. 1901, i. 843; Thoms and Beckstroern, Ber. 1901, 34, 1021) (*v.* ACORUS CALAMUS).

CALAVERITE. A telluride of gold, $AuTe_2$, containing 40-43 p.c. of gold with 1-3 p.c. of silver. It was first found in Calaveras Co., California, and afterwards in considerable abundance in the Cripple Creek district in Colorado and at Kalgoorlie in Western Australia, where it is of importance as a telluride ore of gold. Sp.gr. 9·155-9·39. The small complex (monoclinic or triclinic) crystals from Colorado are tin-white in colour, tarnishing to bronze-yellow on exposure. The massive material from Kalgoorlie is pale bronze-yellow with bright metallic lustre; and with its sub-conchoidal fracture and absence of cleavage it much resembles iron-pyrites in appearance—in fact, before its value was recognised, the mineral had been thrown away on the waste heaps of the mines. L. J. S.

CALCIDINE. Calcium iodide.

CALCINOL. Calcium iodate.

CALCITE or **CALC-SPAR.** One of the dimorphous crystallised forms of calcium carbonate ($CaCO_3$). This rhombohedral form is less dense (sp.gr. 2·72) and less hard (H. 3) than the orthorhombic form aragonite (*q.v.*). It is also the more stable form: when aragonite is heated to low redness it passes into calcite, and paramorphs of calcite after aragonite are of frequent occurrence in nature. From an aqueous solution containing carbon dioxide, calcium carbonate crystallises as calcite at temperatures of 0°–[illegible]°, and as a mixture of calcite and aragonite at higher temperatures: the presence of various salts in the solution also favours the formation of aragonite. (For a summary of the literature on the crystallisation of calcium carbonate, *see* F. Vetter, Zeitsch. Kryst. 1910, xlviii. 45.) Calcite may be readily distinguished from aragonite by the possession of three perfect cleavages parallel to the faces of the primary rhombohedron, the angles between which are 74° 55′ and 105° 5′ (the plane angles on the rhomb-shaped faces are 78° and 102°). The mineral is readily scratched with a knife, and it effervesces briskly in contact with cold dilute acids.

With the exception of quartz, calcite is the commonest of minerals. It frequently occurs well crystallised and in a great variety of forms, the various forms of its crystals suggesting the trivial names 'dog-tooth-spar,' 'nail-head-spar,' 'paper-spar,' 'cannon-spar,' &c. As the essential constituent of the rocks limestone, marble, and chalk, it is of abundant occurrence. In these forms it finds extensive applications as building and ornamental stones, and in the manufacture of lime, mortar, and cement. The clear, transparent variety, known as Iceland-spar or doubly-refracting spar, is used in the construction of nicol prisms for optical polarising apparatus. Material suitable for this purpose is obtained almost exclusively from a quarry in basalt on the Reydar-fjördhr on the east coast of Iceland, but the supply is limited and variable.

A considerable quantity of clear material suitable for optical work has been found (1918) between Greycliff and Bigtimber in Montana, where it occurs in vertical veins in gneiss

L. J. S

CALCIUM. Symbol Ca. At. wt. 40·0. Lime, the oxide of calcium, has been employed in the preparation of mortar from very early times. Interesting accounts of the process of lime-burning are given by Dioscorides and Pliny. It was not, however, until 1756 that the difference between burnt and unburnt lime was explained by Black.

Calcium is universally found as carbonate $CaCO_3$ in the forms of *calcspar*, *marble*, and *limestone*, often in whole mountain ranges or immense coral reefs. *Dolomite* or *bitter spar*, the double carbonate of calcium and magnesium, constitutes the geological formation termed magnesian limestone. Calcium sulphate as *anhydrite* $CaSO_4$ or *selenite* (*gypsum*) $CaSO_4+2H_2O$, is also very plentiful. The phosphate united with the chloride or fluoride also occurs widely distributed, often as minute inclosures in crystals of the primary rocks, as the mineral *apatite*, whilst calcium is an important base in the greater number of natural silicates. The soluble matter carried away by rivers largely consists of the carbonate and sulphate of calcium, while sea-water contains, in addition to these, both phosphate and fluoride of calcium. The bones of animals consist largely of calcium phosphate, and the shells of molluscs of the carbonate. Calcium salts are never absent from plant tissues, concentrating mainly in the leaves.

Calcium also occurs in extra-terrestrial bodies, in the sun, meteorites, and many fixed stars.

Preparation of the metal.—Calcium was obtained as an impure metallic powder by Davy in 1808, by the electrolysis of the chloride, using mercury as negative electrode, and afterwards heating the amalgam thus formed until the mercury was volatilised. It was obtained as a metallic solid by Matthiessen in 1856 (Chem. Soc. Trans. 8, 28), by electrolysing a fused mixture of calcium and strontium chlorides in the proportion of two molecules to one with a little ammonium chloride, the whole being contained in a porcelain crucible. On passing the current, beads of metallic calcium separated at the negative pole and were ladled out. Moissan (Ann. Chim. Phys. [7] 18, 289) repeated the experiment, increasing the size of the apparatus, and obtained a metal possessing a yellowish colour.

Lies-Bodart and Gobin (Compt. rend. 47, 23) obtained calcium by heating the iodide with an equivalent of sodium in an iron crucible, the lid of which was screwed down. Moissan repeated the experiment several times, and states that the yield and purity vary greatly, the richest metal obtained containing from 83 p.c. to 93 p.c. calcium. The reaction proceeds best at a dull red heat, and is reversible if afterwards the temperature is raised to whiteness.

Frei obtained calcium in globules weighing 2·4 to 4 grams by the electrolysis of the chloride.

Another process consists in fusing 3 parts of calcium chloride with 4 parts of zinc and 1 part of sodium, thus forming an alloy of zinc and calcium, which, when heated in a gas-carbon crucible, decomposes, the zinc volatilising and a button of fused calcium remaining (Caron, Annalen, 115, 355).

Moissan obtained the alloy with facility, but was unable to separate the calcium from it.

Moissan (*l.c.*) points out that in all the above methods the difficulty is to free the calcium from the metal with which it has become associated in the preparation. He, however, finally succeeded in obtaining the pure metal by utilising the property, unknown before his researches, of molten sodium to dissolve calcium. For the preparation, he adopted a modification of the method of Lies-Bodart and Gobin. In an iron crucible of about 1 litre capacity he placed a mixture of 600 grams of coarsely crushed anhydrous calcium iodide, with 240 grams of sodium in pieces as large as nuts. The crucible was closed with a screw lid and maintained for 1 hour at a dull-red heat, then allowed to cool. The calcium, which is soluble in excess of sodium at a red heat, separates at the point of solidification and becomes practically insoluble. The metallic portion of the melt is cut up into medium-sized fragments and gradually introduced into absolute alcohol. The sodium dissolves, leaving the calcium in brilliant white crystals, 98·9 p.c. to 99·2 p.c. pure.

Ruff and Plato have succeeded in obtaining the metal in relatively large quantities by the electrolysis of fused calcium chloride by keeping the temperature of the cathode above the melting-point of calcium (U.S. Pat. 806006). Borchers and Stockhem, by electrolysing fused anhydrous calcium salts, keeping the temperature of the cathode below the melting-point of calcium, obtained the metal in a spongy state (U.S. Pat. 808066). By using a vertical cathode, which only just touches the surface of the fused calcium salt, the metal is deposited on this surface, and by mechanically raising the cathode an irregularly shaped rod of calcium, resembling a cabbage stalk, is formed, which itself forms the cathode (Eng. Pat. 20655; *cf.*

Johnson, J. Ind. Eng. Chem. 1910, 2, 466). The electrolyte consisting of a fused mixture of 10 parts of $CaCl_2$ with 17 parts of CaF_2, is contained in a cylindrical vessel of Acheson graphite. The containing vessel forms the anode, whilst the cathode is an iron ribbon which can be run up from below. The best deposits were obtained with a current density of 10 ampères per square cm. If the cathode current density is too high the metal does not adhere, whilst if the anode density is too low the eletrolyte is not all melted, and for proper control the anode and cathode surfaces should be definite for the conditions in use. Maldenhauer and Andersen (Zeitsch. Elektrochem. 19, 144) used a mixture of 85 p.c. $CaCl_2$ with 15 p.c. KCl and a current density of 60-110 ampères per square cm. Rods 9–18 mm. diameter were obtained, containing Ca 96·09–98·18, K 0·0–0·14, Fe 0·3–0·4, Si 0·40–0·70. The current yield varied from 65 to over 90 p.c.

Commercial calcium is usually coated with $CaCl_2$, which can be partly removed by absolute alcohol, and the remainder by re melting in an iron bomb. In this way a metal containing 99·44 p.c. Ca and 0·25 $Al_2O_3 + SiO_2$ is obtained.

Calcium is made commercially at Bitterfeld, Germany. The world's production is about 50 tons a year, and the price in normal times is about 12*s.* 6*d.* a pound. The metal melts at 810°, and has a density of 1·548. It may be turned into cylinders having a brilliant lustre tarnishing in air. It may be drawn into wire of 0·5 mm. diameter. Its electric conductivity is 16, that of silver being 100.

Calcium is a white metal approaching silver in colour. It can be cut with a knife or broken with a blow, and the fracture is crystalline. It scratches lead, but not calcite. It is less malleable than sodium or potassium. The crystals are of tabular habit and belong to the rhombohedral system.

Gently heated in air, it burns with incandescence, or if heated in a current of air at a dull-red heat it leaves a spongy mass which decomposes water, producing ammonia and calcium hydroxide. Calcium, therefore, fixes both nitrogen and oxygen. Calcium inflames when heated in oxygen to 300°, and the heat is so great that the lime formed is both fused and partly volatilised. Fluorine gas violently attacks calcium at the ordinary temperature. Chlorine, bromine, and iodine have no action until heated to 400° or above. Metallic calcium exists in both an active and an inactive form in its power of absorbing gases. Active calcium commences to absorb nitrogen at 300°, and has a maximum action at 440°. As the temperature increases the rate of combination slowly decreases, until at 800° it has ceased. The velocity of absorption is dependent on the presence of a layer of nitride. The inactive form commences to combine with nitrogen at 800°. The difference is not due to the existence of allotropes, but to the state of sub-division. The active variety is prepared by slowly cooling molten calcium. This variety produces a black nitride (Zeitsch. Elektrochem. 22, 15). Water is attacked at the ordinary temperature with the liberation of hydrogen; the action is slow, owing to the formation of a crust of calcium hydroxide; the addition of sugar hastens the action. Fuming nitric acid attacks it only slowly if free from lime; the action is hastened on dilution. Fuming sulphuric acid is immediately reduced in the cold to sulphur and sulphur dioxide. Hydrochloric and acetic acids attack calcium violently, with the liberation of hydrogen. At a red heat, calcium reduces the fluorides and chlorides of potassium and sodium, setting free the alkali metals; under the same conditions, the iodides are not attacked.

Calcium, although soluble in molten sodium, from which it separates in the crystalline state on solidification of the solvent, is not notably soluble in potassium. The only definite compound with mercury appears to be $CaHg_4$, m.p. 266° (decomp.). With magnesium, it furnishes an alloy which decomposes cold water. The freezing-point curve has a simple form, the single compound Ca_3Mg_4 being indicated by a maximum at 715°, whilst there are eutectic points at 514° and 446° and 18·7 and 78·7 p.c. of Ca respectively. The compound Ca_3Mg_4 is brittle, silvery in appearance, stable in air, and is only slowly acted on by water. Lead and calcium react together violently in the molten state; the freezing-point curve has maxima at 649° and 1105°, corresponding with the compounds $CaPb_3$ and Ca_2Pb respectively. Another compound CaPb is formed at 950°. All the alloys fall to a black powder in air. Copper and calcium form a single compound $CaCu_4$, melting at 933°, unstable in air. Silver and calcium form a complicated system of alloys (Zeitsch. Anorg. Chem. 70, 352. With zinc and nickel it forms brittle alloys. Tin, heated just above its point of fusion, combines with it with incandescence, forming a white crystalline alloy, containing 3·82 p.c. calcium.

Calcium hydride. CaH_2. Calcium does not unite with hydrogen at the ordinary temperatures. To prepare it, the metal cut into small pieces contained in several nickel boats, is placed in a glass tube sealed at one end. Hydrogen is fed in at a pressure of 4 to 5 cms. mercury, the tube being heated to redness; the temperature is kept sufficiently low to prevent union between the calcium and the nickel. So obtained, it is a fused white solid; sp.gr. 1·7. It may be heated to redness in air without change. Its characteristic reaction is the decomposition of water in the cold with the liberation of hydrogen. Calcium hydride shows a marked dissociation from 600°, reaching one atmosphere pressure below 800°. This cannot be a true dissociation pressure, as the hydride is readily formed by heating calcium in hydrogen at 830°. A second hydride also exists

$$Ca+H \rightarrow CaH+23{,}100 \text{ cal.}; \quad CaH+H \rightarrow CaH_2+22{,}000 \text{ cal.}$$

(Zeitsch. Electrochem. 20, 81). Brönsted calculates the heat of formation of calcium hydride from solution in hydrochloric acid: for CaH from liquid calcium and hydrogen about 21,000, and for CaH_2 from CaH and hydrogen 21,000. Gunts and Barrett found 46,200 cal. from solid calcium (Zeitsch. anorg. Chem. 82, 130). A mixture of $BaSO_4$ and CaH_2 ignited by a fuse similar to that used in thermite react vigorously according to the equation:

$$BaSO_4+CaH_2=BaS+4CaO+4H_2$$

(Ber. 46, 2264).

Calcium oxide, Lime. CaO. Anhydrous

Calcium oxide (quicklime) is obtained by heating to redness any salt of calcium containing a volatile acid, as the carbonate and nitrate. Calcium carbonate, when heated in a closed vessel, may be fused without decomposition, but when raised to a red heat under ordinary pressure it gives off its carbon dioxide, and becomes converted into lime $CaCO_3 = CaO + CO_2$

To obtain pure lime, Iceland spar or other forms of calcite, or the finest marble, may be employed, the ignition being performed in a crucible with perforated base so as to permit of the entrance of furnace gases, which carry away the carbon dioxide as fast as it is formed; otherwise the decomposition is incomplete, the carbonate undergoing no change in an atmosphere of carbon dioxide.

Lime is made by heating calcium carbonate to a temperature high enough to drive off the carbonic acid. The tension of dissociation of $CaCO_3$ is 27 mm. at 547° and 753 mm. at 812°; in practice, the temperature for burning lime is about 1000°. The raw material may be nearly pure calcium carbonate such as marble or chalk, or may contain so much clayey matter that the product is a cement of the Portland class rather than a lime. On this fact choice of the mode of burning in part depends, because if the lime is needed to be pure it must be burnt out of contact with solid fuel, whereas if it is a cement rather than a lime, the addition of silicious matter from the ash of the fuel may be actually an advantage. The chief uses of lime are for building, in agriculture and for chemical manufacture. For the first purpose an impure limestone, burnt in contact with solid fuel, is to be preferred, whereas the purest obtainable limestone, heated out of contact with fuel, yields the best material for chemical use. In practice these [illegible] rules are not always observed, partly from [illegible] validity and partly [illegible] economical to sacrifice the purity of the product rather than incur the expense in capital and fuel of kilns designed to burn limestone out of contact with solid fuel, but the knowledge of these is of value in deciding on the type of kiln to be adopted in any given case.

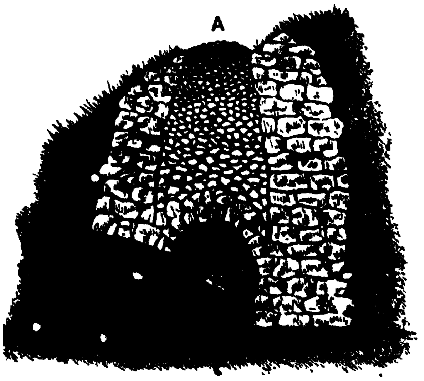

FIG. 1.

The simplest form of kiln is the flare kiln, shown in Fig. 1. The fuel (wood or peat) is burnt under an arch made of the material to be calcined, thus [illegible]duced is uncontaminated with ash [illegible] a device is, of course, not economical of fuel, but its simplicity and cheapness, and the fact that it can produce excellent lime, cause it to be still used to a considerable extent.

Another simple form is the common running kiln shown in Fig. 2. The limestone or chalk is loaded into the kiln with alternate layers of small coal or coke, and the product is from time to time drawn from an eye at the bottom of the kiln, fresh layers of raw material and fuel being added through the charging hole at the top of the kiln. Lime made in kiln of this class, of course, contains the whole of the ash of the fuel.

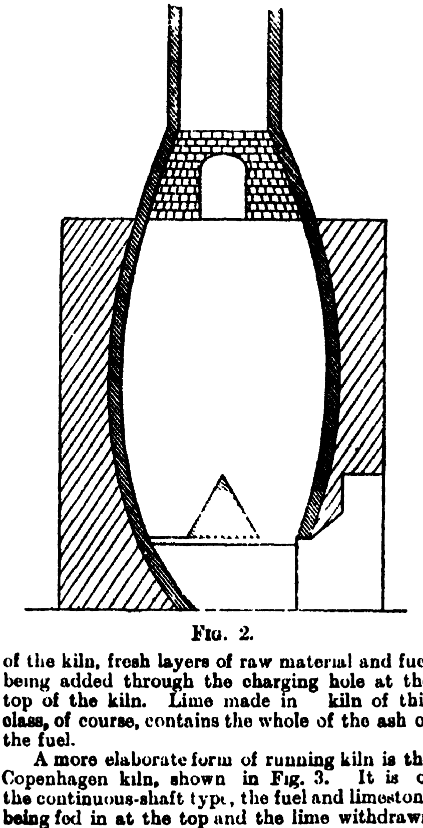

FIG. 2.

A more elaborate form of running kiln is the Copenhagen kiln, shown in Fig. 3. It is of the continuous-shaft type, the fuel and limestone being fed in at the top and the lime withdrawn at the bottom, but in addition a definite burning zone is established by feeding a portion of the fuel in at the side openings giving into the central part of the kiln. The heat can thus be controlled better than when all the fuel is distributed through the whole of the charge, with the result that consumption of fuel is decreased.

Another shaft kiln is the Ryan kiln, used in the Buxton district. Its construction is shown in Fig. 4. The fuel is fed in at the sides and the limestone at the top, so that the ash of the former is less inextricably mixed with the burnt lime. In consequence and because of the hardness and dense structure of Buxton limestone, a large part of the output is in lump practically uncontaminated with ash, so that the product can be picked and the lump of lime of high purity sold for chemical use, such as the manufacture of bleaching powder.

Lime can be burnt in a rotatory kiln, similar to those used for cement but worked at a lower temperature, but few such kilns are in use, the probable reason being that only small lime would be produced, and for many uses lump lime is preferred.

The Hoffmann kiln (Fig. 5) is used in places where labour is sufficiently cheap to allow of loading and unloading by hand being performed at a low cost; it has the advantage of being economical of fuel. The burning chamber consists of an endless tunnel, divided into compartments of approximately equal size by means of combustible dampers. Each chamber is [illegible] an opening in the [illegible] and discharging. [illegible] connecting with the [illegible] fuel of breeze and coal is introduced [illegible] holes in the arched roof. The kiln [illegible] scheme, fuel being charged [illegible] chamber, and air being allowed to [illegible] complete the calcination while [illegible] damper [illegible] production of these [illegible] large.

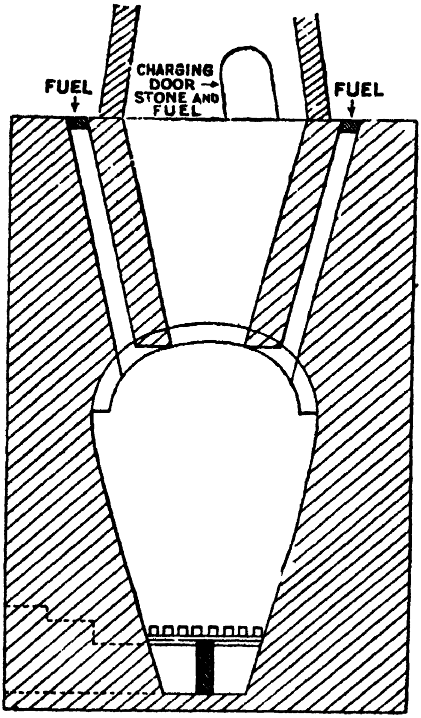

FIG. 3.—COPENHAGEN KILN.

Passing from those kilns [illegible] except the flare kiln, which allow at least some contact of the ash of the fuel with the lime, to gas fired kilns in which contact is wholly avoided, an intermediate type is the Rumford kiln, shown in Fig. 6.

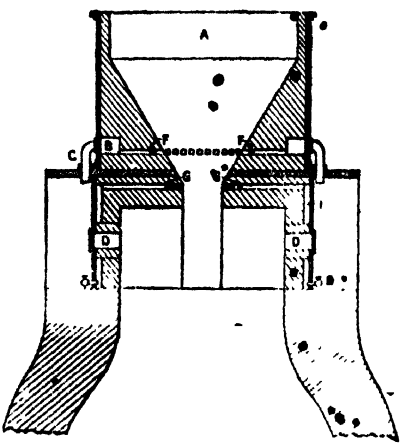

FIG. 4

The fuel is burnt on the hearth of a furnace beneath a bridge up through which the gaseous products of combustion pass to the shaft of the kiln and over which descends the burnt lime to openings at the side where it can be drawn.

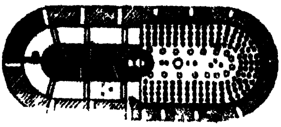

FIG. 5.

A gas-fired kiln proper is the Schmatolla kiln, shown in Fig. 7. Gas, from a producer at the side of the kiln, flows through ports in the walls of the kiln shaft, and there burns with a supply of secondary [illegible] heated [illegible] through the hot lime which has descended below the level [illegible] gas inl[illegible] of [illegible] fuel [illegible] ash [illegible] [illegible] almost entirely [illegible] material closely [illegible] The following an[illegible]

As mentioned above, the purest kinds are needed for chemical manufacture, and the less pure varieties which approach the nature of cement, are generally preferable for building. In the case of limes containing so much silica as does Chaux de Teil and so much silica and alumina as does Blue Lias lime, they may be regarded as hydraulic cements rather than limes proper. A rough trade distinction exists between 'fat' and 'poor' lime. The former is fairly pure and slakes rapidly and with a high rise of temperature; the latter, containing some combined silica and alumina, slakes slowly and relatively feebly. Both, when mixed with sand form mortars, but fat lime sets only [illegible] and subsequent absorption of [illegible] acid from the air, whereas the silicious constituents in poor lime will themselves set, to some small extent, in the manner of a cement. Pure lime, mixed with pure quartz sand, has no appreciable action on it at the ordinary temperature, but may act in slight degree on the more attackable silicious concomitants of common building sand; in any case, however, the action is trifling, and the setting of common mortar is practically unaffected by any such occurrence. In building, therefore, where an hydraulic cement is not necessary, a moderately silicious lime, which will set lightly *per se*, is preferable to the fat lime commonly employed. In this country, lime is almost always slaked on the spot and at the time where it is to be used. Abroad, the lime is usually slaked long before it is used, and is thus allowed to become completely hydrated. The easiest plan is to make a paste of lime and water (lime putty), and keep it in a pit until it is needed. In like manner, slightly hydraulic lime is slaked with a limited quantity of water and allowed to remain in silos until the lime itself is completely hydrated, whilst the cementitious silicates remain unaffected and ready to act as cement when the lime is put to use.

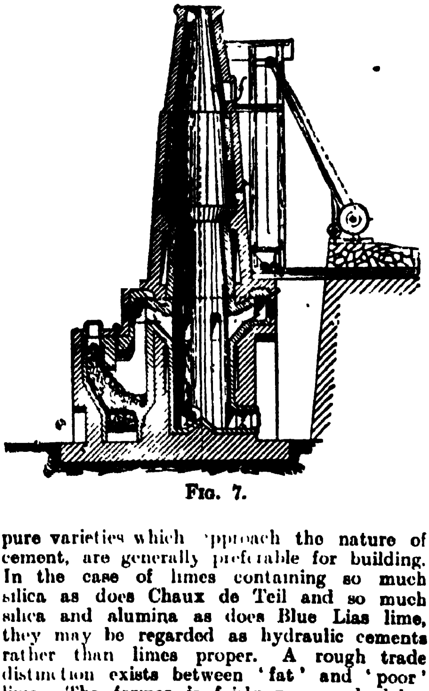

Fig. 7.

When a dolomitic limestone is burnt, it yields a lime of which the following is an example:—

	Per cent
Insoluble silicious matter	2·94
Alumina + ferric oxide ($Al_2O_3 + Fe_2O_3$)	1·90
Lime (CaO)	46·72
Magnesia (MgO)	32 60
Sulphuric anhydride (SO_3)	0·92
Carbonic anhydride (CO_2)	3·27
Combined water and loss	11·65
	100·00

Lime of this kind needs much care in slaking, as the hydration of the magnesia takes place slowly and may occur after the mortar is in place, and by expansion cause destruction of the work.

Although lime will not act on sand at the ordinary temperature, yet, like other alkaline bodies it attacks it readily at a moderate temperature. The manufacture of sand lime bricks is dependent on this fact. The bricks of sand, mixed with 5–10 p.c. of lime just hard enough to stick together, are exposed to steam at about 150°; at that temperature the lime acts on the sand, producing calcium silicates, which are cementitious, and suffice to cement the sand grains together into a brick of ample strength for ordinary building purposes. In places where sand is abundant and clay suitable for brick making is scarce, the process is of considerable use.

Pure calcium oxide forms white porous amorphous masses of sp.gr. 2·3 to 3·08, highly infusible, melting only in the highest temperature of the oxyhydrogen blowpipe flame or in the electric arc. In the ordinary oxyhydrogen flame it emits an intense light, which is much used for lantern projection.

Calcium oxide has been obtained by Brügelmann in minute cubic crystals of sp.gr. 3·251 by heating the nitrate in a porcelain flask (Pogg. Ann. [2] 2, 466; and [2] 4, 277).

A crystalline mass, found upon the lining of a continuous limekiln at Champigny after 28 months' continuous work, was also shown to consist of small cubical crystals of pure lime, of sp.gr. 3 32 (Levallois and Meunier, Compt. rend. 90, 1566).

There is evidence of the existence of two forms of calcium oxide. The oxide obtained by heating calcite at a low red heat is fine grained and porous. When heated at higher temperatures the refractive index increases and cubic crystalline calcium oxide is formed for which $N_D = 1·83$. The melting-point of CaO as determined by the Holborn Kurlbaum optical pyrometer is 2570° (J. Washington [illegible] 133, 315).

Amorphous lime takes up water [illegible] markable avidity, forming calcium hydroxide $Ca(OH)_2$, the combination being accompanied by a contraction in volume and evolution of heat. Owing to this property, it is used extensively in the laboratory and works as a drying agent. On exposure to air, the amorphous variety of lime rapidly absorbs water and carbon dioxide; anhydrous lime, however, only absorbs the gas when heated to near 415°. Comparative tests show that carbon dioxide penetrates to a depth of about 3 inches in 20 days. More water is taken up in summer than in winter, but the carbon dioxide absorption is about the same (Whetzel, J. Ind. Eng. Chem. 1917, 7. 287) Lime is readily soluble in dilute mineral acids. It also reacts with ethyl alcohol when heated in a sealed tube to 115° to 125°, giving a mixture of hydrate and ethylate of calcium.

Calcium hydroxide, or Hydrate of lime, $Ca(OH)_2$, is obtained by slaking fresh well-burnt quicklime with about a third of its weight of water. It forms a white amorphous powder of sp.gr. 2·078, sparingly soluble in water, and less so in hot than in cold water, as seen from the following table (Maben, Pharm. J. [3] 14, 505):—

Temperature	Parts of water required to dissolve one part CaO	Temperature	Parts of water required to dissolve one part CaO
0°	759	55°	1104
5°	764	60°	1136
10°	770	65°	1208
15°	779	70°	1235
20°	791	75°	1313
25°	831	80°	1362
30°	862	85°	1388
35°	909	90°	1579
40°	932	95°	1650
45°	985	99°	1650
50°	1019		

According to Lamy (Compt. rend. 86, 333), the solubility varies slightly with the method of preparation of the hydroxide.

The solution known as lime water has an alkaline reaction, and absorbs the carbon dioxide of the atmosphere, forming a pellicle of calcium carbonate. Lime water of definite strength for pharmaceutical purposes, is best prepared by using freshly ignited lime. In preparing lime water from ordinary lime, the first solutions should invariably be rejected, as they will contain nearly all the soluble salts of the alkalis and the baryta and strontia present in the lime as impurities. Milk of lime is an emulsion of calcium hydroxide suspended in less water than is required for its complete solution. Calcium hydroxide is much more soluble in solution of sugar than in pure water, due to the formation of soluble saccharates (for solubilities, *v.* Weisberg, Bull. Soc. chim. 21, 773).

Calcium hydroxide is precipitated by caustic potash or soda from strong solutions of the chloride; if a saturated solution of calcium chloride be employed, the whole becomes solid.

A solution evaporated over sulphuric acid in a vacuum deposits hexagonal prisms, according to Gay-Lussac. Crystals, however, which had separated on the surface of samples of hydraulic cement were found by Glinka to belong to the rhombic system in spite of their hexagonal appearance. A deposit of grey lamellæ, consisting of calcium hydroxide, was found by Luedecke in a Carré ice machine. Selivanov (J. Russ. Phys. Chem. Soc. 45, 252) finds that supersaturated solutions of hydrated calcium oxide contain 0·260 to 0·264 gram CaO per 100 c.c. These saturated solutions are extremely sensitive to heat. The monohydrate $Ca(OH)_2$ may be obtained in hexagonal plates by heating the solution. The cryohydrate gives on solidification transparent ice, but the solution formed when the ice melts deposits the sesqui-hydrate $2Ca(OH)_2,H_2O$ in elongated hexagonal or rhombic plates. The compound is very unstable.

Calcium hydroxide is an energetic base combining with acids to form salts and displacing ammonia from its compounds.

At a red heat, calcium hydroxide is decomposed, water being driven off and oxide remaining.

Slaked lime is used extensively in the preparation of mortars and cements (*v.* CEMENTS), for softening hard water, in the preparation of lyes and defecation of sugar, and for agricultural purposes. It has been noted that as regards the application of lime to the soil, only a small proportion reappears as carbonate, the remainder being adsorbed by the soil constituents.

Calcium dioxide CaO_2 was first prepared by Thenard by the action of excess of hydrogen peroxide upon lime-water, when microscopic quadratic plates of the composition $CaO_2.8H_2O$, sparingly soluble in water and insoluble in alcohol, were precipitated. According to Conroy (Chem. Soc. Trans. 1873, 810), the peroxide is most conveniently prepared by adding lime-water in considerable excess to an aqueous solution of sodium peroxide acidulated with nitric acid. It is also obtained, as a finely divided white precipitate on adding a neutral or alkaline solution of sodium peroxide to a solution of a calcium salt. The crystals are isomorphous with those of hydrated barium peroxide. On exposure to air they effloresce, and when heated to 130° are converted into the anhydrous peroxide. On increasing the heat, half the oxygen is driven off, leaving a residue of pure lime. CaO_2 in the anhydrous form (Riesenfeld and Nottebohm, Zeitsch. anorg. Chem. 89, 405) separates from very concentrated solutions near 0°, and above 40° even from very dilute solutions. The octahydrate is obtained from very dilute solutions at the ordinary temperature. The octahydrate is dehydrated at 100° There is no appreciable decomposition below 200°. Up to 273° decomposition is slow, but then becomes very rapid. Finely divided CaO_2 decomposes explosively when heated rapidly to 275°. The dissociation pressure at 255° is more than 190 atmospheres.

Calcium chloride $CaCl_2$ is found in the water of nearly all springs and rivers, and is consequently a constituent of the saline matter dissolved in sea-water. This salt also forms the chief saline constituent of an exudation occurring on the face of the old red sandstone rocks at Guy's Cliff, in Warwickshire, occurring to the extent of 27·15 p.c. (Spiller, Chem. Soc. Trans. 1876, 1, 154). Calcium chloride likewise occurs, together with magnesium chloride and alkaline chlorides in the *tachydrite* and *carnallite* of the Stassfurt deposits, *tachydrite* containing 21 p.c. $CaCl_2$ and 36 p.c. $MgCl_2$, while *carnallite* contains 3 p.c. $CaCl_2$, and 31 p.c. $MgCl_2$.

Calcium chloride may be obtained by passing chlorine over the red-hot oxide, or by dissolving lime, chalk, or marble in hydrochloric acid and evaporating. If it is necessary to obtain the salt pure, chlorine water may be added to the solution in hydrochloric acid in order to oxidise any iron present, which may then be precipitated by the addition of milk of lime, and filtered off. The slightly alkaline filtrate is then acidified with hydrochloric acid and evaporated to the crystallising point.

Calcium chloride is obtained in large quantities as a by-product in many manufacturing processes, notably in the preparation of potassium chlorate and in the manufacture of sodium carbonate by the ammonia-soda process; it may be obtained in the pure state from these crude products by the method just indicated. Many attempts have been made to utilise this waste calcium chloride. Richardson (E. P. 10418) treats the purified crude solution with ammonium sulphate in the proportion required to convert all the chloride into sulphate; the calcium sulphate could then be filtered off, and ammonium chloride recovered by crystallisation. Pelouze (Compt. rend. 52, 1267) was the first to point out that calcium chloride mixed with sand to prevent fusion is almost completely decomposed when heated to redness and treated with steam, the chlorine being evolved as hydrochloric acid. The process was patented by Solvay, and the method applied to the waste calcium chloride liquors, but the condensed hydrochloric acid obtained is dilute and does not pay for the coal consumed in the operation. Lunge considers that so long as hydrochloric acid is so cheap, no possible method can be found to utilise the chlorine in the waste liquors at a profit.

Saturated solutions of calcium chloride deposit the hydrated salt in large hexagonal prisms terminated by pyramids, of the composition $CaCl_2,6H_2O$. The crystals melt at 29° in their water of crystallisation and deliquesce rapidly in the air, forming a viscous fluid, formerly termed *oleum calcis*. Heated below 200°, or in a vacuum over sulphuric acid, the crystals lose four molecules of water. The remaining two molecules can only be expelled above 200°. According to Weber (Ber. 15, 2316), the salt dried at 180°-200° is practically anhydrous, containing only 0·2 p.c. of water. Besides the two hydrates above described, Lescœur (Compt. rend. 92, 1158), from determinations of maximum tensions of solutions, shows the probable existence of two others $CaCl_2,4H_2O$ and $CaCl_2,H_2O$. The tetrahydrate, however, can only exist below 129°. Milikan (Zeitsch. physikal. Chem. 92, 496) has examined the equilibrium conditions in the system $CaCl_2-HCl-H_2O$. The solution containing 44·5 p.c. $CaCl_2$ and 3·3 p.c. HCl is in equilibrium with the solid phases $CaCl_2,6H_2O$ and $CaCl_2,4H_2O$ and the solution containing 28·48 p.c. $CaCl_2$ and 21·40 p.c. HCl with the solid phases $CaCl_2,4H_2O$ and $CaCl_2,2H_2O$.

Anhydrous calcium chloride is a white porous mass, which fuses at a red heat or, according to Le Chatelier (Bull. Soc. chim. 47, 300), at 755°. On cooling, the salt solidifies to a translucent mass of crystals of sp.gr. 2·205. A slight decomposition into oxide and carbonate occurs when the fusion is performed in air. On this account, the porous chloride obtained by drying the crystals at 260° is better adapted for desiccating purposes, especially for the absorption of water in organic analysis. McPherson (J. Amer. Chem. Soc. 1917, 39, 1317) has shown that granular calcium chloride when absolutely dry will remove every trace of moisture from a gas passed over a sufficiently long column of it. If the fused mass is exposed to the sun's rays, it becomes phosphorescent in the dark, and was formerly called *Homberg's phosphorus*, after the discoverer of the fact in 1693.

Anhydrous calcium chloride is highly deliquescent. 100 parts of the powder exposed to an atmosphere saturated with aqueous vapour absorb 124 parts of water in 96 days. According to Kremers (Pogg. Ann. 103, 57; 104, 133; J. 1858, 40), the following quantities of water are required to dissolve one part by weight of the anhydrous salt:—

At 10·2°	20°	40°	60°
1·58	1·35	0·83	0·72

In the following table, drawn up by the same author, are shown the specific gravities of solutions of varying strengths:—

Quantities in 100 parts water	Sp.gr. of solutions at 19·5° (water at 19·5°=1)
6·97	1·0545
12·58	1·0954
23·33	1·1681
36·33	1·2469
50·67	1·3234
62·90	1·3806

According to Engel (Bull. Soc. chim. 47, 318), 100 parts of water at 0° dissolve 60·3 parts $CaCl_2$, forming a solution of sp.gr. 1·367.

A solution of 50 parts anhydrous $CaCl_2$ in 100 parts water, boils at 112°, one containing 200 p.c. boils at 158°, and a 325 p.c. solution boils at 180°.

According to Lefebvre (Compt. rend. 70, 684) a supersaturated solution of calcium chloride is formed by dissolving 350–400 grams of the crystallised salt in 50 c.c. warm water or 200 grams of the anhydrous salt in 250 c.c. water; it may be shaken after cooling without crystallisation, but solidifies on contact with a crystal of the salt. If cooled to 5·8°, this solution begins to crystallise, the temperature rising to 28°–29°. A solution containing 55 p.c. $CaCl_2$ deposits at about 15° large plates of the tetrahydrate $CaCl_2,4H_2O$, which do not induce the crystallisation of the supernatant liquor. This solution, in passing from liquid to solid state, undergoes at 70° a contraction 0·0832 of its volume.

The crystallised chloride $CaCl_2,6H_2O$ also deliquesces rapidly, and dissolves in half its weight of water at 0°, in one-fourth its weight at 16°, and in all proportions of hot water. In dissolving it absorbs heat, while the anhydrous chloride dissolves with evolution of heat. A mixture of 1·44 parts crystallised chloride with 1 part of snow produces a cold of −54·9°, more than sufficient to freeze mercury.

Both the anhydrous and hydrated chloride dissolve readily in alcohol, 10 parts at 80° dissolving 6 parts anhydrous $CaCl_2$; on evaporation in a vacuum at winter temperature, rectangular plates of $2CaCl_2,7C_2H_6O$ are deposited.

Anhydrous calcium chloride absorbs ammonia gas, forming the compound $CaCl_2,8NH_3$ as a white powder, which, on exposure to air, solution in water, or on heating, is decomposed. Thrown into chlorine gas, the compound takes fire. Calcium and barium chlorides form the double salt $CaCl_2,BaCl_2$ (m.p. 631°), but no mixed crystals. Calcium and strontium chlorides form a continuous series of mixed crystals with a minimum melting-point at 658° and 60 mol. p.c. $CaCl_2$ (Jahr. Min. 15).

Calcium oxychloride. When calcium chloride solution is boiled with slaked lime, and the liquid filtered, white needle-shaped crystals of calcium oxychloride separate out on cooling of the composition $ClCa{\cdot}O{\cdot}Ca(OH),7H_2O$ or $3CaO{\cdot}CaCl_2,15H_2O$ (Grimshaw, Chem. News, 30, 280). The salt is stable out of contact with air, loses part of its water of crystallisation over sulphuric acid or caustic lime, and absorbs carbon dioxide from the atmosphere. It is decomposed by water or alcohol.

According to André (Compt. rend. 92, 1452), the composition of the salt is

$$CaCl_2{\cdot}3CaO,16H_2O$$

and, on drying in a vacuum, it becomes converted into $CaCl_2{\cdot}3CaO,3H_2O$.

When calcium chloride is fused at a bright-red heat in a current of moist air, it is gradually converted to an oxychloride of the composition $CaCl_2{\cdot}CaO$, and eventually to oxide (Gorgeu, Compt. rend. 99, 256).

Calcium hypochlorite v. BLEACHING POWDER.

Calcium chlorate $Ca(ClO_3)_2$ is produced when chlorine is passed into hot milk of lime, but is difficult to separate from the chloride simultaneously formed. This is the first step in the manufacture of potassium chlorate, and the reaction is supposed to be as follows:—

$$6Ca(OH)_2+6Cl_2=Ca(ClO_3)_2+5CaCl_2+6H_2O.$$

According to Lunge (J. Soc. Chem. Ind. 1885, 722), the reaction really takes place in several stages, calcium hypochlorite and hypochlorous acid being first formed and mutually reacting with production of calcium chlorate:

(1) $Ca(OCl)_2+4Cl+2H_2O=CaCl_2+4HClO.$
(2) $2Ca(OCl)_2+4HClO=CaCl_2+Ca(ClO_3)_2+4Cl+2H_2O.$

The free chlorine serves only as carrier of the oxygen of two molecules calcium hypochlorite to a third molecule of the hypochlorite which is oxidised to chlorate. Lunge's experiments show that the best mode of converting hypochlorite into chlorate is to raise the temperature of the solution, slight excess chlorine being at the same time present. The heat produced by the reaction on the large scale is sufficient.

Calcium chlorate can best be prepared by the electrolysis of a 10 p.c. solution of calcium chloride. The density of the current should be 10 amperes per square decimeter at the anode and double at the cathode; temperature 50° (Zeitsch Elektrochem. 4, 464).

It may also be prepared by precipitating potassium chlorate with calcium silicofluoride. It crystallises in deliquescent rhomboidal plates, very soluble in water and alcohol; the crystals contain 16·5 p.c. water, melt when warmed, and decompose on further heating.

Calcium perchlorate $Ca(ClO_4)_2$ may be obtained by saturating perchloric acid with caustic lime. It is extremely deliquescent and crystallises in prisms soluble in alcohol.

Calcium bromide $CaBr_2$ (m.p. 730°) is formed by burning calcium in bromine vapour, or by dissolving lime or calcium carbonate in hydrobromic acid and evaporating. The silky needles thus obtained are hydrated, but may be converted to the anhydrous salt by heating. Calcium bromide much resembles the chloride in properties, being deliquescent, and very soluble in alcohol. NaBr and $CaBr_2$ solidify to form two series of solid solutions with a eutectic point at 513°, and on further cooling a reaction takes place at 469°, a compound $NaBr,2CaBr_2$ being formed. KBr forms a single compound $KBrCaBr_2$, represented by a maximum on the freezing-point curve at 637°. There are eutectic points at 544° and 563° respectively (Zeitsch. anorg. Chem. 90, 137).

Calcium iodide CaI_2 may also be prepared by combustion of calcium in iodine vapour, or by solution of lime or the carbonate in hydriodic acid, evaporating and fusing the residue in a closed vessel. Heated in contact with air, it fuses below a red heat, and is decomposed with liberation of iodine vapours and formation of lime.

Liebig (Annalen, 121, 222) recommends decomposition of CaI_2 by K_2SO_4 for preparation of iodide of potassium. To prepare the calcium iodide, 1 oz. of amorphous phosphorus is drenched with 30 oz. hot water, and finely pulverised iodine gradually added with constant stirring as long as it dissolves without colour (quantity thus dissolved being 13½ oz.). The colourless liquid is then decanted from the slight deposit, and made slightly alkaline with milk of lime (8 oz. lime being required); the solution is afterwards strained, and residue of phosphate, phosphite, and hydrate of calcium washed. The solution then contains the calcium iodide, which may, if necessary, be obtained by evaporation in the form of hydrate in deliquescent needles.

A double iodide of calcium and silver of the composition $CaI_2{\cdot}2AgI,6H_2O$ has been prepared by Simpson (Proc. Roy. Soc. 27, 120) by saturating a hot concentrated solution of CaI_2 with moist silver iodide. It crystallises on cooling in long white needles, decomposed by water. The basic salts formed by the alkaline earth metal haloids have been studied by the equilibrium relations in the ternary system between the haloids, the corresponding hydroxides and water. The basic salt CaI_2 $3CaO,16H_2O$ is stable at 25° in contact with solutions containing 28·44 p.c. to 66·68 p.c. CaI_2 (Zeitsch. physikal. Chem. 1917, 92, 59).

Calcium iodate $Ca(IO_3)_2$ is obtained by crystallising mixed solutions of potassium iodate and calcium chloride. The hydrated salt forms four-sided prisms which effloresce in the air, and become anhydrous when heated to 200°. From a solution acidulated with nitric acid, it separates in trimetric crystals. The crystals are soluble in 454 parts water at 18°, and in 102 parts of boiling water, but are insoluble in alcohol. The anhydrous salt, gently heated in a porcelain retort, evolves 14·78 p.c. of oxygen, and 54·07 of iodine, leaving 31·14 p.c. of a residue rich in pentabasic periodate of calcium. Heated more strongly, it evolves more oxygen and iodine, and leaves 20·35 p.c. of a mixture of pentabasic periodate and free lime. Calcium iodate detonates violently when heated on charcoal.

Sonstadt proposes (Eng. Pat. 6304, 1884) to use calcium iodate as an antiseptic.

Periodates of calcium. When the sodium salt NaH_4IO_6 is decomposed by calcium nitrate, a crystalline white precipitate of dicalcium periodate CaH_3IO_6 or $2CaO.3H_2O.I_2O_7$ is obtained. When this salt is heated, water, oxygen, and iodine are given off and pentacalcium periodate $Ca_5I_2O_{12}$ remains (Langlois).

Calcium fluoride CaF_2 is found widely distributed in nature and is known as *fluor-spar.* It is the only common mineral in which fluorine forms one of the principal constituents. It occurs both massive and in beautiful crystals, generally cubes or forms in combination with the cube. It is a common vein mineral, occurring usually in association with metallic ores, barytes, calcite, &c. It presents a variety of colours, sometimes shading into one another as in the beautiful 'Blue John' of Derbyshire. All the coloured specimens lose their colour on heating, green specimens being the most difficult to decolourise completely. Thermo-luminescence is very marked in all naturally coloured crystals, a violet light being emitted in most cases, with decrepitation Free fluorine has been shown to exist in a dark violet fluor spar from Quincié, Dept. du Rhône. Crystallised colourless fluor spar can be coloured deep blue by the β- and γ-rays of radium, and then shows on gentle warming a beautiful green thermo-luminescence which fades and changes into the pale violet light characteristic of all fluor spars. Debierne found that certain dark violet fluor spars smell of ozone. When heated they lose their colour and thermo-luminescence and also yield helium in variable but small quantity. On exposure to radium rays the violet colour was restored. It is also a constituent in small quantities of many plant ashes, of bones, and of the enamel of teeth. When calcium fluoride, obtained by precipitating any soluble calcium salt with fluoride of sodium or potassium, is heated with water slightly acidified with hydrochloric acid, the precipitate is found to consist of microscopic octahedrons.

Calcium fluoride is soluble in about 2000 parts of water at 15°, and is slightly more soluble in water containing carbon dioxide. It dissolves in hydrofluoric acid and in strong hydrochloric acid, and is precipitated in the gelatinous form by ammonia. It is fusible at 902°, and is used as a flux in many metallurgical operations, especially in the reduction of aluminium. It is decomposed at a high temperature by water vapour into lime and hydrofluoric acid. Fusion with alkaline carbonates or hydroxides yields carbonate or oxide of calcium and alkaline fluorides. Strong sulphuric acid, on gently warming, decomposes it, forming calcium sulphate and liberating hydrofluoric acid. At a red heat it is also decomposed by chlorine. After being heated fluor spar phosphoresces in the dark. There is a considerable industry carried on in fluor-spar districts in the carving of ornamental vases and other articles, the brilliantly coloured varieties being especially in demand.

Calcium carbide CaC_2. Wöhler (Ann. Chim. Phys. 125, 120) showed that by the action of carbon on a molten alloy of zinc and calcium, a black mass is obtained, which on contact with cold water liberates various gases. Winkler indicated the reduction of the alkaline earths by magnesium (Ber. 22, 120). Maquenne, in 1892, prepared calcium carbide as an impure amorphous black powder, and Travers obtained it by heating together calcium chloride, sodium, and carbon. It was not, however, until the advent of the electric furnace that it became possible to manufacture a pure carbide suitable for the preparation of acetylene. Moissan (Compt. rend. 138, 243) used a mixture of lime 120 grams, sugar carbon 70 grams, which was heated in the crucible of an electric furnace for 25 minutes with a current of 350 amperes and 70 volts. At the temperature of liquefaction of the lime, this reaction occurs: $CaO+3C=CaC_2+CO$. Pure calcium carbide is crystalline, colourless, and transparent, but the commercial variety, discoloured by iron, is usually brownish-red.

Its characteristic reaction is the decomposition of water in the cold, with the liberation of acetylene and the formation of calcium hydroxide (*v.* Acetylene).

One of the most interesting developments of the manufacture is the production of 'nitrolin,' calcium cyanamide $Ca(CN)_2$, from calcium carbide for manurial purposes. The nitrogen required is obtained from the air by the Linde Company's plant, which produces both nitrogen and oxygen. The union of powdered calcium and nitrogen takes place with the evolution of heat, hence the temperature has to be maintained between 800°-1000°, as at higher temperatures the calcium cyanamide decomposes. The absorption occupies 30 to 40 hours, and the product is a cokelike material which is ground to powder before being placed on the market (*v.* NITROGEN, UTILISATION OF ATMOSPHERIC).

Calcium Carbide, Manufacture of. The commercial manufacture of calcium carbide is credited to Willson in America and Héroult in Europe. It was started in the early eighties of last century, and by progressive development acquired the distinction of being the largest consumer of energy in the electric furnace industry. This continued extension resulted in a better design and increased size of furnace, together with the necessary equipment for handling large quantities of raw materials and for preparing the carbide for the market.

The chief factors which have to be considered in the choice of a site for a carbide factory are supplies of raw material consisting of limestone and coke, or anthracite, and an abundant source of cheap electric power. Large works have consequently been established in places where a practically unlimited supply of water power is available. Hence, most progress in the industry has been witnessed in Norway, where—excepting coal—other demands are amply satisfied.

The raw materials used in the manufacture of calcium carbide should be as pure as possible. Special attention should be paid to obtaining them free from phosphorus, sulphur, and magnesia; silica, iron, and alumina should be present only in small quantities (*v.* Witherspoon, J. Soc. Chem. Ind. 1913, 113).

Phosphorus occurs in limestone as calcium phosphate, and is reduced at the temperature of the furnace, and in the presence of carbon, to calcium phosphide, which, when brought into contact with water, evolves phosphoretted hydrogen. This gas mixes with the acetylene, and when the burners are lighted, causes a haze of phosphorus pentoxide, which is very objectionable. So carefully, however, are the raw materials selected that all commercial carbides are practically free from phosphorus, the average content in acetylene being less than 0·002 p.c. by volume. (For a method of examining commercial carbide for calcium phosphide based on that of Lunge and Cedercreutz, *see* Dennis and O'Brien, J. Ind. Eng. Chem. 1912, 4, 834.)

Sulphur, unless present with considerable amounts of alumina, has little influence on the resulting carbide. Calcium sulphide, formed in the furnace by the reduction of calcium sulphate, does not decompose in the production of acetylene, but in the presence of alumina, aluminium sulphide may be formed, which yields hydrogen sulphide when brought in contact with water. Very little trouble, however, is experienced with sulphur, as the lime and coal used in the manufacture rarely contain a prohibitive quantity.

Magnesia has the peculiar property of interfering with the formation of calcium carbide in the furnace. If more than one p.c. of magnesia be present in the lime and coal, the electrical energy required becomes noticeably so much greater, that raw materials containing such impurity are considered unfit for use. A flux of fluor spar has been used to counteract this effect, but with little success. Magnesia mixed with carbon and heated in the electric furnace does not form a carbide and is highly infusible; under similar conditions barium and strontium oxides form carbides with ease.

Silica, iron oxides, and alumina form silicates, aluminates, and ferro-silicon, which reduce the purity of the carbide and the output of the furnace.

The preparation of the raw materials in carbide manufacture is of much importance, owing to the high temperatures employed in the reduction of the lime. Water in the free state in the coal, or combined as hydroxide in the lime, should be entirely eliminated, its presence reducing the output of the furnace in very serious proportions. The coal is, therefore, thoroughly dried at a low heat in some convenient type of oven or rotary dryer. The limestone, consisting of calcium carbonate, requires a high temperature to drive off the carbon dioxide, and the operation is usually conducted in some type of lime kiln fired by coal or gas.—the Alby works at Odda used producer gas-fired kilns—or the limestone may be burnt in specially constructed chambers, using gases evolved from the manufacture of the carbide. The ingredients were formerly ground fine to ensure a uniform product, but this is now found unneccessary, and the limestone is reduced by crushers to 1–2 inch size, and the coal to ¼–½ inch mesh. They are then weighed and mixed roughly in about theoretical proportions required by the equation $CaO+3C=CaC_2+CO$, or approximately 100 parts by weight of lime to 65 parts by weight of the carbon contents of the coal.

The types of electric furnace which have been used in the manufacture of carbide may be roughly divided into the intermittent and continuous forms. In the first and earlier type the carbide was allowed to solidify in the crucible, and was hence known as the ingot furnace. This, or the pot furnace, of which Borcher's is the simplest type, consists of a large iron crucible lined on the bottom with a layer of carbon, this forming one terminal of the electrical circuit. The other terminal is formed of a carbon rod which is suspended vertically in the crucible, and provided with some form of mechanical hoist to give a vertical motion to the rod and holder, which together may weigh as much as one ton. To start the furnace, the moving electrode is lowered, until on passing a current an arc is formed with the carbon bottom. The mixture of lime and coal previously prepared and stored in a bin above the furnace is fed in around the arc until entirely covered. A current of 2000 ampères and 75 volts was used in the early Willson furnace. The arc being started, interaction soon commences between the lime and the carbon, producing a pool of carbide, which gradually deepens, necessitating frequent lifting of the electrode to keep the current constant. The process is continued until the furnace is full, when the crucible is wheeled out and an empty one substituted. When sufficiently cool, the contents are dumped on to a grating to separate the unconverted mixture, and the ingot removed to a clearing room, where the crust is removed and the block of carbide broken up.

In practice four tons of raw material were handled to produce one ton of carbide, and the process was also unsatisfactory on account of the varying quality of the product, which, though pure carbide in the centre, was only a fritted mixture of lime and coke on the crust. In order to improve both the quality and output the American makers adopted a rotating furnace, of which the Horry furnace is the best-known type. This is built in the form of a spool with wide flanges fastened to the drum, producing three sides of a square in cross-section The fourth side is formed by a removable plate, clamped across the flanges. Two electrodes, suspended vertically, form an arc in the furnace, a single-phase current of 4000 ampères and 75–80 volts being employed. The electrodes are fixed, but the furnace is made to rotate at a peripheral speed of about 6 inches an hour. In operating the furnace a layer of broken coke is placed under the electrodes, the arc is sprung, and the charge of lime and coal fed in until the electrodes are covered. As the carbide is formed the rotation brings the electrodes into contact with a fresh charge, while the fluid carbide slowly solidifies to an ingot shape, and is detached in large blocks at the rear end of the furnace. In a modification the fused carbide is made to pass through a die which separates the fused carbide from the unreduced mixture, and cools the carbide sufficiently to determine its shape, whence it is withdrawn progressively and detached in the form of a pig devoid of crust.

In Europe the early pot furnace was soon changed to a tapping furnace, in which the carbide was heated until sufficiently fluid to be run into cast-iron moulds. The earlier furnaces were similar in form to the pot furnace, with one suspended electrode, but it was difficult to get the desired temperature and fluidity. Two or more electrodes were then introduced, and the progress in electric furnace design for high temperatures followed largely its development in the carbide industry. The furnace, as constructed by Alby in Sweden, used a single-phase alternating current of 1500 kilowatts, and produced 50–60 tons of carbide per week.

The electrodes, which in the early days of the industry were obtainable only in comparatively small sizes, could later be purchased up to 22 inches square and more, and were also used by some manufacturers as an assembly of smaller ones. The working temperature in the furnace attained 3000° C., though the casting temperature may be somewhat lower. To withstand such a great heat the furnace, which is constructed of steel framework and plates, has to be lined with some refractory material, preferably as inert as possible towards the elements of the charge, and, where the heat is most intense, water cooling tubes may be built into the lining. It is necessary also to insulate the electrodes to prevent short circuiting through the furnace construction, as also to make a gas tight joint where the closed form of furnace is employed.

Considerable progress has been made in attaining size and efficiency by the use of multiphase current, which has resulted in advantage not only to the carbide industry but also in the manufacture of ferro silicon and other ferro alloys. According to Helfenstein and Taussig (Seventh Congress of Applied Chemistry), the largest power consumption possible with a built-up electrode amounts to 2500–3000 kw., the current being 30,000–40,000 ampères at 75–95 volts at the electrode. In a three-phase furnace—the only type used for large units—this means a total power consumption of from 7500 to 9000 kw., or 10,000 to 12,000 h.p. In the manufacture of carbide a further step has been taken in the construction of double three-phase furnaces, in which in the same hearth six instead of three electrodes are employed, connected to two separate three-phase units; the power required being from 15,000 to 18,000 kw., corresponding to a production of from 80 to 110 tons of carbide in 24 hours. In this modification there is no increase in loading, but it is interesting as showing that the power capacity so attainable is unlimited, whereas any attempt to increase the power of consumption beyond 2500 to 3000 kw. per electrode is found to be impracticable unless the furnace is operated by entirely special methods.

In open furnaces the heat due to the burning of the gaseous products of the reaction is so great, that even with less than 3000 kw. per electrode special protection against the heat has to be provided both for the workers and the electrical plant. Simultaneously the gases evolved become a serious nuisance in open carbide furnaces, and smoke is developed disproportionately as the power is increased, for which reason it is not advisable to exceed 3000 kw. per electrode. Another obstacle to the use of higher concentration of power is the difficulty of satisfactorily charging the raw materials into the furnace so as to keep the electrodes uniformly covered, any undue exposure leading to fuming, or distillation of material due to overheating.

As the capacity of the furnace is increased the utilisation of the gases produced by the reaction becomes of greater economic moment. In the carbide furnace 70–85 p.c. of the gases is carbon monoxide, with carbon dioxide and water, which are easily removable in practice as the sole impurities. Furnaces are now designed entirely closed in, so that evolved gas can be utilised for heating purposes, and by so doing smoke nuisance and excessive radiation of heat is avoided.

The type of furnace as covered by Helfenstein's patents illustrate the main features of interest in connection with mechanical charging and other general problems of management of the electrical furnace for the manufacture of carbide. Fig. 8 shows an elevation and section of an 8000–10,000 kw. single three-phase furnace. About 8–10 metres above the bottom plate is a charging floor, where the raw material is brought, as in blast furnace plants, by tipping waggons to the charging apparatus at regular intervals. The charging arrangements consist of a large mixing chamber, which can be closed gas tight, communicating with the body of the furnace, through which the central hanging electrode, of 3000–4000 k.g. weight, passes, being thus surrounded on all sides by the mixture. The mixing reservoir, which has a capacity of from 5000 to 7000 k.g., is fed continuously as the material is used in the process through large pipes from the charging floor above. Wide slits provided with gas-tight covers are made in the top of the furnace proper, near the mouth of the reservoir, for observation and control of the process.

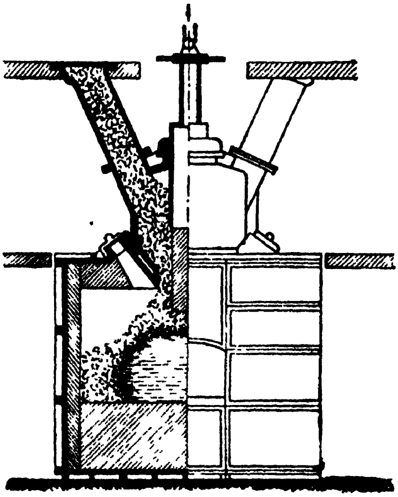

Fig 8.

When no more profitable use of the waste gases is required, their immediate application in preheating the charge can be carried out as illustrated in Fig. 9. The general form of the furnace is the same as Fig. 8. It is seen that in the upper part of the hearth there is a gas-filled corner space bounded by the naturally sloped surface of the raw materials; by blowing or sucking air in at the nozzles, as indicated in the diagram, this space is converted into a combustion chamber, the gases burning in contact with the mixture of material in the hearth. In another Austrian modification the furnace is provided with charging vessels in the form of shafts similar in design to Helfenstein's, but with a branch for taking off the waste gases.

The A.G. works near Cologne, which are capable of producing 200 tons of carbide a day, are described by Allmand and Williams (J. Soc. Chem. Ind. p. 304 R., 1919). The power is obtained from five three-phase turbo generators of 11,250 kw. each, and three smaller ones capable of supplying power and current for seven furnaces. When visited, two of the large generators were working four furnaces, 3000 kw. being consumed on power and light. The furnaces consist of steel plate shells 30 by 14 by 10 feet deep, lined with 18 inches of firebrick, the hearth or crucible being afterwards rammed with carbon concrete. The electrodes 50 by 20 inches cross section, and 7 feet 6 inches to 8 feet in length, were built up of sections 20 by 20 and 20 by 10 inches. Flange, boss, and contact head of each electrode were separately water cooled, and the current was carried by groups of flexible copper wires suspended by chains, each with separate electric motor control. The furnaces were of the open type, the smoke and dust being exhausted from openings in the back wall of the furnace. 260 tons of lime to 185 tons of coke per day were required at full working pressure. The lime was passed through a 4-inch ring, and the coke was in pieces 1 to 3 inches across. The electrode consumption was five kilo. per ton of carbide. One tap hole was tapped in each furnace every 45 minutes by an arc tapper, and each furnace was provided by three tap holes placed below the three electrodes.

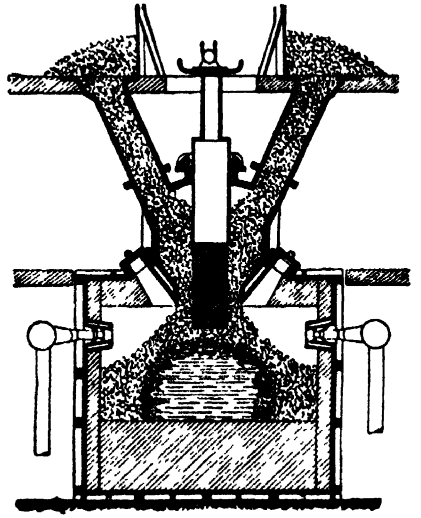

FIG. 9.

The subsequent treatment of the carbide requires special machinery, according to whether the material is to be used for the preparation of acetylene or for the manufacture of cyanamide. In the former case the clean ingots are broken into large blocks and fed into jaw crushers, from whence it is passed for granulation through slow-moving rolls, the object being to attain the desired state of division with a minimum production of dust. The crushed material is sized on trommels or rotary screens, which deliver the product in sizes varying from large lumps 8 by 4 inches, for the manufacture of acetylene on a large scale, to 16–30 mesh size, for automobile lamps, &c. A sheet-iron plant, where steel drums and air-tight cans are manufactured for storing and transport of the carbide, is a necessary part of every works. The standard packages are 100, 110, 200, 220 lbs. net weight of carbide, and small tins from 1 to 25 lbs. for lamps.

The largest use of calcium carbide is for making acetylene, but the cyanamide (*q.v.*) industry is dependent on calcium carbide for its manufacture. For this purpose it is necessary to reduce the material to a fine state of division, and to prevent oxidation and explosion it is usually performed in an atmosphere of nitrogen.

The manufacture of calcium carbide at prices prevailing in normal times depends upon the supply of cheap electric power. Norway, having abundance of water power and deposits of suitable limestone, has long been the largest producer of carbide. According to C. Bingham (J. Soc. Chem. Ind. March 15, 1918), to produce a ton of carbide requires 4250 units of electric power, this figure including not only the current required for the furnaces themselves, but that absorbed by transformers and loads, as also that consumed by motors to drive crushers, elevators, pumps, and drum-making plant. The cost in Norway with cheap water power amounted in normal times to 22*s.* to 25*s.* per ton of carbide, and its selling price was £10 15*s.* in England.

The only factory in Great Britain was at Thornhill, Yorks, which, owing to lack of electric power, was removed to Manchester, where a large plant has been built. At 0·4*d.* per unit the cost in Great Britain for current alone would be £6 3*s.* 4*d.* per ton of carbide, but if the process was run in connection with blast furnaces and coke ovens having a surplus of electric power or gas for the manufacture thereof, it is calculated that this figure could be reduced to £2 10*s.* per ton of carbide, reckoning 0·11*d.* per unit for depreciation and running cost, and 2*d.* per 1000 cu. ft. for gas used in gas engines consuming 27 cu. ft. per kw. hour, or for the 1250 units mentioned, a cost of 19*s.* 2*d.*

The Nitrogen Products and Carbide Co., Ltd., amalgamated with the Alby United Carbide Factories, Ltd., have acquired the St. Helens Colliery and Coke Ovens, Workington, with the object of producing carbide and nitrolim in this country on an economical basis. Electrodes are being produced at Hebburn-on-Tyne.

Calcium carbonate $CaCO_3$ occurs naturally in the forms of limestone, chalk, marble, and calcite; it also constitutes the principal ingredient in egg-shells, mollusc-shells, and coral. It is formed when the oxide or hydroxide is exposed to moist air containing carbon dioxide, but is not produced by the action of dry carbon dioxide on dry lime. It may be obtained in the pure state by dissolving chalk, or marble, or calcined oyster-shells in hydrochloric acid, precipitating the alumina, oxide of iron, and earthy phosphates by ammonia or milk of lime, filtering, then precipitating the calcium by ammonium carbonate, washing and drying.

Calcium carbonate is dimorphous, crystallising in the hexagonal system as calcite (*q.v.*) and in the rhombic system as aragonite (*q.v.*).

A litre of water dissolves about 18 milligrams of calcium carbonate. The solution has a slight alkaline reaction. Gothe (Chem. Zeit. 39, 305) gives the solubility of $CaCO_3$ in water free from CO_2 as being 31·0 mg. per litre. It is increased by the presence of chlorides, nitrates, and sulphates in the water, but decreased by alkaline carbonates, and by chlorides, nitrates, and sulphates of the alkaline earths. When boiled with water $CaCO_3$ (Gazz. chim. ital. 47, ii. 49) slowly dissociates with evolution of CO_2. This dissociation stops at a certain point, and is prevented, if a solution of $Ca(OH)_2$ (saturated at the ordinary temperature) is added to the boiling calcium carbonate in water in the proportion of 15 c.c. per litre. Sodium carbonate (0·05 gram per litre) prevents dissociation. Seyler and Lloyd (Chem. Soc. Trans. 111, 994) find that the ionic solubility product of calcium is $[Ca^{\cdot\cdot}]\cdot[CO_3{}^{\cdot\cdot}]=71{\cdot}9\times10^{-10}$, which gives $[Ca^{\cdot\cdot}]=14{\cdot}6\times10^{-6}$ for a saturated solution $CaCO_3$ in pure water. In this solution the carbonate is hydrolysed to the extent of 66 p.c. Water containing carbonic acid dissolves it much more readily, forming the acid carbonate $CaH_2(CO_3)_2$, which is known only in solution. Solubility at higher pressures in water containing carbonic acid follows the law of Schloesing pretty closely (Engel, Compt. rend. 101, 949). The solubility increases under an increase of pressure only up to 3 grams per litre according to Caro. One litre of water saturated with carbon dioxide dissolves 0·7 gram of the carbonate at 0°, but 0·88 gram at 10°. The solubility of calcite in water, determined at different temperatures by bubbling air containing 3·18 parts of CO_2 per 10,000 until saturation occurs, expressed in parts of $CaCO_3$ per million is: at 10°, 82; 21°, 60; 22°, 57; 23°, 57; 30°, 55. Cavazzi (Gazzi chim. ital. 46, ii. 122) finds that the maximum quantity of $CaCO_3$, which after prolonged shaking, dissolves at 0° in one litre of water saturated with CO_2 and maintained so in the presence of the gas at atmospheric pressure is 1·56 grams (2·5272 grams $Ca(HCO_3)_2$); at 15°, 1·1752 $CaCO_3$ (1·9038 $Ca(HCO_3)_2$). A supersaturated solution is obtainable, containing 2·29 grams $CaCO_3$ per litre. This acid carbonate plays a most important part in nature, for whenever water containing carbonic acid comes in contact with carbonate or silicates of calcium, the calcium is gradually converted into this soluble form, and is therefore found in almost all natural waters. Hence also the deposits in kettles and boilers; the formation of which may be prevented by the addition of ammonium chloride to the water.

Calcium carbonate, when heated to full redness in open vessels, is decomposed into lime and carbon dioxide. The decomposition commences at a low red heat, and in a current of air, or better steam, the temperature of dissociation is lower still. The tension of dissociation becomes equal to the pressure of the atmosphere, according to Le Chatelier (Compt. rend. 102, 1243), at about 812°. If heated rapidly, the stationary temperature of dissociation is 925°. At 547° the tension of dissociation is 27 mm.; at 610°, 46 mm.; at 625°, 56 mm.; at 740°, 245 mm.; at 810°, 678 mm.; and at 865°, 1333 mm. If the carbonate be ignited in a closed vessel, it fuses, resolidifying to a mass of marble-like calcite. According to Becker (Jahrb. Min. 1886, 1, Ref. 403), any form of $CaCO_3$, even at a low pressure, is changed on heating in a closed space with exclusion of air into the rhombohedral form without fusion. The crystalline forms of calcium carbonate dissociate very slowly below 400°; at this temperature the dissociation pressures are of the order of 0·003–0·009 mm. At 425° aragonite is transformed into calcite within an hour when heated in a vacuum. Besides the two well-known forms a third crystalline form, referred to as $\mu CaCO_3$ (Merwin and Williamson, Amer. J. Sci. 41, 473), is obtained by precipitation at 60° along with calcite and aragonite. It has D. 2·54, and can be separated from calcite D. 2·71, and aragonite D. 2·88 by flotation in a liquid D. 2·6. If small quantities of the precipitated carbonate are thrown into a fused mixture of sodium and potassium chlorides in equivalent proportions, no carbon dioxide is evolved, but the carbonate becomes crystalline calcite, usually in aggregations of crystals like snow crystals (Bourgeois, Bull. Soc. chim. [2] 37, 447).

Pentahydrated calcium carbonate
$CaCO_3,5H_2O$.

The evaporation of natural solutions of the acid carbonate generally results in the deposition of the ordinary carbonate, forming the stalactites and stalagmites of caverns, travertine, and other forms of deposit; but sometimes the solution yields six-sided rhombic prisms of the composition $CaCO_3,5H_2O$. These crystals are often found in pumps and pipes leading from wells, also adhering to the confervæ in ponds. They keep unaltered under water at 20°, but at slightly higher temperatures lose their transparency and water of crystallisation In air they crumble to powder through loss of water (Pfeiffer, Arch. Pharm. [2] 15, 212). This salt, according to Pelouze (Ann. Chim. Phys. [2] 48, 301), is obtained in small acute rhombohedra, sp.gr. 1·783, by boiling lime in a concentrated solution of sugar, starch, or gum, and leaving the solution for some months in a cold place. Becquerel, by exposing a solution of lime in sugar water to a voltaic battery of 12 cells, obtained crystals of the same composition, but in form of rhombic prisms.

Basic carbonates of lime. Calcium oxide commences to absorb carbon dioxide at a temperature of 415°, forming a basic carbonate of the composition $2CaO{\cdot}CO_2$ (Birnbaum and Mahu, Ber. 12, 1547).

Raoult (Compt. rend. 92, 1457) shows that when freshly burnt lime is heated in a current of carbon dioxide, it glows strongly, forming $2CaO{\cdot}CO_2$, which does not disintegrate in moist air, and does not take up water from steam at 200°. When finely powdered and treated with a little water, it hardens like hydraulic cement. The hydrated product has the composition $CaCO_3{\cdot}Ca(OH)_2$. On heating to dull redness, it loses water and is converted into a mixture of $CaCO_3$ and CaO.

When burnt lime is heated in contact with carbon dioxide for several days, the basic salt $2CaCO_3{\cdot}CaO$ is obtained, which still absorbs CO_2, forming a third salt $3CaCO_3{\cdot}CaO$. The carbon dioxide continues to be absorbed, however, and appears eventually to form the normal carbonate.

Calcium nitride Ca_3N_2 is best obtained by passing dry nitrogen over metallic calcium contained in a nickel boat and tube heated to bright redness. Two to three hours are required, and the resulting material is fritted and possesses a brownish-red colour. Its fusion point is about 1200°; sp.gr. 2·63 at 17°. When thrown into water it produces a lively effervescence, yielding ammonia and calcium hydroxide

$$Ca_3N_2+6H_2O=3Ca(OH)_2+2NH_3$$

(Moissan, Ann. Chim. Phys. [7] 18, 289). The nitride, heated in a current of hydrogen, gives a compound having the formula $Ca_3N_2H_4$ (Monatsh. 34, 1685).

Calcium ammonium $Ca(NH_3)_4$ is formed when a current of dry ammonia gas is passed over metallic calcium, maintained at a temperature of 15° to 20°. It possesses a brownish-red colour, and takes fire when exposed to air.

Calcium amide $Ca(NH_2)_2$. Calcium ammonium slowly decomposes, forming transparent crystals of calcium amide, hydrogen and ammonia being evolved.

Calcium imide CaNH is formed by passing equal volumes of hydrogen and nitrogen over heated calcium. It has not been obtained pure (Monatsh. 34, 1685).

Calcium nitrite $Ca(NO_2)_2.H_2O$ is prepared by decomposing a boiling solution of silver nitrite with lime-water, treating the filtrate with sulphuretted hydrogen and carbonic acid to remove excess of silver and calcium, and evaporating at a gentle heat. It crystallises in deliquescent prisms insoluble in alcohol.

Calcium nitrate $Ca(NO_3)_2,4H_2O$ occurs as a silky efflorescence in limestone caverns, especially those of Kentucky, also on the walls of places where there is much organic refuse. It is found in many well waters, being derived from the soil. It is extremely deliquescent and soluble, and causes rapid disintegration of mortar, and hence is called 'saltpetre rot.' It may be prepared by dissolving the carbonate in nitric acid, the solution depositing on slow evaporation monoclinic six-sided prisms terminated by acute pyramids of the above composition. On evaporating the solution to dryness, the anhydrous salt of sp.gr. 2·472 is obtained, possessing a warm bitter taste and readily soluble in water and alcohol. On heating more strongly, it becomes phosphorescent, as noticed by Baldwin in 1674, and hence is termed *Baldwin's phosphorus*. At a higher temperature, oxygen and nitric peroxide are evolved, and with combustible bodies detonation occurs. The nitrate is formed with liberation of nitrogen when nitrogen peroxide acts on lime, whatsoever be the conditions of temperature $2CaO+5NO_2 \rightarrow 2Ca(NO_3)_2+0{\cdot}5N_2$ It is extensively prepared on the Continent for the manufacture of nitre by mixing vegetable and animal refuse with chalk, marl, cinders, &c., moistening from time to time with liquid stable manure, and exposing to the air for two or three years, when the mass is lixiviated and the crude nitrate of calcium decomposed by carbonate, sulphate, or chloride of potassium. Large quantities of calcium nitrate are now produced by the Haber process. At the Svälgfos works, Notodden (55,000 h.p.), and the Ryukan works (120,000 h.p., to be increased to 300,000 h.p.), the nitrous fumes from the Birkeland and Eyde furnaces or the Schonherr furnaces are absorbed in granite towers and the waters neutralised by limestone. The wet method of absorption is now being replaced by a dry method, which does not necessitate the use of towers, the nitrous fumes being absorbed by passing over lime kept at a temperature of about 300°. The conversion to ammonium nitrate cannot be accomplished satisfactorily by the interaction of ammonium sulphate and calcium nitrate owing to the fine condition of the calcium sulphate, but this becomes crystalline if heated in an enclosed vessel to 150°–175°, which can then be readily separated.

Calcium phosphide. Moissan (Compt. rend. 128, 787) prepared calcium phosphide from pure crystallised calcium and red phosphorus. The two bodies were placed apart in a tube which was exhausted and the phosphorus was gently heated. The vapours evolved combined with the calcium with incandescence. He also obtained it by reduction of pure calcium phosphate with carbon in an electric furnace, using 310 parts and 96 parts respectively of the ingredients and a current of 950 ampères and 45 volts. So obtained, it is a brownish-red body, crystalline when prepared in the electric furnace. Its characteristic reaction is the decomposition of water in the cold with the production of calcium hydroxide and hydrogen phosphide. Prepared by either of the above methods, it has the composition Ca_3P_2.

Thenard (Ann. Chim. Phys. [3] 14, 12) obtained calcium phosphide mixed with phosphate by passing the vapour of phosphorus over red-hot lime. The substance may be prepared on a larger scale by filling a crucible with a hole in its base with pellets of lime, and placing it upon the grate of a furnace. A flask containing phosphorus is placed below the grating with its neck passing into the hole of the crucible. When the lime has been heated to redness, the phosphorus is gradually heated so that its vapour passes through the lime. The brown mass is stated by Gmelin (Handb. 3, 188) to be a mixture of monocalcium phosphide and tricalcium phosphate.

When thrown into water, the product is instantly decomposed with evolution of spontaneously inflammable phosphoretted hydrogens.

Owing to this property, calcium phosphide is utilised for the production of signal fires at sea. The manufacture is carried on in an arrangement similar to the above, the crucibles being larger and divided by a false perforated bottom into two compartments, in the upper of which the pieces of lime are raised to a red heat, the phosphorus placed in the lower compartment being afterwards volatilised by the heat radiated from above. In about 6 hours, a charge, yielding 20 lbs. of product, is finished. The brown stony mass is immediately worked up into the 'lights.' These consist of cylindrical tinned-iron boxes, the lower half of which is filled with about 16 oz. of the fragments of phosphide.

Two small circular portions of the upper and under surfaces of metal are formed of soft lead, so that they may be pierced by a knife just before being thrown overboard. The tins are supported by a wooden float when in use. The water enters below and the gas issues from the upper outlet, burning with a flame 9 to 18 inches high, lasting about half an hour. Larger but similar 'lights' are prepared to be placed in a bucket of water on deck. In the British Navy torpedo practice, a peculiar form of the phosphide is also used.

Calcium phosphite $CaHPO_3,H_2O$ separates as a crystalline crust from a solution of the ammonium salt mixed with calcium chloride. It is sparingly soluble in cold water, and the solution decomposes when heated, depositing a basic salt, an acid salt remaining dissolved. It gives off its water at 100°. It is a white crystalline powder, which, on heating, evolves spontaneously inflammable phosphoretted hydrogen, accompanied by slight detonations. At a certain temperature, it becomes incandescent, and leaves a residue of calcium phosphate.

An acid phosphite $CaH_4(PO_3)_2,H_2O$ is obtained as a crystalline crust by acting upon marble with aqueous phosphorous acid as long as carbon dioxide escapes. The crust consists of needle-shaped crystals soluble in water, and losing their water at 100°.

Calcium hypophosphite $Ca(PO_2H_2)_2$ or $CaH_4(PO_2)_2$ is used medicinally, and is prepared by boiling phosphorus with milk of lime

$$3Ca(OH)_2+2P_4+6H_2O=2PH_3+3CaH_4(PO_2)_2.$$

On evaporation the hypophosphite is obtained in monoclinic flexible prisms insoluble in alcohol. When heated it evolves phosphoretted hydrogen and water, leaving calcium pyrophosphate.

Calcium orthophosphate $Ca_3(PO_4)_2$ occurs pure in the mineral *osteolite*, and as

$$Ca_3(PO_4)_2,2H_2O$$

in *ornithite*. Combined with calcium fluoride or chloride, it occurs in nature as *apatite*

$$3Ca_3(PO_4)_2+CaF_2$$

in which form it is found in large crystals in the metamorphic limestones at Burgess, Ontario, Canada. The massive variety, *phosphorite*, is mined on a large scale at Odegarden, Norway. In certain apatites, the CaF_2 is more or less replaced by $CaCl_2$. Specimens of apatite and phosphorite are occasionally coloured brown, mauve, and green, and become colourless on heating. Apatite is phosphorescent when heated, especially after exposure to radium.

Calcium phosphate also forms a principal constituent of the coprolites frequently found in extensive beds in the stratified rocks. This material forms the principal source of the rock phosphate of commerce. It is the chief inorganic material of bones, forming about 80 p.c. of burnt bones.

It is obtained in the amorphous state by precipitating an ammoniacal solution of calcium chloride with excess of hydrogen disodium phosphate. The precipitate is gelatinous, but dries up to a white earthy powder, nearly insoluble in water, but is decomposed by long boiling into an insoluble basic salt of the composition

$$Ca_3(PO_4)_2 \cdot Ca_2(PO_4)OH$$

and a soluble acid salt. This reaction also occurs slowly in the cold. Calcium phosphate is also soluble in water containing carbonic acid (1 part in 1789 parts of water saturated with carbon dioxide), ammonium salts, sodium nitrate, sodium chloride, and other salts. Its absorption by the roots of plants is therefore promoted by the agency of saline solutions.

Bassett has shown that only two phosphates more basic than dicalcium phosphate exist; these are tricalcium phosphate $Ca_3P_2O_8$ and hydroxy apatite $(Ca_3P_2O_8)_3,Ca(OH)_2$. The latter is the only stable solid phase over a range of acidity of great practical importance, as it can exist in faintly acid, neutral, or alkaline solutions. It is probable that this compound is the only calcium phosphate that can permanently exist under normal soil conditions. Bone phosphate is considered to be a mixture of hydroxyapatite and calcium carbonate, with small amounts of absorbed bicarbonates of sodium, potassium, and magnesium.

The melting-point of calcium phosphate is 1550°. It is not reduced by CO, but H reduces it at 1300° to a mixture of CaO and phosphorus. Carbon begins to reduce it at 1400°. It is not decomposed by silica in a neutral atmosphere, but a chemical combination occurs at 1150°, and the product is completely reducible by carbon. The compound has the composition $3CaO,3SiO_2,P_2O_5$, and is indicated by a strong maximum on the freezing-point curve of the system calcium-phosphate calcium-silicate. Two compounds $2,SiO_2,P_2O_5$, $3SiO_2,P_2O_5$, have also been isolated, the latter melting in the oxyhydrogen flame.

Freshly precipitated calcium phosphate combines with sulphur dioxide, becoming soluble in water. On heating the solution, some of the gas is liberated and a crystalline precipitate, having the composition $Ca_3SO_2P_2O_8,2H_2O$, is formed, a compound which is very stable (Ber. 15, 1441).

Calcium orthophosphate may be obtained in the crystalline form by heating dicalcium pyrophosphate with water, whereby it is resolved into phosphoric acid and tricalcium phosphate, which separates in rectangular plates

$$3Ca_2P_2O_7+3H_2O=2Ca_3(PO_4)_2+2H_3PO_4.$$

Tricalcium phosphate is not decomposed by ignition.

Dicalcium orthophosphate $Ca_2H_2(PO_4)_2$. An aqueous solution of phosphoric acid acts on precipitated chalk, forming small needle-shaped crystals of dicalcium phosphate. Dried at 100°, the salt contains $5H_2O$, which it does not lose below 115°. It is soluble in ammonium citrate, Boiled with water, it is partially decomposed into tricalcium phosphate.

On mixing boiling solutions of sodium phosphate, calcium chloride, and acetic acid,

$$Ca_2H_2(PO_4)_2,H_2O$$

is formed; if the solutions are mixed in the cold, $Ca_2H_2(PO_4)_2,5H_2O$ is formed (Millot, Bull. Soc. chim. [2] 33, 194). The salt is also formed (Joly and Sorrel, Compt. rend. 118, 741) when saturated solutions are mixed in the cold if hydrochloric acid is added.

When a solution of calcium chloride is mixed with one of ordinary sodium phosphate, a white crystalline precipitate of $Ca_2H_2(PO_4)_2,4H_2O$ is thrown down. It is this salt which is occasionally deposited from wine in stellar aggregates. According to Becquerel and Berzelius, a trihydrate may also be obtained. These different results as regards water of crystallisation are probably owing to the fact that the precipitates vary in amount of water and solubility in acids according to the conditions of their precipitation.

Monocalcium phosphate $CaH_4(PO_4)_2$ is obtained in rhombic tables by dissolving either of the former phosphates in phosphoric acid and allowing the solution to spontaneously evaporate. It has a strong acid reaction, and deliquesces in air, dissolving readily in water. A small quantity of water decomposes it, forming insoluble dicalcium phosphate and free phosphoric acid. If cold, the hydrate $Ca_2H_2(PO_4)_2,4H_2O$ is formed; if hot, the same salt, free from water. is precipitated.

Monocalcium phosphate fuses on heating, giving up its water, and when heated to 200° it parts with the elements of water, leaving a mixture of calcium pyrophosphate and metaphosphoric acid

$$2CaH_4(PO_4)_2 = Ca_2P_2O_7 + 2HPO_3 + 3H_2O.$$

When the mixture is heated to a still higher temperature, pure calcium metaphosphate remains.

Superphosphate of lime is a mixture of monocalcium phosphate and calcium sulphate, which is manufactured as a manure. It is prepared by acting on bone-ash, rock phosphate, phosphorites, or other mineral phosphates with two-thirds their weight of sulphuric acid:

$$Ca_3(PO_4)_2 + 2H_2SO_4 = CaH_4(PO_4)_2 + 2CaSO_4.$$

Besides its use as a manure for root-crops, it is used in the manufacture of phosphorus (*v.* FERTILISERS).

Calcium pyrophosphate $Ca_2P_2O_7$ is prepared by action of aqueous pyrophosphoric acid upon lime water, or sodium pyrophosphate upon calcium chloride. If the precipitate thus obtained is dissolved in sulphurous acid and the solution heated, the salt separates as a crystalline crust. The crystals contain four molecules of water.

Calcium metaphosphates. The monosalt $Ca(PO_3)_2$ is obtained by dissolving calcium carbonate in orthophosphoric acid, evaporating, and heating the residue to 316°. It is an insoluble white powder.

The dimetaphosphate $Ca_2(PO_3)_4,4H_2O$ is obtained pure in the crystalline form by precipitating the corresponding alkali salt with excess of calcium chloride. It is insoluble in water, but is decomposed by strong sulphuric acid. A double dimetaphosphate of calcium and ammonium $Ca(NH_4)_2(PO_3)_4,2H_2O$ is obtained in spicular crystals by mixing a solution of calcium chloride with excess of the ammonium salt. It is insoluble in water.

Phosphato-chlorides of calcium are obtained by evaporating solutions of tricalcium phosphate in hydrochloric acid. A saturated solution, on spontaneous evaporation, deposits rhomboidal plates of $7CaH_4(PO_4)_2{\cdot}CaCl_2,14H_2O$. If the solution is evaporated over the water-bath, dicalcium phosphate is first deposited, then, on further evaporation, the above phosphatic chloride comes down, and afterwards white scales of $CaH_4(PO_4)_2{\cdot}CaCl_2,H_2O$. When a solution of dicalcium orthophosphate in hydrochloric acid is saturated at ordinary temperatures with tricalcium phosphate, then mixed with half the quantity of hydrochloric acid already contained in it, and evaporated, on cooling below 6° crystals separate out of the composition

$$4CaH_4(PO_4)_2{\cdot}CaCl_2,8H_2O$$

(Erlenmeyer, J. 1857, 146).

Calcium silico-phosphate. According to Carnot and Richard (Compt. rend. 97, 316), the brownish-black slag, formed in working the Thomas-Gilchrist process at Joeuf (Meurthe-et-Moselle), is covered with black crystals, some slender needles, others right rhombic prisms with brilliant faces, frequently aggregated in columnar masses terminating in vitreous, translucent, blue crystals. Similar blue crystals are found in the cavities, possessing the constant composition $8P_2O_5{\cdot}8SiO_2{\cdot}Al_2O_3{\cdot}FeO{\cdot}36CaO$, essentially a calcium silico-phosphate

$$Ca_3(PO_4)_2 + Ca_2SiO_4.$$

Calcium arsenates. Dicalcium arsenate occurs native as *haidingerite* $Ca_2H_2(AsO_4)_2,H_2O$, and *pharmacolite* $Ca_2H_2(AsO_4)_2,5H_2O$, and may be prepared by adding a solution of disodium arsenate to excess of calcium chloride. The tetrahydric arsenate obtained by addition of lime water to arsenic acid is soluble, while the tricalcium arsenate is insoluble in water, and may be prepared by precipitating calcium chloride with trisodium arsenate. On evaporating a hydrochloric acid solution of calcium ammonium arsenate with platinum chloride, the mass left on ignition of the platinochloride is found to contain fine white prisms of the tricalcium orthoarsenate $Ca_3(AsO_4)_2$ insoluble in acids. The metaarsenate $Ca(AsO_3)_2$ is formed as an insoluble crystalline powder when mixtures of arsenious anhydride and calcium carbonate are ignited.

According to R. H. Robinson (J. Agric. Res. 1918, 13, 281), pure calcium hydrogen arsenate ($CaHAsO_4,H_2O$) may be prepared by pouring an acidified solution of calcium chloride into an acidified solution of sodium hydrogen arsenate. It forms a heavy voluminous precipitate which may be obtained crystalline. It becomes anhydrous at 175°. Tricalcium arsenate $Ca_3(AsO_4)_2,2H_2O$ may be prepared by pouring an alkaline calcium chloride solution into an alkaline sodium hydrogen arsenate solution, when a heavy voluminous sparingly soluble precipitate of sp.gr. 3·23 is formed.

Calcium ammonium arsenate

$$CaNH_4AsO_4,7H_2O$$

is produced by mixing a hot solution of arsenic acid in excess of ammonia with calcium nitrate or chloride, when it crystallises on cooling in tables. In a vacuum over sulphuric acid, they become $Ca_2(NH_4)H_2(AsO_4)_2,3H_2O$, and when dried at 100° have the composition

$$Ca_8(NH_4)H_3(AsO_4)_6,3H_2O$$

On ignition they are converted into calcium pyroarsenate $Ca_2As_2O_7$ (Bloxam, Chem. News, 54, 168).

Another salt, $Ca(NH_4)_2H_2(AsO_4)_2$, is obtained by adding excess of ammonia to a solution of dicalcium arsenate in nitric acid, as a flocculent precipitate, soon becoming a mass of needles. The same salt is obtained in crystals belonging to the regular system when the solution of the dicalcium salt is only partially precipitated and allowed to stand; hence it appears to be dimorphous (Baumann).

Calcium silicide was obtained by Moissan by heating calcium oxide with excess of silicon in a carbon tube by means of the electric furnace. It forms greyish crystals, sp.gr. 2·5, which are slowly decomposed by water with evolution of hydrogen.

Tamaru (Zeitsch. anorg. Chem. 62, 81) found that molten silicon is miscible with molten calcium in all proportions.

Kolb (Zeitsch. anorg. Chem. 64, 342), by heating together calcium and silicon, obtained two silicides according to the component in excess. The products contain 53·5 p.c. and 36·68 p.c. silicon respectively, corresponding approximately with the formulæ Ca_6Si_{10} and $Ca_{11}Si_{10}$. Both silicides are crystalline, evolve hydrogen with acetic acid, and evolve spontaneously inflammable hydrogen with dilute hydrochloric acid. Silicones are obtained with strong hydrochloric acid. Both silicides absorb nitrogen near 1000°, the products having the respective compositions $CaSi_2N_2$ and $Ca_{11}Si_{10}N_{10}$.

Calcium silicates. Calcium oxide is an important base in a large number of natural silicates, and is the principal basic constituent of the following minerals *Wollastonite* $CaSiO_3$ or tabular spar, occurring in monoclinic crystals; *okenite* $CaH_2(SiO_3)_2,H_2O$; *xonalite*

$$4CaSiO_3,H_2O;$$

gurolite $Ca_2H_2(SiO_3)_3,H_2O$; and *apophyllite* $4CaH_2(SiO_3)_2{\cdot}KF,4H_2O$.

Gorgeu (Compt. rend. 99, 256) obtained artificial wollastonite by fusing 1 gram of silica with 15 grams calcium chloride and 3 grams common salt at a cherry-red heat in a current of moist air for half an hour.

Doelter (Jahrb. Min. 1886, 1, 119) found that in absence of steam, a hexagonal $CaSiO_3$ is always formed; hence wollastonite must have been formed in presence of steam. Calcium silicate is therefore dimorphous.

Rankin and Wright (Amer. J. Sci. 39, 1) have examined the system $CaO-Al_2O_3-SiO_2$. The melting-points of the three components are 2570° for lime, 2050° for alumina, and 1625° for cristabolite, the high temperature modification of silica. Of the binary systems involved alumina and silica form one compound, sillimanite Al_2SiO_5, whilst lime and alumina form four distinct compounds, $Ca_3Al_2O_6$, $Ca_5Al_6O_{14}$, $CaAl_2O_4$, and $Ca_3Al_{10}O_{18}$. The third binary system, lime-silica, also gives rise to four compounds, Ca_3SiO_5, Ca_2SiO_4, $Ca_3Si_2O_7$, and $CaSiO_3$, the first mentioned of which, however, does not separate from the fusion. In the ternary system three compounds exist, but only anorthite $Ca_2Al_2Si_2O_8$ and $Ca_2Al_2SiO_8$ (? pure gehlenite) are stable at their melting-point, the third $Ca_3Al_2SiO_8$ being unstable. The above compounds do not form solid solutions to any extent, and the authors did not detect in the crystallisations the eutectic (β) structure commonly seen in alloys.

On precipitating the solution of any calcium salt with sodium or potassium silicate, the silicates $2CaO{\cdot}9SiO_2,3H_2O$ and $CaO{\cdot}SiO_2$ have been obtained by Lefèvre and Von Ammon respectively.

Gorgeu (Compt. rend. 99, 256) obtained two chlorosilicates by heating to a high temperature silica and calcium chloride in proportion of one molecule to seven in presence of water vapour. The first, $2CaO{\cdot}SiO_2{\cdot}CaCl_2$, forms birefractive rhombic plates. The second, $CaO{\cdot}SiO_2{\cdot}CaCl_2$, forms hexagonal plates, and is produced more rapidly than the former, which requires prolonged heating. Both compounds are decomposed by water.

Calcium boride CaB_6 was obtained by Moissan and Williams by heating quicklime with boron in an electric furnace, and by reducing calcium borate with aluminium in the presence of carbon, then washing with hydrochloric and hydrofluoric acids and ether. It is a black crystalline body; sp.gr. 2·33. Nitric acid attacks it vigorously.

It is also formed (Ber. 46, 1885) when calcium metaborate (30 grams) is reduced by means of calcium (50 grams), the theoretical quantity of calcium boride being produced. The reaction product is extracted with dilute acetic acid, and then dilute HCl and hot water. So obtained it is a light brown micro-crystalline powder $D^{18}=2{\cdot}11$.

Calcium borate occurs in nature in several combinations. The best known is colemanite $HCa(BO_2)_3,2H_2O$, which crystallises in beautiful monoclinic prisms.

Calcium silicoborate $CaO{\cdot}2SiO_2{\cdot}CaB_2O_4$ occurs with one molecule of water as *datholite*, and with two molecules of water as *botryolite*.

Calcium titanate or $CaTiO_3$ occurs in nature as *perovskite*.

Calcium silicotitanate $CaSiTiO_5$ is a common constituent of many igneous and metamorphic rocks, and is known as *titanite* or *sphene*. Synthetic titanite forms blue crystals (melting-point 1221°), which usually enclose small crystals of perovskite (Zeitsch. anorg. Chem. 73, 293).

Calcium monosulphide CaS. Perfectly dry lime remains unaltered on passing over it a current of dry sulphuretted hydrogen; but on hydrating the lime and again passing the gas, calcium sulphide is formed:

$$Ca(OH)_2+H_2S=CaS+2H_2O.$$

The most favourable temperature is 60° (Veley, Chem. Soc. Trans. 1885, 478).

It may also be prepared by heating the sulphate with coal or charcoal, or by action of carbonic oxide at a red heat:

$$CaSO_4+4CO=CaS+4CO_2.$$

It may be prepared in the crystalline state by direct reduction of the sulphate with carbon in the electric furnace; Müller (Cent. Min. 1900, 178) has obtained it in small cubes.

Anhydrous calcium sulphide is a white powder which emits a smell of SH_2 in the air. It turns yellow on moistening, due to the formation of oxidised products. It is but sparingly soluble in water, and is decomposed by boiling water, with formation of hydroxide and sulphydrate of calcium $2CaS+2H_2O=Ca(HS)_2+Ca(HO)_2$. Suspended in water, it is readily decomposed by carbonic acid, with formation of calcium carbonate and sulphuretted hydrogen

$$CaS+H_2O+CO_2=CaCO_3+H_2S.$$

After being heated, calcium sulphide shines in the dark, and was long known as *Canton's phosphorus*.

According to Verneuil (Compt. rend. 103, 600), calcium sulphide with a violet phosphorescence may be prepared as follows: 20 grams of finely powdered lime, obtained by heating the shells of *Hypopus vulgaris*, is intimately mixed with 6 grams of sulphur and 2 grams of starch, and 8 c.c. of a solution containing 0·5 gram basic bismuth nitrate and 100 c.c. of absolute alcohol acidified with a few drops of hydrochloric acid are added. The mixture is exposed to the air until most of the alcohol has evaporated, and is then heated to cherry redness for 20 minutes. When completely cooled, the upper layer of calcium sulphate is removed, and the calcined mass powdered and again heated for 15 minutes. The violet phosphorescence of the product is due to the trace of bismuth. 0·1 p.c. of sulphides of antimony, cadmium, mercury, tin, copper, lead, uranium, platinum, or zinc imparts a bluish- or yellowish-green tint to the phosphorescence. Manganese produces an orange shade. A mixture of 100 parts lime, 30 parts sulphur, 10 of starch, and 0·035 of lead acetate yields a sulphide with a beautiful yellowish-green phosphorescence.

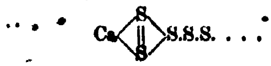
Pure calcium carbonate mixed with 2 p.c. sodium carbonate, and 0·02 p.c. common salt, heated with 30 p.c. sulphur and 0·02 p.c. bismuth nitrate, yields a similar product to that obtained by use of *Hypopus* shells. Pure calcium sulphide does not phosphoresce; the phenomenon is due to small quantities of impurities; thus in the last mixture it has been shown by Verneuil to be due to simultaneous presence of traces of bismuth oxide, sodium carbonate and chloride, and calcium sulphate.

These phosphorescing varieties of calcium sulphide are utilised in the manufacture of luminous paints. Abney (Phil. Mag. [5] 13, 212) found that the emission spectrum showed greatest luminosity between G and F, and a feebler one extending from between E and F as far as the red. The rays of the electric light somewhat beyond H on one side and G on the other are most active in exciting phosphorescence.

Calcium disulphide CaS_2 is deposited in yellow crystals of the composition $CaS_2,3H_2O$ from the solution obtained by boiling sulphur with milk of lime and filtering while hot.

Calcium pentasulphide CaS_5 is formed when the monosulphide or hydrate of calcium is boiled for a long time with excess of sulphur. Concentrated solutions of calcium hydrosulphide $Ca(HS)_2$ also react energetically upon powdered roll sulphur; on preventing access of air by performing the operation in a current of hydrogen, an orange-red solution is produced with fall of temperature, and on warming the calcium is completely converted into CaS_5. The reaction is reversible, a current of sulphuretted hydrogen causing deposition of sulphur and reformation of hydrosulphide.

Auld obtained evidence indicating the possible existence of polysulphides as high as CaS_7, and suggests the constitution



the atoms of sulphur in the chain becoming progressively more loosely attacked. (For the chemical composition of lime-sulphur animal dips, *see* Chapin, U.S.A. Dept. Agric. Bull. 451, 1916).

Calcium oxysulphides. When calcium hydroxide is used as above, besides CaS_5 there is also formed an oxysulphide of the composition $5CaS{\cdot}CaO,20H_2O$ (Rose). The same substance is obtained in gold-coloured needles when the solution obtained by boiling crude calcium monosulphide with much water is evaporated.

According to Hoffmann (Compt. rend. 62, 291), a mixture of two molecules of calcium monosulphide and one molecule lime at a red heat, forms the oxysulphide $2CaS{\cdot}CaO$. This oxysulphide is contained in recently lixiviated soda residues.

Geuther (Annalen, 224, 178) obtained crystals of $CaS_5{\cdot}2CaO,10H_2O$ by boiling sulphur in milk of lime. They dissolve in hydrochloric acid, forming hydrogen persulphide H_2S_5, and a little H_2S. On boiling calcium monosulphide and sulphur with water, crystals of $CaS_5{\cdot}3CaO,15H_2O$ were obtained. Divers obtained a compound of the formula $11CaS{\cdot}5CaO$ by igniting lime in a mixture of carbon dioxide and carbon disulphide.

Auld (Chem. Soc. Trans. 107, 480), by boiling together lime and sulphur in proportions calculated to give the disulphide obtained in each case Herschell's crystals, for which he proposes the formula $CaO,CaS_2,7H_2O$. A lime sulphur wash, used as a fungicide, is prepared by boiling together one part of quicklime, two or more parts of sulphur, and ten parts of water. The concentrated commercial product contains calcium polysulphides and thiosulphate, generally with minor proportions of sulphite and sulphate.

Calcium sulphydrate $Ca(HS)_2$ is formed together with the hydroxide when the monosulphide is boiled with water. The best mode of preparing it is to pass sulphuretted hydrogen through the hydroxide or sulphide suspended in water, with constant agitation, until it ceases to be absorbed. It is difficult to obtain in the solid state, being decomposed, when the stage of crystallisation is reached, into SH_2 and CaS which separates in silky prisms.

Divers (Chem. Soc. Trans. 1884, 270) obtained it in the solid form by forcing sulphuretted hydrogen through semi-solid calcium hydroxide and water so as to obtain a saturated solution of the sulphydrate. Air was excluded, and, on settling, decanting in a stream of H_2S, and cooling by ice, crystals formed in abundance. They were colourless prisms, melting on slight rise of temperature with partial decomposition. They readily dissolved in a fourth of their weight of water, and could not be removed from the atmosphere of sulphuretted hydrogen without decomposition. They possessed the formula

$$CaH_2S_2,6H_2O.$$

Calcium sulphydrate may be used as a depilatory. If sulphuretted hydrogen be passed into thin milk of lime till the mass acquires a bluish-grey colour, the paste thus formed, when thinly laid upon the surface from which the hair is to be removed, permits of the ready removal of the hair a minute or two afterwards by scraping with a dull knife. It has been proposed to employ it in the tan-yard.

Calcium hydroxy-sulphydrate $Ca(SH)(OH)$ is formed, according to Divers, by action of water upon the crystals of the last-described salt:

$$Ca(SH)_2+H_2O = Ca(SH)(OH)+H_2S.$$

Also by union of water with calcium sulphide, as in interior of heaps of soda waste; and by reaction between $Ca(OH)_2+H_2S$ in the coal-gas purifier. Exposed to air, crystals of $Ca(HS)_2$ are rapidly converted to $Ca(SH)OH$, and concentrated solutions of the sulphydrate exposed to air become rapidly covered with crystals, and an abundant crop of crystals of $Ca(SH)OH$ is obtained on passing in a current of air. The crystals are colourless four-sided prisms of silky lustre, easily obtained dry, of the composition $Ca(SH)OH,3H_2O$. They slowly evolve SH_2 in air, and become yellow by absorption of oxygen They are readily soluble in water, but the solution rapidly decomposes into hydroxide and sulphydrate. They are insoluble in alcohol.

According to Folkard (Chem. News, 49, 258), by exposing calcium hydroxide to the action of sulphuretted hydrogen until it ceases to gain weight a grey powder of the composition $4Ca(HO)_2\cdot 3H_2S$ is obtained. By the action of coal gas sulphuretted hydrogen is evolved from it, and at 100° water is eliminated, leaving

$$Ca(OH)_2\,Ca(SH)OH.$$

This greyish-green powder, when gently heated in coal gas, leaves a yellowish-white salt

$$2Ca(HO)_2\cdot Ca(SH)OH\,CaS,$$

and this at a red heat forms $2CaO\cdot Ca(SH)OH\cdot CaS$, which, when ignited in air, burns like tinder to $CaSO_4$.

The lime-sulphur solutions employed as insecticides and plant sprays in agriculture, prepared by boiling together water, lime, and sulphur, consist mainly of calcium polysulphides, calcium hydroxysulphydrate, calcium thiosulphate with sulphur held in solution. For their analysis, *see* Bodnar, Chem. Zeit. 1915, 39, 715; Analyst, 1915, 513; Ramsay, J. Agric. Sci. 1914, 6, 476. The following is an analysis of a typical lime-sulphur spray, sp.gr. 1·3735, the results being expressed in grams per 100 c.c. (Ramsay, *l.c.*):–

	Sulphur.		Lime.
Hydroxy-sulphydrate containing .	0·911	associated with calcium	1·653
Disulphide containing	11·716	„	12·877
Free sulphur .	23·11		––
Thiosulphate containing	0·99		0·86
Sulphate „	0·07		0·11
	30·83		15·50

Calcium sulphocarbonate $CaCS_3$. Lime over which coal gas containing sulphuretted hydrogen has been passed readily absorbs carbon disulphide. Absorption is most complete when the lime is moistened with water; this material, when fouled, is mixed with an equal weight of slaked lime. The absorption of carbon disulphide stops when one-third of the sulphide is converted to sulphocarbonate $CaS+CS_2=CaCS_3$. On exposing the product for a short time to the air, it is again rendered capable of removing carbon disulphide.

On passing hydrogen saturated with vapour of carbon disulphide into a mixture of calcium monosulphide and a little water, the liquid becomes red, and *in vacuo* deposits red prismatic very deliquescent needles of composition

$$Ca(OH)_2\cdot CaCS_3,7H_2O.$$

When the hydroxy-sulphydrate is employed instead of monosulphide, yellow crystals of

$$2Ca(OH)_2\cdot CaCS_3,10H_2O$$

are obtained.

From these facts Veley (Chem. Soc. Trans. 1885, 478) concludes that the carbon disulphide is absorbed by $Ca(SH)OH$, and not by CaS, and that the reactions are as follows:—

(1) $CaS+H_2O=Ca(SH)OH.$

(2) $Ca(SH)_2+H_2O=Ca(SH)OH+H_2S.$

(3) $2Ca(SH)OH+CS_2=Ca(OH)_2\cdot CaCS_3+H_2S.$

The basic sulphocarbonate is unstable, being decomposed slowly by sulphuretted hydrogen and readily by carbon dioxide.

When milk of lime is agitated with carbon disulphide, bright orange needles of a basic sulphocarbonate $Ca(HO)_2\cdot CaCS_3,6H_2O$ are deposited.

Calcium selenides. The monoselenide is formed as a flesh-coloured precipitate by precipitating calcium chloride with potassium monoselenide. Lime water saturated with seleniuretted hydrogen deposits crystals of calcium selenide when exposed to the air. When lime and selenium are heated just below redness, a polyselenide mixed with calcium selenite is formed.

Calcium sulphite $CaSO_3$ is formed when a solution of an alkaline sulphite is added to the solution of a calcium salt: it is a white powder soluble in 800 parts of water. It dissolves in sulphurous acid, and the solution on exposure to air deposits six-sided needles of the composition $CaSO_3,2H_2O$.

The solution in sulphurous acid is known commercially as bisulphite of lime, and is manufactured by passing sulphur dioxide into milk of lime. In Kynaston's process (Pat. 15659, 1884) a mixture of calcium chloride solution, magnesia, and a little carbonate of lime is brought into contact with sulphur dioxide. The SO_2 is caused to ascend a flagstone tower packed with pigeon-holed brickwork, while the mixture is allowed to run down the tower in such proportions, that from the base there runs a mixture of neutral calcium sulphite, suspended in a solution of magnesium chloride containing the excess of sulphurous acid. The sulphite is settled out in tanks, the supernatant liquor drawn off and concentrated to 40°–45°Tw.; then a quantity of alkali waste is added to it in a closed iron vessel, and the whole heated, when sulphuretted hydrogen is given off, and calcium chloride, magnesia, and calcium carbonate with alkali cinders remain. The latter are removed in a strainer, and the emulsion is ready to be again treated with sulphur dioxide. The whole of the calcium carbonate present is converted to sulphite, carbon dioxide being evolved.

According to Birnbaum and Wittich (Ber. 13, 651), calcium oxide does not absorb sulphur dioxide gas below 400°, but at this temperature combination takes place rapidly with formation of a basic sulphite $Ca_6S_5O_{16}$ or $6CaO\cdot 5SO_2$. At 500° the gas is rapidly absorbed, but the sulphite splits up into sulphate and sulphide.

Calcium sulphate $CaSO_4$ is frequently found in limestone rocks or in company with common salt in the anhydrous state as the mineral *anhydrite*. Anhydrite occurs both in rhombic crystals and in a semi-crystalline massive form. Clear colourless crystals are coloured blue by exposure to radium, and are slightly phosphorescent when heated. More frequently the sulphate is found hydrated as *gypsum* $CaSO_4,2H_2O$, of which the well-crystallised form is termed *selenite*, a fibrous variety *satin spar*, and a finely crystallo granular form *alabaster*. Selenite occurs in fine monoclinic prisms, frequently twinned in characteristic arrow head shapes.

Gypsum is found in the Keuper marls in Nottinghamshire, and at Chellaston in Derbyshire. Selenite crystals exposed to radium are occasionally coloured, in parts, a faint smoky brown.

The anhydrous sulphate may be artificially obtained in crystals resembling anhydrite, of sp gr. 2·9, by fusing calcium chloride with excess of potassium sulphate (Manross, J. 1852, 9).

Hydrated calcium sulphate is precipitated on adding dilute sulphuric acid or a soluble sulphate to an aqueous solution of calcium chloride. The sp gr of gypsum is 2·31. When it is heated to 100°–200° it gives up three fourths of its water rather quickly, but it requires a temperature of 200°–250° to expel the remainder. Dried at 100°, the hydrate $2CaSO_4,H_2O$ of sp gr. 2·7 is left. The anhydrous salt fuses at a red heat without decomposition, and on cooling, assumes the structure of anhydrite. When dehydrated calcium sulphate is pulverised and mixed with water, it absorbs two molecules of water, and solidifies to a very hard mass with evolution of heat, expanding in so doing so as to fill any mould in which it is cast, due probably to the outward thrust of the lath shaped crystals of the hydrated salt during growth; hence the use of gypsum or plaster of Paris in preparing casts. If the gypsum has been heated to a little over 200°, thus being deprived of all its water, it becomes dead burnt, and takes up water very slowly and without hardening.

Calcium sulphate is very slightly soluble in water, the anhydrous sulphate being nearly insoluble. The solubility of the hydrate attains a maximum at 35°, one part dissolving in 393 parts water (Poggiale); at 0° in 488 parts, and at 100° in 460 parts. The solubility is increased by presence of hydrochloric or nitric acids, or chlorides of ammonium or sodium, hence its presence in salt springs; probably in most cases partial double decomposition has occurred.

According to Lunge (J. Soc. Chem. Ind. 1885, 31), the solubility of calcium sulphate in solutions of sodium chloride increases with the percentage of salt, but diminishes with increase of temperature.

At 21·5°, 100 c.c. of a 3·53 p.c. solution of NaCl dissolves 0·5115 gram $CaSO_4$.

At 18·0°, 100 c.c. of a 14·18 p.c. solution of NaCl dissolves 0·7340 gram $CaSO_4$.

At 101·0°, 100 c.c. of a 3·53 p.c. solution of NaCl dissolves 0·4891 gram $CaSO_4$.

At 102·5°, 100 c.c. of a 14·18 p.c. solution of NaCl dissolves 0·6248 gram $CaSO_4$.

Calcium chloride diminishes the solubility of $CaSO_4$ the more it is concentrated, but at the boiling-point the concentration is immaterial. Hydrochloric acid increases the solubility both with increase of concentration and of temperature.

Gypsum is readily soluble in excess of sodium thiosulphate, forming calcium thiosulphate, which combines with the excess of the sodium salt to form a soluble double thiosulphate. On addition of alcohol, this double salt separates as a thick heavy liquid, which solidifies, forming needle-shaped crystals.

Both calcium and barium sulphate can be conveniently and quantitatively reduced at a temperature of 900°–950° by means of a dry current of carbon monoxide. Reduction commences at 680°–700°, becomes vigorous at 750°–850°, and is practically finished at 900°. The reduction with carbon in an atmosphere of nitrogen begins at 700°, is vigorous at 800°–900°, and is complete at 1000° (Bull. Amer. Inst. of Min. Eng. 1910, 917).

A large experimental plant for utilising, in Germany, the dumps of calcium sulphate resulting from the neutralisation of excess sulphuric acid in the sulphonation processes, consists in mixing the presscake with coal and a slagging material, presumably of the composition required to give a cement mixture; this is fed into a type of rotary kiln 50 metres long and 3 metres in diameter which is coal dust fired. The fumes containing sulphur dioxide are cleaned from dust by electrostatic means (unsatisfactory at the time) and are passed into the sulphur trioxide converters. The cement produced from the clinker is of satisfactory quality. (J. Soc. Chem. Ind. 287, 19[illegible])

Calcium sulphate cements. Gypsum, hydrated calcium sulphate $CaSO_4,2H_2O$, is the source of this class of cements, which depend for this property of setting on the reacquisition of the water associated with calcium sulphate in gypsum.

The chemistry of calcium sulphate cements, though much the simplest of that concerned with cements depending for their setting on hydration, is of considerable difficulty, and its present condition is far from definitive. Putting aside controversial views, the situation may be summarised thus: When $CaSO_4,2H_2O$ is heated, it loses water, and at a temperature of about 107° becomes converted into the hemi-hydrate $2CaSO_4,H_2O$. When this substance is mixed with water, it is hydrated, and reforms $CaSO_4,2H_2O$, which crystallises first in the orthorhombic, and finally in the monoclinic, system. The quantity of water sufficient to bring the hemi-hydrate back to the fully hydrated condition is much smaller than is necessary to dissolve it; but, nevertheless, complete crystallisation is accomplished thus: the hemi-hydrate readily forms a supersaturated solution, from which not it but the dihydrate is deposited. The water thus released dissolves another portion of the hemi hydrate, and the process of deposition is repeated indefinitely until, provided there was originally enough water to transform $2CaSO_4,H_2O$ into $CaSO_4,2H_2O$, the whole of the former will have been dissolved in detail and deposited in detail in the shape of the latter. As stated in the section dealing with Portland cement, it is believed that this formation of a supersaturated solution, deposition of the surplus dissolved material, and re-use of the water for the solution of another fraction of the material is general for cements which set when mixed with water, and, although there are many gaps in the proof, yet the hypothesis is useful. In the case of calcium sulphate cements, it may be regarded as well established.

The hemi-hydrate $2CaSO,H_2O$, constitutes plaster of Paris. If gypsum is heated to a higher temperature, *e.g.* above 130°, it becomes completely dehydrated, and yields $CaSO_4$. It appears that $CaSO_4$ can exist in two or more modifications, which behave differently with water As all eventually become hydrated, but not all will set as plaster of Paris, it is probable that only those which will set possess the characteristic property of forming a supersaturated solution, and allowing the mass to crystallise in stages in the manner described above. Keene's cement and Estrichgips (flooring plaster) are examples of cements consisting substantially of anhydrous calcium sulphate. Their setting is influenced by both the temperature at which they have been burnt and by the presence in them of small quantities of substances other than $CaSO_4$, the *modus operandi* of which is exceedingly obscure. In whatever way they are prepared, the final product of setting is $CaSO_4,2H_2O$.

Keane (J. Phys. Chem. 1916, 20, 701) shows that on heating gypsum with slow rise of temperature and constant stirring a halt occurs in the rise of temperature at 90° C., and under some conditions another halt at 139°. There is also an inversion into plaster of Paris $(CaSO_4)_2,H_2O$ at 107° and 971 Hg. pressure, though the temperature may be raised to 200° without this inversion being complete. In German practice the maximum temperature employed is 130°, in English practice 110°–120°, and in American 200° may be reached. These differences are possible because of the rate influence of time and temperature on the inversion and the slowness with which gypsum and plaster develop their true vapour pressures. The same author considers there is only one modification of anhydrous calcium sulphate, but that its properties vary with the degree of agglomeration, and these with the method of formation. The setting of plaster may be retarded by adding flooring plaster, colloids, or any substance which will decrease the solubility of the gypsum and increased by adding substances which increase the solubility.

The manufacture of plaster of Paris is conducted by heating the mineral gypsum to a temperature above that necessary to remove ¾ of its water of crystallisation, and below that requisite to dehydrate it completely. Several methods of burning are in use, ovens, kettles, and rotatory kilns being employed. In English practice a simple oven of the kind shown (Figs. 10 and 11) is adopted, the gypsum in lumps being piled on arches in which the fuel is burnt. In the United States the common plan is to grind the gypsum first, and heat it in a large iron pot or kettle set in brickwork and heated from below. This method is known as 'boiling,' owing to the fine material being kept in a state of agitation by the escaping steam. During the process the powdered material is stirred by an agitator driven by power. A superior quality of plaster is produced, but the method is slow and expensive, and is gradually being abandoned in favour of the rotary calciner.

In Scanegatty's oven the interior is divided by an arch about a foot from the floor, upon the under side of which play the flames from a furnace connected with a lower chamber, the hot air and gases passing afterwards through apertures into the gypsum chamber. The aqueous vapour passes away by a chimney at the top of the oven.

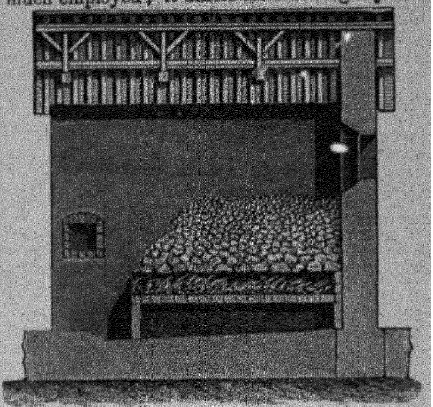


FIG. 10.

Dumesnil's oven is a form which has been much employed; it differs from Scanegatty's in the peculiar arrangement of the lower fire-room, which has twelve openings, the lower blocks of gypsum being arranged so as to facilitate the circulation of the draught from these. The firing is continued for about 4 hours, then the heat is increased for 8 hours, when all openings are closed, and 5–6 cubic metres of coarse gypsum powder spread equally over the top of the burning sulphate. By this means considerable saving of fuel is effected. After standing 12 hours to cool, the contents of the kiln are removed. It is mostly in a state of powder, and the pulverisation is completed by grinding in a stamp or roller mill. The powder is then sifted and stored in a dry place.

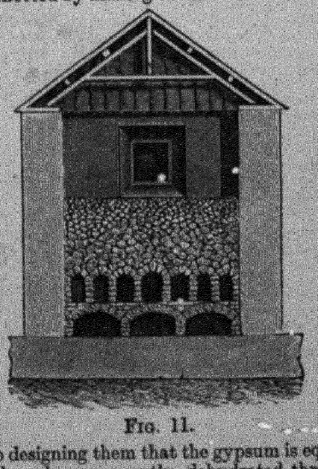

FIG. 11.

Many improvements on the old forms have been effected by making the furnaces continuous, and so designing them that the gypsum is equally heated, and, consequently, dehydrated throughout. This end is also ensured by grinding the gypsum before calcination. The types of ovens employed are very numerous. That of Petry and Hecking, Dortmund, is a rotary kiln, with mill and furnace arranged similarly to those of a cement works. The barrel oven of Perin of Paris is a revolving cylinder, supported upon hollow trunnions, one of which serves for the entrance of the heated gases from the furnace, and the other for exit. The charging is performed from a hopper placed above through a trap-door in the side of the cylinder, which similarly serves to discharge the material when burnt. The Mannheim calciner is provided with a pre-heating chamber, which is placed above the rotating cylindrical furnace. The crushed gypsum is passed through the former by means of a worm conveyor and then into the rotating cylinder, whilst the hot gases from the furnace pass in the opposite direction. In the Cummer rotary calciner, which is much used in the United States, the rotating cylinder is surrounded by a brick chamber, into which the hot gases first pass, and are reduced to a suitable temperature by cold air through inlets in the walls before passing through the calciner. Other ovens are made stationary, but are provided with revolving screws or vanes, which serve to keep the ground gypsum in constant motion, and also to discharge it. Some ovens are heated by means of superheated steam.

In all cases the temperature must be carefully regulated so that only the hemi-hydrate is obtained. On account of the fact that a considerable quantity of water has to be driven off, the temperature of the source of heat may be and in practice is considerably higher than 107°, but the temperature of the mass of gypsum must not be allowed to rise above this, lest complete dehydration occur.

Plaster of Paris varies in composition according to the purity of the gypsum from which it is made. The following analyses are illustrative, and for comparison the composition of the hemi hydrate is appended:—

—	$2CaSO_4,H_2O$	Commercial plaster of Paris	
		1	2
	p.c.	p.c.	p.c.
Calcium sulphate ($CaSO_4$)	93·8	94·53	83 55
Water (H_2O)	6·2	4·12	6·67
Silica (SiO_2)	—	—	4·27
Alumina and ferric oxide ($Al_2O_3+Fe_2O_3$)	—	0·57	0·47
Calcium carbonate ($CaCO_3$)			3·07
Magnesium carbonate ($MgCO_3$)	—	—	1·47

Keene's cement is usually made in this country by first burning the gypsum to the condition of plaster of Paris, dipping the lumps in a solution of alum or of aluminium sulphate, and reburning at a temperature of about 500°, the operation being conducted in ovens in which the fuel is prevented from coming into contact with the material, so as to avoid discolouration. The following is a typical analysis of Keene's cement of good quality:—

	Per cent.
Silica (SiO_2)	**trace**
Alumina (Al_2O_3)	**trace**
Lime (CaO)	**42·04**
Magnesia (MgO)	**trace**
Sulphuric anhydride (SO_3)	**53·54**
Carbonic anhydride (CO_2)	**1·37**

It will be seen that Keene's cement is almost chemically pure $CaSO_4$, the quantity of added matter, such as alum, being negligible. As mentioned above, the function of this and similar additions is obscure, and even the necessity for their use appears doubtful because flooring plaster (*Estrichgips*) is made by burning pure gypsum at about 500°, and, though destitute of alum and the like, sets well. Mack's cement is produced by adding calcined sodium sulphate or potassium sulphate to the completely dehydrated gypsum. Martin's cement is prepared like Keene's, but a solution of potassium carbonate replaces the alum.

There are many different qualities of plaster, but all are of the type of plaster of Paris, or of Keene's cement. The former set in a few minutes, whilst the latter take several hours, and as the rate of setting of plaster of Paris is inconveniently rapid for some purposes, 'retarders,' consisting of such organic substances as glue, blood, and vegetable juices, are often added. These substances of a colloidal nature probably act by obstructing the growth of the crystals of $CaSO_4,2H_2O$, and thus delaying the process of hydration, and, consequently, the setting.

The chief uses of plasters made from calcium sulphate are for making castings or mouldings for interior decoration, for which their white colour, conspicuous in the purer kinds, and their expansion on setting and causing the production of sharp outlines, peculiarly adapt them. On account of the solubility of calcium sulphate in water, these plasters cannot be used for outdoor work. Minor uses are for making moulds for any material which can be cast at a sufficiently low temperature, for making surgical support for broken limbs, and, as an addition to Portland cement, to lengthen its time of setting.

Acid calcium sulphate $CaSO_4 \cdot H_2SO_4$ is formed by heating the neutral sulphate with strong sulphuric acid to 80°-100°. A portion of the porous mass produced dissolves and separates on cooling in microscopic prisms of the composition above indicated. It is decomposed by water, even the moisture of the air, into gypsum and sulphuric acid.

Calcium sodium sulphate $CaNa_2(SO_4)_2$ occurs native in rhombic prisms as the mineral *glauberite*. It may be obtained in the same form by fusing together calcium and sodium sulphates. On heating 50 parts sodium sulphate (Glauber's salt) with an emulsion of 1 part gypsum in 25 parts water to 80°, crystalline needles of

$$CaSO_4 \cdot 2Na_2SO_4,2H_2O$$

are deposited. On further heating, these crystals are transformed into microscopic rhombohedral crystals of glauberite.

In the Welsh process of manufacturing sodium acetate, during evaporation of the liquor formed by double decomposition of calcium acetate by sodium sulphate, **micaceous spangles of glauberite have been noticed by Folkard (Chem. News, 43, 6) to separate out. This explains why calcium sulphate so tenaciously retains sodium sulphate.**

Calcium potassium sulphate

$$CaSO_4,K_2SO_4,H_2O$$

occurs native in monoclinic crystals as *syngenite*.
